The Handbook of Organizational Economics

This page intentionally left blank

Introduction

Robert Gibbons and John Roberts

Organizational economics involves the use of economic logic and methods to understand the existence, nature, design, and performance of organizations, especially managed ones. As this handbook documents, economists working on organizational issues have now generated a large volume of exciting research, both theoretical and empirical. However, organizational economics is not yet a fully recognized field in economics—for example, it has no *Journal of Economic Literature* classification number, and few doctoral programs offer courses in it. The intent of this handbook is to make the existing research in organizational economics more accessible to economists and thereby to promote further research and teaching in the field.

The Origins of Organizational Economics

As Kenneth Arrow (1974: 33) put it, “organizations are a means of achieving the benefits of collective action in situations where the price system fails,” thus including not only business firms but also consortia, unions, legislatures, agencies, schools, churches, social movements, and beyond. All organizations, Arrow (1974: 26) argued, share “the need for collective action and the allocation of resources through nonmarket methods,” suggesting a range of possible structures and processes for decisionmaking in organizations, including dictatorship, coalitions, committees, and much more.

Within Arrow’s broad view of the possible purposes and designs of organizations, many distinguished economists can be seen as having addressed organizational issues during the first two centuries of the discipline. For example, Adam Smith (1777) famously was concerned about moral hazard and free riding by directors of joint-stock companies, and his pin factory is a discussion of job design. A century after the initial publication of Smith’s volume, in the first volume of the *Quarterly Journal of Economics*, the founding president of the American Economic Association, Francis Walker (1887), argued that differences in the quality of management account for persistent intra-industry differences in productivity and profitability. Frank Knight (1921) discussed entrepreneurship and the nature of the firm, which he saw as an institution in which the more uncertainty-averse worked for fixed wages, whereas the entrepreneur bore the

risk but had authority over the employees. Berle and Means (1932) described conflicts of interest arising from the separation of corporate ownership by shareholders from corporate control by top managers. Ronald Coase (1937) raised the question of the boundaries of the firm, arguing that economizing on the costs of transacting would determine what was done in the market versus under hierarchic control.

Herbert Simon (1951) offered perhaps the first formal model in organizational economics, treating the employment relationship as the use of authority rather than as contracting in response to uncertainty and the need for adaptation. Edith Penrose (1959) studied managerial activities and decisionmaking, organizational routines, and knowledge creation in firms and argued that these are critical determinants of the success and growth of the firm. Alfred Chandler (1962, 1977) documented the historical emergence of the modern corporation and professional management.

At the edges of economics, there was related work in organizational theory. Chester Barnard (1938) was one of the earliest contributors, seeing organizations as systems of collaborative activity and discussing the roles of incentives and authority in the formal and informal aspects of organization. Building on Barnard, the Carnegie School then focused on two major issues: bounded rationality and conflict of interests. Simon (1947) and March and Simon (1958) asked how the organization can orchestrate the acquisition and communication of information and the allocation of decisionmaking so as to produce a tolerable outcome for the organization when its members are boundedly rational. Cyert and March (1963: 30) argued that “people (i.e., individuals) have goals; collectivities of people do not” and that “since the existence of unresolved conflict is a conspicuous feature of organizations, it is exceedingly difficult to construct a useful positive theory of organizational decision making if we insist on internal goal consistency.” Instead, March (1962) described “The Business Firm as a Political Coalition.”

Reflecting on these early developments, Arrow (1964: 397–398) noted that “the large organization, so prominent on our contemporary social landscape, is of great antiquity. . . . But it is perhaps only in our era, and even then haltingly, that the rational design of organization has become a subject of inquiry.” Around 1970, however, the field began to take off.

Many important contributions in the 1970s concerned the nature and boundaries of the firm. Oliver Williamson (1971, 1975) proposed a theory of the replacement of market dealings by authority in the firm, based on the potential for inefficient haggling when unplanned adaptations are required. In contrast, Armen Alchian and Harold Demsetz (1972) argued against the idea that the firm is a manifestation of authority, proposing instead that the firm was best viewed as a collection of contracts. George Richardson (1972) undercut the simple firm-versus-market dichotomy by accentuating the great variety of organizational forms and relationships between firms that actually populate the economy, and he wrote convincingly of the role of capabilities—information, knowledge, and skills—in determining the effectiveness of activities in and between firms. And Benjamin Klein et al. (1978) and Williamson (1979) explored the consequences of specific assets and hold-up for firms’ make-or-buy decisions and contracting between firms.

Other important contributions were focused within organizations. Arrow’s (1974) beautiful little book addressed topics ranging from authority and codes to responsibility, trust, and values. Richard Nelson and Sydney Winter (1982) wrote in evolutionary terms about organizational routines that enable the organization to do what it does (and hence may convey competitive

advantage or its opposite). And Michael Jensen and William Meckling (1976) provided the first treatment of agency costs as a necessary consequence of the separation of ownership from control.

In formal modeling, Jacob Marschak and Roy Radner (1972) modeled optimal communication and decisionmaking processes in uncertain environments with dispersed information but shared objectives. Leonid Hurwicz (1973) introduced the concept of incentive compatibility and initiated mechanism-design theory, where the institutions used to allocate resources become a choice variable, thereby setting the stage for economic analysis of organizational design. And James Mirrlees (1975/1999) and Bengt Holmström (1979) introduced formal models of moral hazard, launching a literature that would have tremendous influence on organizational economics.

What Are the Questions Addressed by Organizational Economics?

These early contributions laid the foundations for the work that has emerged in the past 30 years, which is the focus of this handbook. Extrapolating from this early work suggests a wide range of issues for organizational economics, including the following.¹ What are the vertical boundaries of the organization? How are relations with suppliers and customers organized? Who owns which assets, and how are the activities of the organization financed? How is governance defined and exercised, both internally, within the organization, and by external parties with ownership claims? What are the horizontal boundaries of the firm (i.e., what businesses is it in)? How are departments and divisions defined? How are resources of different types allocated? What is the role of hierarchy, how many levels are there, and what are the spans of control? Is the organization an expression of authority or a nexus of contracts? What are the roles of formal versus relational contracts in the organization? Where does decisionmaking occur in the organization? How is power achieved and exercised, and what role does politics play in organizations? What information is collected, by whom, to whom is it communicated, and how is it used? How are people recruited, trained, and assigned to jobs? How is performance measured? How are people rewarded? What effects do rewards have on behavior? What norms exist regarding behavior toward others in the organization, as well as outsiders, and how do these norms affect behavior and organizational performance? How do other aspects of corporate culture manifest themselves and affect behavior? What is the nature and role of leadership in organizations? And, finally, how do the answers to these questions depend on the markets in which the organization operates; the strategies it adopts to compete; and the social, legal, regulatory, and technological environment in which it is embedded; and how do all these choices interact and affect performance?

Related Fields

Given this agenda, it is clear that organizational economics overlaps with many other fields in economics, as well as with a variety of other disciplines in the social sciences and management.

In economics, there is a large intersection with personnel economics, which studies the relationship between employer and employee and the economics of managing human resources

1. We phrase these questions in positive terms, but their normative versions are equally important.

in firms. Industrial organization also has significant overlaps, sharing interest in the vertical and horizontal scope of the firm, supplier relations, and other contracts between firms, and the impact of compensation on firm behavior. More recently, international economics has begun investigating outsourcing and offshoring, as well as the multinational corporation, all of which raise organizational issues. In addition, development economics is studying the role of firms in economic growth, including the effects on their productivity of improving their organization and management and relaxing financial constraints. And researchers studying different economic systems and the transition from one to another—both historically and today—also share interests with organizational economics.

There are also important connections with disciplines beyond economics. The law literature has central interests in contracts and in governance. Social psychology is concerned with motivation, decisionmaking, and culture. Organizational sociology (and, more recently, economic sociology) studies the sociology of economic institutions, including firms, markets, and networks. And political science studies decision processes in government agencies, legislatures, communities, and more. However, this handbook focuses more on making organizational economics accessible to economists and hence less on forging the connections to other disciplines that ultimately could and should be made; see the Smelser and Swedberg (2005) *Handbook of Economic Sociology* for surveys of work in one social science and Ostrom (1990) for a leading example of work from another.

In business schools, scholars in organizational behavior have not only harnessed the insights of psychology and sociology to understand firms, they have also developed large bodies of research on issues ranging from compensation and job design to leadership and organizational change. And the overlaps between organizational economics and other areas of management are also significant. Corporate finance is concerned with the allocation of resources within the firm, the effects of the financing of the firm on managerial behavior, and issues of corporate governance. Managerial accounting is also concerned with resource allocation inside firms and with internal governance, as well as with acquiring and communicating information and with performance measurement and pay. Marketing addresses relations with suppliers and customers and also the management of sales forces. And strategy studies organizational capabilities (as a source of competitive advantage) and the vertical and horizontal boundaries of the firm (as a problem of corporate strategy). As with social sciences beyond economics, this handbook barely begins to explore the current and potential connections with management fields; see Baum's (2002) *Companion to Organizations* for surveys of work in organizational behavior and related fields.

Outline of the Handbook

Beyond this introduction, the handbook consists of six parts. Part I contains foundational material. Erik Brynjolfsson and Paul Milgrom survey the theory and econometrics of complementarity, seen as an alternative to the usual assumptions of microeconomics (concavity, divisibility, etc.) that allows modeling organizational questions with great richness and still permits drawing strong conclusions. Ilya Segal and Michael Whinston organize a broad literature on property rights and break new ground on this central issue in organizational economics. Steven Tadelis and Oliver Williamson discuss the theoretical and empirical literatures on transaction cost economics and develop a formal model that yields new insights. In addition, we offer an exposition

of the means of motivating people in organizations, focusing on agency and performance contracting, but also mentioning nonfinancial means of motivating behavior.

Part II describes three empirical methods that loom large in organizational economics but may not be completely familiar to those not involved in the field. George Baker and Ricard Gil examine the role of clinical or case studies in organizational economics, arguing that (ever since the discussion of Fisher Body in Klein et al. [1978]) case studies can and do play a vital role in the process of scientific investigation and suggesting what characteristics of such studies make them particularly valuable. Colin Camerer and Roberto Weber discuss the role of experiments in studying organizational issues, describing a number of such studies and again explicating what makes for a good experimental study. Finally, Casey Ichniowski and Kathryn Shaw discuss insider econometrics, which involves careful econometric analysis of data whose collection inside organizations is guided by detailed knowledge of the phenomena gained both from insiders (managers and other employees) and from personal observation.

Each part in the remainder of the handbook then focuses on a specific set of organizational issues. Part III studies individuals and groups in organizations. It involves three contributions on employment by James Baron and David Kreps, by Edward Lazear and Paul Oyer, and by Michael Waldman; two chapters on authority, power, politics, and influence by Patrick Bolton and Mathias Dewatripont and by Niko Matouschek and ourselves; and an essay on culture and leadership by Benjamin Hermalin. The three chapters on employment illustrate the significant intersection between organizational economics and personnel economics, as well as connections to economic sociology and human resource management. The other three chapters in Part III can be seen as discussing different aspects of decisionmaking in organizations, often echoing Barnard (1938) and the Carnegie School's view of "the organization as a decision-making process" (Cyert and March 1963: 202), in which individuals compete for resources, power, and influence, and information is a strategic tool.

Part IV studies structures and processes in organizations, with two chapters on hierarchy by Luis Garicano and Timothy Van Zandt and by Dilip Mookherjee, and individual chapters on innovation and organization by Pierre Azoulay and Josh Lerner, on corporate governance by Benjamin Hermalin, on strategy and organization by John Roberts and Garth Saloner, on resource allocation by Robert Gertner and David Scharfstein, and on organizational capability by Robert Gibbons and Rebecca Henderson. The two chapters on hierarchy are complements, in that Garicano–Van Zandt follows the emphasis in Simon (1947), March and Simon (1958), and Marschak and Radner (1972) on the acquisition and communication of information, to the exclusion of incentive issues, whereas Mookherjee focuses entirely on the ways in which hierarchy may either ameliorate or exacerbate incentive issues (especially when Hurwicz's [1973] mechanism-design approach seems to offer a centralized method for all organizational communication and decisionmaking). The Azoulay-Lerner and Hermalin chapters—on innovation and corporate governance—connect to other fields in economics, such as growth on the one hand and law and economics on the other, with Azoulay-Lerner building on themes from Knight (1921) and Penrose (1959), and Hermalin on themes from Smith (1977) and Jensen and Meckling (1976). And the Roberts-Saloner, Gertner-Scharfstein, and Gibbons-Henderson chapters—on strategy, resource allocation, and capabilities—connect to management research on strategy, corporate finance, and managerial practices, echoing Walker (1887), Penrose (1959), Chandler (1962, 1977), and Nelson and Winter (1982).

Part V considers the boundary of the firm, contracts between firms, and multifirm governance structures, with chapters by Timothy Bresnahan and Jonathan Levin on vertical integration, Francine Lafontaine and Margaret Slade on the empirics of contracting between firms, Claude Ménard on hybrid organizations, James Malcomson on relational incentive contracts, Lewis Kornhauser and Bentley MacLeod on contract law and contract economics, and Henry Hansmann on legal forms of organization. The Bresnahan-Levin and Lafontaine-Slade chapters—on vertical integration and contracting—illustrate connections between organizational economics and industrial organization (building on Coase [1937], Williamson [1971, 1975, 1979], and Klein et al. [1978]). And Ménard's chapter on hybrids—such as alliances, joint ventures, and consortia—illustrates the rich middle ground between integration and simple contracting (building on Richardson [1972]). Malcomson's chapter on relational incentive contracts is cast in terms of buyer-supplier relations but applies as well within firms and so complements our chapter on motivation (building on Mirrlees [1975/1999] and Holmström [1979]). And the Kornhauser-MacLeod and Hansmann chapters illustrate connections with the legal literatures on contracts and organizations (connecting to Alchian and Demsetz [1972]).

Finally, although much of the foregoing could be applied to organizations other than firms, Part VI explicitly adopts this focus, with chapters by Abhijit Banerjee, Rema Hanna, and Sendhil Mullainathan on corruption and by Terry Moe on government agencies. The Banerjee et al. chapter applies a mechanism-design approach to understanding both the endogeneity and the net costs and benefits of corruption, illustrating connections to economic development. In contrast, Moe's chapter informally applies ideas about organizational design and performance to understand the complexity (and, at times, seeming perversity) of government agencies, illustrating connections to political science.

What Have We Left Out?

Despite the rich set of studies contained in this volume, there are other issues and areas of research that we see as potentially (and sometimes currently) important to organizational economics but that we could not include here for various reasons.

One of the most exciting of these is econometric investigation of management practices and managers and their impact on productivity and growth in organizations (e.g., Bertrand and Schoar 2003; Bloom and Van Reenen 2007). Closely related to this are field experiments in organizational economics (e.g., Paarsch and Shearer 1999; Bandiera et al. 2011). A very large fraction of the experimental work going on in firms concerns randomized controlled experiments in enterprises in emerging markets. The vast bulk of these studies is in micro and small enterprises (e.g., Bruhn et al. [2012] or the extensive references in Banerjee and Duflo [2011]), although there is also recent work in large companies in these markets (Bloom et al. 2012). More generally, it would be interesting to have more work on the connections between economic organizations and economic development. In addition, more work relating organizations and international economics (including trade, investment, and location choices and the choice of organizational form for multinationals) would be welcome.

Another class of subjects in which we would like to promote more research involves different organizational forms. Legislatures, government bureaus and departments, the courts, political parties, clubs, cooperatives, mutuals, family firms, state-owned enterprises, charities and not-

for-profits, hospitals, universities, and schools—all raise interesting organizational issues and deserve more attention than they have received. Particularly prominent in current business school research (largely in operations) is the organization and management of supply chains (e.g., Lee et al. 1997). Finally, we are only too aware that the vast bulk of the work discussed here is rooted implicitly in the institutional context of the English-speaking economies. We would very much like to see this imbalance righted.

Hopes for the Future

To reiterate, our goal in assembling this handbook is to make existing research in organizational economics more accessible to economists. We hope that several things might then follow. First, we see the prospect of a coherent field here—with topics that relate to one another and methods that cut across topics. We hope this handbook's sketch of the field will inspire discussion and elaboration of what organizational economics is and could be. Second, we see exceptional potential for several dialogues—between theoretical and empirical researchers; between research and practice; and between organizational economics, other fields of economics, and other social sciences and management disciplines. We hope this handbook will facilitate those dialogues. Finally, turning from research to teaching, we think it is possible and desirable to teach doctoral courses in organizational economics, thereby preparing new generations of organizational economists who can build on and surpass the exciting developments of the past three decades. We hope the chapters in this handbook will appear in many syllabi—as central elements of courses on organizational economics and as complements to courses on industrial organization, labor, trade, development, and economic history.

Complementarity in Organizations

Erik Brynjolfsson and Paul Milgrom

1. Introduction

According to the *American Heritage* dictionary, a *synergy* is “the interaction of two or more agents or forces so that their combined effect is greater than the sum of their individual effects” or “cooperative interaction among groups, especially among the acquired subsidiaries or merged parts of a corporation, that creates an enhanced combined effect.” *Complementarity*, as we use the term, is a near synonym for “synergy,” but it is set in a decisionmaking context and defined in Section 1.2 with mathematical precision.

Complementarity is an important concept in organizational analysis, because it offers an approach to explaining patterns of organizational practices, how they fit with particular business strategies, and why different organizations choose different patterns and strategies. The formal analysis of complementarity is based on studying the interactions among pairs of interrelated decisions. For example, consider a company that is evaluating a triple of decisions: (i) whether to adopt a strategy that requires implementing frequent changes in its technology, (ii) whether to invest in a flexibly trained workforce, and (iii) whether to give workers more discretion in the organization of their work. Suppose that more-flexibly trained workers can make better use of discretion and that more-flexibly trained and autonomous workers make it easier to implement new technologies effectively, because workers are more likely to know what to do and how to solve problems. Then, there is a complementarity between several pairs of decisions, which is characteristic of a system of complements. The theory of complementarities predicts that these practices will tend to cluster. An organization with one of the practices is more likely to have the others as well. Suppose an organization employs these three practices. Should this organization now adopt job protections, incentive pay, or both? The answer depends in part on the presence or absence of complementarities: if these new practices enhance worker

We thank Josh Mollner, Shachar Reichman, and Adam Saunders for providing useful research assistance; Bob Gibbons and John Roberts for helpful comments; and the National Science Foundation (IIS-0085725 and ITR-0427770) and the Massachusetts Institute of Technology Center for Digital Business for research support.

Table 1. Interactions in a system of complements

Practice	(1)	(2)	(3)	(4)
(1) Make frequent technical changes	■	+	+	+
(2) Train workers flexibly	■	■	+	
(3) Give workers discretion	■	■	■	+
(4) Protect workers' jobs	■	■	■	■
(*) Frequent opportunities to upgrade technology	+			

Notes: The double rule separates the environmental variable from the practices being analyzed. An entry containing a plus symbol indicates a complementary practice to the one listed in the row containing the entry. Entries that do not need to be evaluated are shaded in gray.

cooperation with management in periods of technical change, then they, too, should be part of the same system.

Often there is a related environmental variable that drives an entire system. In our example, suppose the organization operates in an environment that contains frequent, substantial opportunities to upgrade technology to save costs or improve products. Then it would be natural for the organization to favor the first practice—making frequent technical changes. Because of complementarities, this would in turn favor adopting the whole group of practices described above. The clustering of practices, the way choices depend on the environment, and the influence of each practice on the profitability of the others are all empirical propositions that we summarize with our example in Table 1.

Table 1 is a prototype for portraying and discussing the interactions in a system of complements. Each decision about a particular practice is labeled and appears in both a row and a column. We put the environmental variables in the rows below the double rule. In this case, there is just one: the frequency of valuable opportunities to upgrade technologies. To verify the system of complements, it suffices to check just the upper half of the table, because the complementarity relation is symmetric. Also, we can omit checking the diagonal entries, because complementarity is defined in terms of interactions among different decisions. The plus symbols in cells (1, 2) and (1, 3) of the table represent the complementarities that we have hypothesized as present between frequent technical changes and two other labor practices, while the plus in cell (2, 3) represents our hypothesis that flexibly trained workers use discretion more effectively than other workers do. Worker protection aligns workers' long-term interests more closely with the firm's interest, reducing resistance to change and enlisting workers in implementation. That accounts for the plus symbols in cells (1, 4) and (3, 4).

The plus in the last row indicates that the environmental variable directly favors one of the choices and, through the system of complements, indirectly favors all the others. We leave the cells blank when a priori we do not believe there to be a direct interaction. A version of this tool, called the "Matrix of Change," has been used by managers and MBA students to analyze complementarities and thereby assess the feasibility, pace, scope, and location of organizational change efforts (Brynjolfsson et al. 1997).

1.1. Some Applications and Implications

Complementarity ideas can be usefully combined with ideas about the limits to coordination among separate firms to explore the scope of the firm. For example, in the early twentieth century, General Electric (GE) produced a wide array of products based on electric motors. Its intensive research into designing and producing electric motors complemented its strategy of producing a broad range of products using those motors. Improvements in the costs or capabilities of electric motors for one product line increased the probability of improvements for other product lines. Coordinating such variety in a single firm was favored by the concurrent development of a multidivisional organizational architecture.¹

In addition, the analysis of complementarities can provide insights into organizational dynamics. For example, even when senior executives have a clear vision of a new strategy for a company, managing the change can be difficult or impossible (e.g., Argyris 1982; Siggelkow 2002b; Schein 2004).

Why is organizational change so difficult? Complementarities can provide part of the answer (Milgrom and Roberts 1990, 1992, 1995; Brynjolfsson et al. 1997). When many complementarities among practices exist in an established system, but practices from the established system and those from the new one conflict, then it is likely that the transition will be difficult, especially when decisions are decentralized. Because of the complementarities, changing only one practice, or a small set of them, is likely to reduce overall performance.² The natural conclusion is that the organization should change all the practices in the new system simultaneously. However, making these changes all at once can be difficult or infeasible for at least three reasons.

First, there is a basic coordination problem. Actors who control different business practices, assets, markets, and strategies, including some that may be outside the direct control of the firm, need to coordinate on the scope, time, and content of the change. Furthermore, because the exact outcomes and optimal levels of each factor are likely to be at least partially unpredictable, these actors need to continue to agree to and coordinate on any additional adjustments and rent reallocations. All this effort requires accurate communication and an alignment of incentives.

Second, organizations inevitably consist not only of numerous explicit well-defined practices and choices but also many that are implicit or poorly defined. These factors may include the “culture” of the organization and rules of thumb that employees use in completing their tasks. Employees and business partners are likely to continue to act with the same implicit mental

1. There can be several explanations for why coordination is often easier within a firm than across firm boundaries. One possibility based in contract theory is that contracting on knowledge inputs is especially difficult. A second possibility based on differences in beliefs (rather than differences in information) is that GE management may have been more confident about the potential of the electric motors technology than managers in similar firms. For each of these explanations, one is led to the conclusion that GE’s role as the center for research in electric motors created a complementarity that favored its making a broader range of products.

2. Performance will suffer in absolute terms when adopting practices one at a time for a particular type of complementarity: the case where the benefit from adopting a practice in isolation is negative, even when the benefit from adopting the whole bundle of practices is positive. More generally, performance will increase less than proportionately whenever the sum of the benefits of adopting isolated practices is less than the benefit from adopting them as a bundle—in other words, whenever complementarities are present.

models, assumptions, and heuristics, despite changes in the explicit practices. Even if changes of all known practices are coordinated, the organization may end up worse off if the implicit practices are unchanged.

Third, even if a sufficient set of the relevant changes can be identified and defined, and all the relevant actors agree on an action plan (or the decision rights are re-assigned to a group that is in agreement), the timing of change can present difficulties. Because some variables (e.g., building a new plant, hiring and training new employees, or developing a new brand or reputation) take time, it will be difficult to synchronize all the changes. Some will need to start earlier than others (Jovanovic and Stolyarov 2000). Furthermore, when resources are limited and changes are costly, a firm may not have the capacity to do everything at once but must instead phase in the changes.

Each of these types of difficulties has distinct implications for firm and industry dynamics, favoring different subpopulations of organizational types and predicting different trajectories for technical and organizational change. For instance, if firms evolve more complex interdependent structures over time (e.g., Baron et al. 1999), then one might expect older firms to have more difficulty in adapting to rapid unpredictable changes in the environment insofar as this would require changing more complementary practices. If other conditions are right, start-ups might thrive in dynamic or volatile industries.

Thus, the complementarities framework is suitable for modeling situations where combinations of practices can lead to multiple local maxima, such as when the payoff function is discontinuous or the practices are discrete variables that cannot be adjusted continuously. These situations are characteristic of the “rugged landscapes” described by Levinthal (1997) and Rivkin (2000), where adaption and imitation can be difficult. In contrast, as noted by Roberts (2004), much of the standard economic treatment of firms assumes that performance is a concave function of a set of infinitely divisible design choices, and the constraint set is convex. Under these conditions, decisionmakers can experiment incrementally to gradually identify an optimal combination of practices.

The transition difficulties identified with complementarities also imply distinct managerial approaches. In some cases, it may make sense to reassign responsibilities and modularize activities. In other cases, change may be so difficult that it is best to start fresh at a greenfield site or an isolated skunkworks (i.e., a separate subsidiary or new spin-off). Some changes may simply be too costly to pursue for an organization starting with a given set of practices.

The insights into organizational change provided by complementarities also illuminate the difficulties firms have in imitating successful competitors. Such firms as Lincoln Electric, Walmart, or Toyota enjoyed sustained periods of high performance. As a result, they were intensively studied by competitors, consultants, and researchers, and many of their methods were documented in great detail. Nonetheless, even when competitors aggressively sought to imitate these methods, they did not have the same degree of success as these market leaders. Complementarities in organizations can help explain why. As noted by Rivkin (2000), it can be exceedingly difficult to search through a space of strategies with numerous elements that are complementary, and imitators may suffer large penalties from even small errors in attempting to match a particular combination of practices. Subtle complementarities can make imitation difficult even across plants in the same firm, where the participants are working to facilitate knowledge transfer, let alone across firm boundaries. Intel now follows a “copy-exactly” policy when new

chip fabs are built. Previously, when the company copied only those elements of a previous fab that managers thought were important, the new fabs experienced much lower yields for several months. Rather than try to identify and implement each of the missing complementary elements of the coherent system, the copy-exactly approach replicates every element of the old fab, down to the choice of paint color and orientation of windows, regardless of whether it has any known relationship to the chip fabrication process.

Yet another related issue is mergers and acquisitions. When two organizations are combined, each brings with it a set of explicit and implicit business methods. Complementarities within and between these systems will influence how successful such a merger is likely to be, and whether one or the other organization will need to make significant changes to avoid a decline in performance. For example, Cisco Systems, a company that engages in frequent acquisitions, has implemented an explicit process for changing all acquired firms' processes to match Cisco's. The company has employed a director of culture, who issues "culture badges" to all employees in recognition of the complementarity of culture to the functioning of the rest of their systems.

1.2. Using Theory and Data to Study Complementarities

To define complementarity mathematically, we focus initially on the decision of a profit-maximizing firm that is considering changing one or both of two practices. The first assumption is that if it is possible to make the changes separately, it must be possible to make them together.

Definition *Let Δ_1 and Δ_2 be the increase in profits that would result from changing either alone, and let Δ_B be the increase that results from doing both together. Any Δ can be positive or negative and can depend on the other choices that the firm makes. The two changes are (weakly) complementary if $\Delta_B \geq \Delta_1 + \Delta_2$, regardless of the firm's other choices.*

If one or both changes involves setting the level of a variable, such as the number of workers or the amount of capital to be employed, then the relevant change is understood to be an increase in that level. For example, in the neoclassical theory of the firm, capital and labor inputs to production are complementary if the increase in output from raising both inputs together exceeds the sum from increasing either separately.³

The notion of complementarity can be extended to evaluate a larger set of practices or changes. If all combinations of changes are possible, then a set of changes is complementary if each pair in the set is complementary. In practice, this definition means that checking complementarity involves checking the entries of a table like Table 1. The full formal definition in which only some combinations are possible is postponed to the next section.

The formal definitions lead to a set of ten theorems about systems of complements (see Section 2). Importantly for the applications we have in mind, the theorems depend on complementarity alone; none depends on such additional assumptions as convexity of the feasible set or

3. For a firm choosing levels of two inputs, the textbook economic definition of complements is a property of the demand function. It holds that the two inputs are complements if an increase in the price of one leads to a decrease in the demand for the other. If the firm's technology is strictly convex, so that the firm's demand at any price vector is unique and the demand function is continuous, then inputs are complements in our sense if and only if they are demand-theoretic complements.

concavity of the objective. Two of these theorems are characterizations that tell us what needs to be checked to verify the complementarity relationship. One is about common mathematical structures that give rise to complementarity. The example of shared knowledge described above is an important example. Another theorem describes how the static optimum changes with parameters, yielding predictions about clustering and comparative statics. There are also dynamical implications about how such systems evolve over time, creating momentum for a series of changes. Accordingly, long-run changes in the maximum for such a system are always larger than short-run changes. There is a result characterizing the global maximum in a system of complements as a point from which no set of coherent complementary changes is an improvement. More strongly, starting from any position in a system of complements, at least half of the maximum improvement by changing decisions in any arbitrary way can be achieved by restricting attention to coherent complementary changes.

The empirical analysis of complementarities can take several forms. Examining or reexamining case studies through the lens of complementarities can often clarify outcomes and behavior that would otherwise resist explanation. More formal econometric techniques can also be used to explore complementarities. One approach examines firms' choices to assess theories of complementarity. Assuming that firms do maximize profits and that prices or other conditions facing the firm change, the goal is to test whether practices that are predicted to be complementary are shown to be so in the choice data. One may also ask about other implications of the theory and whether those are consistent with the data.

A second form of econometric analysis focuses on performance differences. Suppose that organizations sometimes make mistakes that lead to variation in the sets of choices observed by seemingly similar firms. The challenge then is to infer from the differences in performance across organizations whether the supposedly complementary practices actually lead to higher performance when adopted together than they do when adopted separately.

Complementarities theory promises answers to some of the most interesting questions about firms' practices and characteristics. For example, focusing on the different practices adopted for employees and independent contractors, one might ask:

- Why do employees usually work with assets owned by the firm, whereas independent contractors usually work with their own assets?
- Why do employees work exclusively for their employer during their work hours, whereas independent contractors more often have multiple clients and control their own work hours?
- Why are employees paid by the hour, whereas independent contractors are more often paid based on performance or deliverables?
- Why is training typically more extensive for employees than for independent contractors?

Such clusters of practices may reflect a simple complementarity: each change from an independent contracting practice to an employment practice makes the other changes of that sort more valuable, creating a tendency for practices to be grouped in a particular way. The complementarity relation is symmetric, so the logic can also be applied in the reverse direction:

each change from an employment practice to an independent contracting practice makes other changes of that sort more valuable.

Such complementarities make it risky for a manager to pick and choose best practices from various organizations or systems. For instance, an incentive system that leads to high performance in one context may be highly dysfunctional in a different one that lacks the supporting complementarities. Thus, complementarities can complicate learning and increase inertia, especially if they are not well understood.

2. Theory

For a precise mathematical treatment of complementarities, it is convenient to treat all choices as numeric. Some variables we study are inherently numeric, such as levels of inventory, years of training, or commission rates for salespeople. Others are qualitative binary choices, such as the decision to make or buy, to use an employee or a contractor, or to scrap or retain a line of business. For the qualitative choices, we represent the choice as being from the set $\{0, 1\}$, with 0 denoting what we call the “baseline” decision and 1 denoting the “alternative.” When the variable is inherently numeric, the relevant change can be an increase or decrease, for example, a switch to higher or lower levels of inventories. For the mathematical development, we assume that the baseline refers to the lower level of the variable.

With n binary choices to make, the decisionmaker’s payoff can be denoted by $f(x)$, $x \in \{0, 1\}^n$, which we may also write as $f(x_i, x_j, x_{-ij})$. The i th and j th choices are (weakly) complementary if for all x ,

$$\begin{aligned} f(1, 1, x_{-ij}) - f(0, 0, x_{-ij}) &\geq (f(1, 0, x_{-ij}) - f(0, 0, x_{-ij})) \\ &\quad + (f(0, 1, x_{-ij}) - f(0, 0, x_{-ij})) \end{aligned} \quad (1)$$

To treat groups of coordinated changes, it is helpful to introduce some notation. Given profiles of decisions $x, y \in \{0, 1\}^n$, let $x \vee y$ be the profile that specifies the union of the changes in x and y . Mathematically, $x \vee y$ is the componentwise maximum of x and y . Similarly, let $x \wedge y$ be the profile that specifies the intersection of the changes in x and y . Mathematically, $x \wedge y$ is the componentwise minimum of x and y .

Using this notation, complementarity entails two mathematical conditions on the decisionmaker’s optimization problem. The first condition restricts the constraint set: when x and y are both feasible decision profiles, then so are $x \vee y$ and $x \wedge y$. If $x \vee y$ were not included, then implementing some changes could preclude other changes, blocking the tendency for the changed practices to appear together. If $x \wedge y$ were not included, then failing to implement some changes could require implementing others, blocking the tendency for the unchanged practices to appear together. A set that satisfies this first restriction is a *sublattice* and is defined formally as follows.

Definition A set $S \subseteq \mathbb{R}^n$ is a sublattice if

$$(\forall x, y)(x, y \in S) \Rightarrow (x \vee y, x \wedge y \in S).$$

The second condition is a payoff property similar to that identified by (1). The property can be written as $f(x \vee y) - f(x \wedge y) \geq (f(x) - f(x \wedge y)) + (f(y) - f(x \wedge y))$. This inequality asserts that starting from a point where all practices described by $x \wedge y$ are sure to be implemented, the additional return to implementing all remaining practices, which is $f(x \vee y) - f(x \wedge y)$, is at least as great as the sum of the returns from implementing each separately. A function with this property is said to be *supermodular*. For the definition, we rewrite this inequality in a more symmetrical form.

Definition A function $f: S \rightarrow \mathbb{R}$ is *supermodular* if $(\forall x, y \in S) f(x \vee y) + f(x \wedge y) \geq f(x) + f(y)$.

The decision problems we evaluate are ones in which there may be some separate costs of returns $C_i(x_i)$ associated with each decision, but all payoff interactions are described by the function f . We impose no restrictions on the cost functions, except that each takes a single argument: $C_i: \mathbb{R} \rightarrow \mathbb{R}$. These choices lead us to the following formulation.

Definition The *decision problem*

$$\max_{x \in S} f(x) - \sum_{i=1}^n C_i(x_i) \quad (2)$$

has *complementarities* if S is a sublattice and f is supermodular.

2.1. Example: Producer Theory

One example to illustrate complementarity arises in the neoclassical theory of a competitive firm. With two inputs x_1 and x_2 and a Cobb-Douglas production function, the firm solves the problem $\max_{x \geq 0} \lambda x_1^\alpha x_2^\beta - w \cdot x$, where $\lambda > 0$ and w is a vector of input prices. We may check the two complementarity conditions for this problem. First, the constraint set $S = \mathbb{R}_+^2$ is a sublattice, because for any $x, y \in \mathbb{R}_+^2$ and for $i = 1, 2$, $(x \wedge y)_i = \min(x_i, y_i) \geq 0$ and $(x \vee y)_i = \max(x_i, y_i) \geq 0$, so $x \vee y, x \wedge y \in \mathbb{R}_+^2$. Also, the incremental return to any increase from, say, x_1 to $\hat{x}_1 > x_1$ is $\lambda(\hat{x}_1^\alpha - x_1^\alpha)x_2^\beta - w_1(\hat{x}_1 - x_1)$, which is increasing in x_2 if $\alpha, \beta > 0$. With continuous choice variables, a convenient way to make the same point is to observe that the marginal return to x_1 , $\lambda\alpha x_1^{\alpha-1}x_2^\beta - w_1$, is increasing in x_2 .

2.2. Theorems about Decision Problems with Complementarities

The core of the theory comprises ten mathematical statements about decision problems with complementarities. The sections below report theorems that depend only on the complementarity conditions—sublattices and supermodularity—and not on any other common economic structure, such as divisibility (commonly assumed to justify the use of first-order conditions) or convexity (commonly assumed to imply the existence of supporting prices). These theorems are about decision problems with complementarities, and their scope is not limited, for example, to problems in price theory.

2.2.1. Complementarity Is a Pairwise Relationship

Theorems 1a and 1b explain the claim in Section 1 that complementarity is, essentially, a pairwise relationship among decisions. Theorem 1a is about sublattices. It asserts that a subset of $\mathbb{R}^n$ is a sublattice exactly when it can be expressed as the conjunction of a set of sublattice restrictions for each pair of decision variables separately. Theorem 1b concerns supermodularity. It asserts that a function on a product set (e.g., $\mathbb{R}^n$) is supermodular exactly when it is supermodular in each pair of variables separately.

Theorem 1a (Topkis 1978). *The set $S \subseteq \mathbb{R}^n$ is a sublattice if and only if for each $1 \leq i < j \leq n$, there exist sublattices $S_{ij} \subseteq \mathbb{R}^2$ such that $S = \bigcap_{i,j=1, i < j}^n \{x | (x_i, x_j) \in S_{ij}\}$.*

Theorem 1b (Topkis 1978). *Suppose that $f: S \rightarrow \mathbb{R}$, where S is a product set $S = \times_{i=1}^n S_i$, and each $S_i \subseteq \mathbb{R}$. Then f is supermodular if and only if for all $1 \leq i < j \leq n$ and all $x \in S$, the function $g(z_i, z_j) \equiv f(z_i, z_j, x_{-ij})$ is supermodular.*

2.2.2. The Set of Optimizers Is a Sublattice

Theorem 2 is about the structure of the set of optimizers in a decision problem with complementarities, claiming that such a set is a sublattice. Thus in practice, when searching for an optimum, if we find an optimal profile at which certain optimal changes are made, then there is also an optimal profile at which all such optimal changes are made. Symmetrically, if there is an optimal decision profile in which certain changes are not made, then there is an optimal profile in which none of those changes are made. At an optimum, the individual decisions cluster at least weakly: they are adopted together or not at all.

Theorem 2 (Topkis 1978). *Suppose that (2) is a decision problem with complementarities. Then the set of optimal solutions $\arg \max_{x \in S} f(x) + \sum_{i=1}^n C_i(x_i)$ is a sublattice.*

2.2.3. “Coherent” Searches Can Find and Verify the Optimum

The message of Theorem 2 is further reinforced by considering how to locate and verify an optimum. Suppose that, in a decision problem with complementarities, we start our search for an optimum at some point z . Because z is arbitrary, the optimum might be in any direction, perhaps at some point with higher values of some components and lower values of others. We have made no convexity assumptions, so even if z is optimal in some local neighborhood, it may still fail to be a global optimum. As noted by Levinthal (1997) and Rivkin (2000), it can be particularly difficult if the landscape is “rugged,” with numerous local optima, and the general problem may even be intractable in the sense of NP-completeness. Is there some way to restrict the search?

If the decision problem has complementarities, then two important statements can be made. First, more than half of the gain from moving from decision profile z to the optimum can be realized just by optimizing over the sets with coherent changes, that is, with all choices weakly increased or all weakly reduced. Second, as a corollary, if there are no gains to be had in those coherent directions, then z is actually an optimal choice. To make these statements precise, we define $x \geq y$ to mean $x_i \geq y_i$ for $i = 1, \dots, n$.

Theorem 3 (Milgrom and Roberts 1995). *Suppose that (2) is a decision problem with complementarities. Then*

$$\begin{aligned} & \left(\max_{\{x \in S | x \geq z\} \cup \{x \in S | x \leq z\}} f(x) - \sum_{i=1}^n C_i(x_i) \right) - \left(f(z) - \sum_{i=1}^n C_i(z_i) \right) \\ & \geq \frac{1}{2} \left(\max_{x \in S} \left(f(x) - \sum_{i=1}^n C_i(x_i) \right) - \left(f(z) - \sum_{i=1}^n C_i(z_i) \right) \right). \end{aligned}$$

Corollary 3 *Suppose that (2) is a decision problem with complementarities. Then*

$$z \in \arg \max_{x \in S} f(x) + \sum_{i=1}^n C_i(x_i)$$

if and only if

$$z \in \arg \max_{x \in S \text{ and } (x \geq z \text{ or } x \leq z)} f(x) + \sum_{i=1}^n C_i(x_i).$$

Thus, an understanding of complementarities may simplify the process of finding an optimum.

2.2.4. Comparative Statics Are Like Those of Demand Theory

The fourth theorem is about *comparative statics*, that is, about how the solution changes when a parameter changes. To motivate the discussion, suppose there is an exogenous change affecting just one of the variables, such as a price change, that makes increasing x_1 more profitable. If that change is enough to change the optimal decision, then the complementarity of choices would tend to favor the other choices as well, leading to increased levels of those decisions, too. Indeed, this is the very definition of complementarity in demand theory: reducing the price of an input raises the demand for complementary inputs. So, a comparative statics theorem of this sort is both useful for applications and verifies that the new definition of complements is consistent with earlier uses in demand theory.

For our formulation, we do not limit attention to changing prices, because many of the relevant decisions are not input quantities. Instead, we specify the payoff to consist of a joint part that depends on the parameter θ and individual costs $C_i(x_i)$ that may remain incompletely specified. We rewrite the choice problem with $x \in \mathbb{R}^n$ and $S \subseteq \mathbb{R}^{n+1}$ as follows:

$$X(\theta) = \arg \max_{\{x | (x, \theta) \in S\}} f(x, \theta) - \sum_{i=1}^n C_i(x_i) \quad (3)$$

Here, $X(\theta)$ is the set of optimizers, which we discuss as if it were a singleton. Formally, the next theorem applies even when the set has multiple elements or is empty (has no elements). The parameter θ in (3) enables us to capture changes in the constraint set or in the objective.

If we limit attention to parameters for which $X(\theta)$ is a singleton, it is clear what it means for the optimal solution to be nondecreasing in θ , but we cannot guarantee in general that the optimal solution will be unique. To treat the general case, we need a word and a definition that agrees with “nondecreasing” for the well-understood case but also describes a useful corresponding concept for the general case. The word is “isotone,” and the definition is the following one.

Definition *The set-valued function $X(\cdot)$ is isotone if for all $\theta > \theta'$, if $x \in X(\theta)$ and $x' \in X(\theta')$, then $x \vee x' \in X(\theta)$ and $x \wedge x' \in X(\theta')$.*

Theorem 4 (Topkis 1978). *In (3), suppose that S is a sublattice and f is supermodular. Then $X(\cdot)$ is isotone.*

If we limit attention to parameters for which $X(\theta)$ is a singleton, then the theorem asserts that, on that domain, all components of the decision profile are nondecreasing functions of θ . So this theorem states that the new notion of complementarity coincides with the demand theory notion in such cases. Moreover, if we think of θ as a random variable and assume that $X(\theta)$ is almost always a singleton, then if what is observed are optimal choices, the choices will be positively correlated. This happens because they are all nondecreasing functions of the same one-dimensional random variable.

2.2.5. Complementarity Conditions Are Necessary for Some Comparative Statics . . .

The comparative statics implications of complementarity are interesting, but one might wonder whether similar results can be derived from alternative conditions. They cannot. Both the sublattice condition and the supermodularity condition are essential. We assert this with two theorems that treat the two conditions separately. We limit attention to finite feasible sets to avoid certain technical complications.

Theorem 5a (Milgrom and Shannon 1994). *Suppose that the constraint set S is finite but is not a sublattice. Then for some cost functions C_i , $i = 1, \dots, n$, and some $j \in \{1, \dots, n\}$, the function*

$$X(\theta) = \arg \max_{\{x | (x, \theta) \in S\}} f(x) - \sum_{i=1}^n C_i(x_i) + \theta x_j$$

is not isotone.

Theorem 5b (Milgrom and Shannon 1994). *Suppose that constraint set S is $\{0, 1\}^n$ and the function f is not supermodular. Then for some cost functions C_i , $i = 1, \dots, n$, and some $j \in \{1, \dots, n\}$, the function*

$$X(\theta) = \arg \max_{x \in S} f(x) - \sum_{i=1}^n C_i(x_i) + \theta x_j$$

is not isotone.

2.2.6. . . . But Limited Results Extend to Some Related Systems

Sometimes we study decision problems that can be broken into modules in which decisions about the modules, denoted by x , are complementary, but a set of more specialized decisions in each module has a more complicated structure. To study such cases, let y_i denote the decisions in module i , which may interact with x_i or with other decisions in the module but not with decisions in any other modules. Formally, the optimization problem is:

$$(X(\theta), Y(\theta)) = \arg \max_{\{x|(x,\theta) \in S\}, y_1 \in Y_1, \dots, y_n \in Y_n} f(x, \theta) - \sum_{i=1}^n C_i(x_i, y_i). \quad (4)$$

Theorem 6 *In (4), suppose that S is a sublattice and f is supermodular. Then $X(\theta)$ is isotone.*

The theorem asserts that we can still make assertions about the complementary variables, even if their interaction with other related variables outside the cluster is arbitrarily complicated. The important condition for this conclusion is that these other variables do not interact with variables outside their own modules.

2.2.7. Long-Run Changes Are Larger Than Short-Run Changes

Another important idea that we borrow from demand theory is that, in certain circumstances, long-run adaptations are larger in magnitude than short-run adaptations. As is standard in economics, “short run” refers to a period over which some decisions are fixed, whereas “long run” refers to a period over which all decisions can change. Let x denote the group of decisions that are free (i.e., not fixed) in the short run and y the decisions that are free only in the long run.

For simplicity of our statement, we limit attention to values of the parameter for which the optimal long- and short-run decisions are unique. Thus, let $x^*(\theta, y)$ denote the short-run optimum for any given values of the parameter and the long-run decision y :

$$x^*(\theta, y) \in \arg \max_{\{x|(x,y,\theta) \in S\}} f(x, y, \theta) - \sum_{i=1}^n C_i(x_i) - \sum_{j=1}^m K_j(y_j), \quad (5)$$

where K_j is any cost function associated with decision y_j . We use $y^*(\theta)$ to denote the long-run optimal value of y for any fixed value of the parameter θ :

$$y^*(\theta) \in \arg \max \left(f(x^*(\theta, y), y, \theta) - \sum_{i=1}^n C_i(x_i^*(\theta, y)) - \sum_{j=1}^m K_j(y_j) \right) \quad (6)$$

Notice that the long-run optimal value of x is just $x^*(\theta, y^*(\theta))$.

When the parameter changes (e.g., by increasing from θ' to θ), the short-run reaction is for x to increase in response to the parameter change. In the long run, y also increases, and that acts like a parameter change to lead to a further increase in x . So x changes more in the long run

than in the short run. A symmetric argument applies when the parameter change is a decrease. These relations are summarized by the following theorem.

Theorem 7 (Milgrom and Roberts 1996). *If S is a sublattice and f is supermodular, then x^* and y^* are both nondecreasing. In particular, if $\theta > \theta'$, then*

$$x^*(\theta, y^*(\theta)) \geq x^*(\theta', y^*(\theta)) \geq x^*(\theta', y^*(\theta'))$$

and

$$x^*(\theta, y^*(\theta)) \geq x^*(\theta, y^*(\theta')) \geq x^*(\theta', y^*(\theta')).$$

2.2.8. Dynamical Systems of Complements Exhibit Momentum

A related conclusion applies not merely to long- and short-run equilibrium changes but also to explicitly dynamical systems in which frictions may limit the rate of adjustment. The system starts in a state x_0 and moves, by optimization, through a series of states x_1, x_2 , and so on. The states may, for example, include levels of assets and associated employment, where an overly rapid adjustment of assets is impossible or costly. For example, building a structure in half the usual time typically entails significant additional costs, while attempting to complete a large software project in half the time may be impossible at any price. The conclusion is that there is momentum in a system of complementary choices: once the system variables begin moving in a given direction (up or down), they will tend to continue in that direction.

The assumption that adjustments are impossible or costly is quite naturally modeled by the idea that there are restrictions on successive choices, that is, $(x_{t-1}, x_t) \in S$, and that today's payoffs depend on choices from yesterday as well as today: $f(x_{t-1}, x_t)$. We study both myopic and far-sighted optimizations, as represented by the following two problems:

$$\max_{(x_{t-1}, x_t) \in S} f(x_{t-1}, x_t) - C(x_t), \quad (7)$$

$$\max_x \sum_{t=1}^{\infty} \delta^t (f(x_{t-1}, x_t) - C(x_t)) \quad \text{subject to } (x_{t-1}, x_t) \in S \text{ for all } t \geq 1, \quad (8)$$

where δ is the time discount factor.

Theorem 8 (Milgrom et al. 1991). *If S is a sublattice and f is supermodular, then for both (7) and (8), if $x_1^* \geq x_0^*$, then for all $t \geq 1$, $x_t^* \geq x_{t-1}^*$.*

2.2.9. Complementarities Create a Value to Simple Coordination

Finally, we look at the implications of complementarities for coordination. Any decision system can entail errors, but in a system of complements, it is especially important that any errors be coherent (i.e., coordinated). Going too far in some direction is less costly if the other choices are exaggerated in the same direction.

Theorem 9 Let $\varepsilon_1, \dots, \varepsilon_n$ be independent identically distributed random variables. If f is supermodular, then, for every x and every vector $\alpha \in \mathbb{R}_+^n$,

$$E [f(x_1 + \alpha_1 \varepsilon_1, \dots, x_n + \alpha_n \varepsilon_n)] \leq E [f(x_1 + \alpha_1 \varepsilon_1, \dots, x_n + \alpha_n \varepsilon_1)], \quad (9)$$

where E is the expectations operator.

The point of Theorem 9 is that, regardless of the starting point x , if there are to be random errors in all choices, then regardless of their magnitudes (which are governed by α), it is better that all errors are perfectly correlated rather than being independent. In a system with complementarities, even if choices cannot be optimized, coordination remains important. Thus, having a single, decisive leader in an organization may be better than distributing decision rights, even if the central decisionmaker is imperfectly informed.

2.2.10. Returns to Scale and/or Scope Can Create Complementarities

One of the most common ways for complementarities to arise is from increasing returns to scale. A simple example is the function $f(x_1, x_2) = g(x_1 + x_2)$. It is easy to check that if g is convex, then f is supermodular. Indeed, the marginal return to x_1 is $f_1(x_1, x_2) = g'(x_1 + x_2)$, which is nondecreasing in x_2 if and only if g is convex.

A related example comes from the use of shared inputs for which there are economies of scale. Suppose that research that reduces the costs of chip manufacturing can be used both for memory chips and for microprocessors. Let k denote the expenditures on knowledge—research—and suppose the costs of production for goods $i = 1, 2$ are $c_i(x_i, k)$, where $\partial c_i / \partial x_i$ is decreasing in k . Then the firm's total profit

$$f(x_1, x_2, k) = R_1(x_1) + R_2(x_2) - c_1(x_1, k) - c_2(x_2, k) - k$$

is supermodular, regardless of the revenue functions $R_i(x_i)$. The shared input, which reduces the marginal cost of both kinds of manufacturing, makes the two complements.

Formally, this analysis relies on explicitly including the choice variable k in the formulation. If it is convenient, k can be legitimately pushed into the background by applying the following result.

Theorem 10 (Topkis 1978). Suppose that $f(x, k): \mathbb{R}^n \times \mathbb{R}^m \rightarrow \mathbb{R}$ is supermodular and $S \subseteq \mathbb{R}^n \times \mathbb{R}^m$ is a sublattice. Then the function $g(x) = \max_{\{k | (x, k) \in S\}} f(x, k)$ is supermodular and the set $S_x = \{x | (\exists k)(x, k) \in S\}$ is a sublattice.

The theorem tells us that if the original decision problem exhibits complementarity and if some variables k are optimized away to allow us to focus just on the variables x , then the decision problem for these remaining variables also exhibits complementarity.

3. Empirical Evidence

Much of the first evidence on the relevance of organizational complementarities has come from case studies of individual firms. Cases often provide the richest insight into the nature of complementarities and can be very powerful for shaping our intuition about the underlying

mechanisms at work. Conclusions drawn from case studies, however, can be misleading, because the observer may identify relationships that are idiosyncratic and not generalizable. To address these failings, econometric techniques have increasingly been used over the past decade to test theories of complementarities using sets of firms or establishments, rather than just a single case. Recently, some economists have argued that international differences in business practices and performance can be traced back to complementarities in organizations. Here we review this literature⁴ with a more formal discussion of empirical techniques in Section 4.

3.1. Case Studies

A Harvard Business School case (Berg and Fast 1975) detailing Lincoln Electric's unique business methods and compensation scheme is among the school's best-selling cases ever, and it is still widely taught today. Lincoln Electric, an arc-welding company that began operations in 1895, has not laid off a worker in the United States since 1948⁵ and has average earnings for hourly workers that are double those of their closest competitors (Milgrom and Roberts 1995: 200). The company uses piece rates as its main form of compensation, where workers are paid by the amount of output they produce, rather than a fixed salary. Once the piece rates are set, the company commits to that rate forever, unless new machinery or production methods are introduced. In addition, the company pays individual annual performance bonuses based on its profits that typically amount to 60–90% of the regular annual earnings for an average employee. If the company's methods are so widely studied, why has the remarkable success of Lincoln Electric not been copied by other firms? Rather than looking for the answer in the piece rates alone, Milgrom and Roberts (1995) hypothesize that it is the complementarities inherent in the workplace that make Lincoln Electric so difficult to copy. To copy piece rates may be easy enough, but all the other distinctive features of the company, such as internal ownership, promoting from within, high bonuses, flexible work rules, and credible commitments, are part of a reinforcing system. A system is much more difficult to reproduce than just one or two parts, especially when one considers that many of the important complements, such as corporate culture, may be difficult to accurately observe and even harder to translate to other contexts.

More recently, longitudinal case studies by Siggelkow (2001, 2002a,b) have found that complementarities can explain the evolution of the Liz Claiborne cosmetics company and Vanguard Group in financial services. For instance, Siggelkow found that complementarities at Liz Claiborne can limit managers' options when responding to environmental changes. This restriction leads them to favor "fit-conserving" change, even when it decreases the appropriateness of the overall choice set.

Holmes (2001) develops a model of complementarities relating to the use of technology in the retail sector in an attempt to explain the emergence of big-box retailers. The author explores

4. Appendix A provides a list of empirical studies of complementarities. Inevitably, our review will be incomplete. Ennen and Richter (2010) conducted a computerized search of the literature and found that between 1988 and 2008, 1,398 papers in management, economics, marketing, research and development (R&D), and information systems journals contain the word stem "complement." They review 73 of these papers, an overlapping set with those discussed below. See also useful discussions by Ichniowski and Shaw (2003) and Porter and Siggelkow (2008).

5. See <http://web.archive.org/web/20090523223033/http://www.lincolnelectric.com/corporate/career/default.asp>.

the complementarities between the use of bar codes and computer tracking of inventory. His model shows that “new technology induces stores to increase delivery frequency” (Holmes 2001: 708). This result leads to his second finding, that with more frequent deliveries, it is more efficient for stores to be larger. He points out that if the store remained the same size but received twice as many deliveries as before, then the trucks would only be half as full for each delivery (Holmes 2001: 708).

Barley (1986) explores the introduction of identical computed tomography (CT) scanners in two different hospitals in the same metropolitan area and finds that identical technology led to very different organizational outcomes, depending on what other practices were also in place. The CT scanners disrupted the existing power structure between the radiologists and technicians and led to different forms of organization around the technology. He concludes that

Technologies do influence organizational structures in orderly ways, but their influence depends on the specific historical process in which they are embedded. To predict a technology’s ramifications for an organization’s structure therefore requires a methodology and a conception of technical change open to the construction of grounded, population-specific theories. [Barley 1986: 107]

Autor et al. (2002) study the effect of introducing check imaging and optical character recognition technologies on the reorganization of two floors of a bank branch. In the downstairs deposit-processing department, image processing led to computers substituting for high-school educated labor. In the upstairs exceptions-processing department, image processing led to the integration of tasks, with “fewer people doing more work in more interesting jobs” (Autor et al. 2002: 442). The authors conclude that the same technology can have radically different effects on workplace reorganization, depending on the level of human capital and other nontechnology-related factors, even within one building of a single company.

In some cases, the complementarities among practices are subtle and not well understood even by the participants themselves. Brynjolfsson et al. (1997) write about the business process reengineering efforts at one of Johnson & Johnson’s manufacturing plants. The company sought to make almost exactly the sort of transition that Milgrom and Roberts (1990) describe from traditional manufacturing practices, similar to those used by Ford Motor Company in the early years of the twentieth century, to “modern manufacturing.”⁶ Despite a clear plan and an explicit written description by senior management of many of the specific complementarities inherent in both the old and the new systems,⁷ the initial reengineering efforts were unsuccessful. After spending millions of dollars on new, highly flexible production equipment, key performance

6. Milgrom and Roberts (1990) trace a broad set of organizational practices to improvements in information technology. One extended example they explore involves the use of computer-aided design/computer-aided manufacturing (CAD/CAM) engineering software in manufacturing. This software promotes the use of programmable manufacturing equipment, which makes it possible to offer a broader product line and more frequent production runs. This in turn affects marketing and organization. Shorter production runs lower inventory costs, which lower prices. Buyers also value shorter delivery times. Thus, the firm now has a substantial incentive to reduce other forms of production delays and invest in computerized ordering systems. The example illustrates how important it is to think in terms of systems of activities, rather than trying to adopt one particular practice.

7. See Appendix B for an example of reengineering efforts at Merrill Lynch.

metrics were largely unchanged. An interview with a 30-year veteran line supervisor revealed a potential explanation. He was sincerely intent on making the transition a success and he explained, "I've been here a long time and I know that the key to productivity is avoiding change-overs [the transition from one product to another using the same equipment]. You get killed in the change-overs." Accordingly, he and his team were using the new flexible production equipment to produce long, unchanging product runs. This is precisely the opposite of what management had intended and what Milgrom and Roberts (1990: 524) predicted in their paper. However, the supervisor and his team had built up numerous such heuristics as part of their decades-old investment in work practices. In other words, their organizational capital, much of it implicit, turned out to be a poor fit for the new physical capital. Ultimately, the company canceled the change effort at the existing site and restarted it at a new site, with a hand-picked set of new, mostly very young, workers. The new effort was such a success that the windows were painted black to make it more difficult for competitors to learn about the new system of technology and practices.

This kind of difficulty in managing transitions appears to be common. For instance, McAfee (2002) quantitatively examines an enterprise resource planning (ERP) system implementation over a period of several months in one firm. The ERP system was introduced without any other business process changes at first. McAfee finds a significant dip in company performance after it adopted the system, which he attributed to this lack of business process redesign. After several months, however, the firm adapted, and post-ERP performance was better than pre-ERP adoption, reflecting the successful adjustment of complementarity practices.

In many other cases, change efforts remain unsuccessful when the complementarity organizational practices are not revised along with the introduction of new technologies. For instance, General Motors (GM) spent \$650 million on new technology at one plant in the 1980s but did not make any important changes to its labor practices. The new technology at GM did not result in any significant quality or productivity improvements (Osterman 1991).

3.2. Econometric Studies of Complementarities

3.2.1. *United States*

One of the clearest analyses of complementarities and productivity comes from Ichniowski et al. (1997). They use data from 36 steel finishing lines in 17 different companies and measure the impact of different clusters of workplace practices on productivity and product quality. By focusing on a single production process, they are able to use a narrow productivity metric (uptime of the production line) and avoid many potential sources of unobserved heterogeneity. One important difference that remained was the choice of work practices adopted at the line, which varied across lines, as well as across time at the same line in about 14% of the cases. Ichniowski et al. (1997) looked at both correlations as well as productivity regressions and found evidence that work practices that include incentive pay, teams, flexible job assignments, employment security, and training were mutually complementary, compared to a more traditional set of work practices. Their two key conclusions are that (i) workplace practices tend to cluster more than random chance would predict, and (ii) clusters of workplace practices have significant and positive effects on productivity, but isolated changes in individual work practices have little effect on productivity.

Bresnahan et al. (2002) run an analysis at the firm level and reach similar conclusions. The authors examine 300 large firms using data for 1987–1994 from both manufacturing and service industries in the United States. They study the organizational complements to technology and their impacts on productivity, and find that “increased use of IT [information technology], changes in organizational practices, and changes in products and services *taken together* are the skill-biased technical change that calls for a higher skilled-labor mix” (Bresnahan et al. 2002: 341). Furthermore, the interaction of IT, workplace organization, and human capital are good predictors of productivity. Because organizational changes take time, this can help explain the finding that the largest productivity increases often come several years after major IT investments (Brynjolfsson and Hitt 2003).⁸

Using plant-level data on almost 800 establishments for 1993–1996, Black and Lynch (2004) find that productivity is positively correlated with the proportion of nonmanagers using computers, teams, profit sharing, employee voice, and reengineering. They assert that “workplace organization, including re-engineering, teams, incentive pay and employee voice, have been a significant component of the turnaround in productivity growth in the US during the 1990s” (Black and Lynch 2004: F97). In a related 2001 paper, Black and Lynch examine the impact of a total quality management (TQM) system on productivity. Using data from 600 manufacturing plants for 1987–1993, they find that adopting a TQM system alone does not meaningfully affect productivity. However, they do find that giving employees greater voice or profit-sharing programs alongside a TQM program has significantly positive effects on productivity.

Autor et al. (2003) conduct a study the impact of computerization on job tasks. They use job and occupation data from the U.S. Department of Labor’s Dictionary of Occupational Titles from 1960 to 1998. In line with the other studies we examined, the authors derive two main conclusions. First, computers substitute for routine tasks, and second, computers complement workers doing complex or problem-solving tasks.

More recently, Garicano and Heaton (2010) find support for complementarities in a public sector context. They use information from a panel of police departments in the United States that contains detailed information on IT usage and organizational practices between 1989 and 2003. The productivity variables in this context are local crime clearance rates and crime rates, controlling for local demographics. They find that IT by itself has little positive impact on either of those performance metrics—that is, departments that invested more in IT did not see larger drops in crime or better arrest rates. However, when IT was introduced together with a new system of organizational practices, IT had significant effects on police performance. The successful system of practices in this context is the CompStat system, which combines real-time geographic information on crime with strong accountability by middle managers in the form of daily group meetings, geographic resource allocation, and data-intensive police techniques. The CompStat practices were associated with crime clearance rates an average of 2.2 percentage points higher in agencies implementing this integrated set of practices; the individual practices

8. Using data from about 500 large firms for 1987–1994, Brynjolfsson and Hitt (2003) find that the returns to IT are no different than those of ordinary capital when looking only at the short-term, 1-year impact. However, when they look at 5- or 7-year time horizons, the productivity and output contributions of the same technology investments are five times as large. For a broader review of related findings, see Brynjolfsson and Hitt (2000).

composing CompStat had no independent ameliorative impact on crime levels or clearance rates.

Complementarities have also been explored in the strategy literature, often as part of the resource-based view of the firm. For instance, Tanriverdi and Venkatraman (2005) analyze 303 multibusiness firms and find evidence of complementarities in the performance benefits of combining customer knowledge, product knowledge, and managerial knowledge. In contrast, both market-based and accounting-based performance metrics are not significantly improved from any of these types of knowledge in isolation.

Researchers in the R&D literature have identified complementarities in interfirm relationships. For instance, Belderbos et al. (2006) found evidence of complementarity relationships when measuring the productivity effects of R&D cooperation strategies among competitors, customers, and universities. Similarly, Colombo et al. (2006) found that complementarity assets, including technologies and commercial assets, could explain the success of alliances for high-tech start-ups.

3.2.2. *International Comparisons*

There has been much debate about why productivity growth has been higher in the United States than in Europe (for a review of the literature, see O'Mahony and van Ark 2003). One class of possible explanations focuses on various country-specific factors that are external to the organization of the firm, such as taxes, regulation, and culture. However, another promising line of research studies the differences in the ways that firms organize themselves from country to country.

Recent research suggests that differences in productivity between the United Kingdom and the United States may indeed be due to organizational differences and, more specifically, to the firm-specific IT-related intangible assets that are often excluded in accounts of macroeconomic growth. The research compares differences between U.S.- and British-owned firms operating in the United Kingdom. With this data, the authors hope to discover whether there is something unique about American ownership versus being located on U.S. soil (with less regulation or stronger product market competition) that drives higher productivity growth.

Bloom et al. (2007) conduct a study on a panel of about 8,000 establishments across all industries in the United Kingdom from 1995 to 2003. They found that U.S.-owned establishments were both more IT-intensive and more productive than British- or other foreign-owned companies operating in the United Kingdom. They specifically attribute this difference to complementarities between IT and the types of organizational capital that are more common in American firms.

Crespi et al. (2007) present similar evidence that American firms operating in the United Kingdom are more productive and implement more related organizational capital than do their British counterparts. Their study, based on a dataset including approximately 6,000 British firms from 1998 to 2000 across all industries, introduces a variable as a proxy for organizational capital. The authors find that IT has high returns regardless of organizational factors. However, when they control for an organizational proxy variable, the measured returns attributed to IT are lower, which suggests that some of the measured IT-related boost in productivity actually came from organizational factors. In contrast to the evidence of complementarity between IT and organization, the authors find that there is "no additional impact on productivity growth

from the interaction of organizational capital and non-IT investment” (Crespi et al. 2007: 2). The authors’ new findings are that organizational change is affected by ownership and market competition, and that U.S.-owned firms operating in the United Kingdom are more likely to introduce organizational change than non-U.S.-owned firms. In turn, non-American multinationals are more likely to introduce organizational change than domestically owned (British) firms.

Bugamelli and Pagano (2004) work with a dataset for about 1,700 Italian manufacturing firms and conclude that Italian firms have a 7-year technological gap compared to similar American firms. They reject the notion that the gap is due to sectoral specialization of the Italian economy into such industries as textiles, clothing, and food, which are not IT intensive. Rather, they argue that it is the missing complementary business reorganization that has been the barrier to investment in IT in Italy.

Caroli and Van Reenen (2001) generate three major findings with British and French establishment data from 1984 and 1990 (Great Britain) and 1992 (France). First, organizational change is associated with a decline in demand for unskilled workers. Second, higher cost of skills leads to a lower probability of organizational change. Third, organizational changes are associated with greater productivity in establishments with more skilled workers. All three findings are consistent with complementarities between workplace reorganization and skilled labor.

4. Testing for Complementarities: Theory and Practice

When the costs and benefits of organizational practices can be accurately measured, complementarities theory provides clear empirical predictions. In this section, we consider two types of statistical tests for complementarities: performance differences and correlations. For each test, we discuss the assumptions that are necessary to make them effective ways to reveal the existence and magnitude of complementarities. In many cases, the conditions that make it difficult to identify complementarities by examining performance differences will actually make it more likely that they can be identified via correlations, and vice versa. We then analyze the role of unobserved heterogeneity in the costs or benefits of changing organizational practices. Such differences can bias tests for complementarities. Finally, we discuss various empirical approaches for overcoming these problems.

4.1. Performance Equations

Consider a case where potential complements y_1 and y_2 each vary independently and exogenously. For instance, a new computer system, y_1 , is implemented randomly across offices based on a lottery, while employee training, y_2 , is deployed randomly across employees based on the last digits of their social security numbers. Each choice is binary, so $(y_1, y_2) \in \{0, 1\}^2$. Thus, given the independence of the design choice, we will have a random sample in each of the four ordered pairs $(0, 0)$, $(0, 1)$, $(1, 0)$, and $(1, 1)$. If the practices are complements, then by (1) in Section 2, the change in total output is greater when both practices are implemented together than the sum of the changes when each practice is implemented separately:⁹

$$f(1, 1) - f(0, 0) \geq f(1, 0) - f(0, 0) + f(0, 1) - f(0, 0).$$

9. To simplify notation, we omit reference to other choices of the decisionmaker x_{ij} or to exogenous variables.

This suggests an obvious test statistic for complementarities using performance differences:

$$\kappa_p \equiv f(1, 1) + f(0, 0) - f(1, 0) - f(0, 1). \quad (10)$$

Of course, f may be measured with error and other exogenous factors may affect performance, either directly or in combination with one of the complements. Thus, a typical approach is to estimate performance with a multivariate regression, which accounts for these other factors and their interactions, holding them fixed and thereby allowing the researcher to focus on the potential complementary practices themselves. When κ_p is significantly greater than zero, we can reject the null hypothesis of no complementarities.

Many authors have implemented this approach. For instance, as noted in Section 3.2.1, Ichniowski et al. (1997) compared steel finishing lines and, using ordinary least squares and fixed effects regressions, found that those implementing certain human resources practices together were significantly more productive than implementing the same practices separately. More recently, Bloom et al. (2009a) gathered data on IT and organizational practices for a sample of American and European firms. In each case, the predicted pattern of complementarities was evident.

Of course, in many cases the variables will naturally be continuous, such as the quantity of IT capital stock or hours spent on training, so information would be lost if they were discretized into two categories. Instead, the continuous versions of the variables can be included in a performance regression along with an interaction term that multiplies two of the choice variables together. If the variables are normalized with their means set equal to zero, then it is easy to interpret the coefficient of the interaction term, assuming that the choices were made independently and exogenously. A value greater than zero at a chosen significance level (such as 5%) is evidence of complementarity. Brynjolfsson et al. (2002) provide a plot that shows market value as a continuous function of both IT and an index of organizational practices (Figure 1).

The performance tests can be generalized to the case of three or more complements. For instance, Aral et al. (2012) and Tambe et al. (2012) each model different three-way systems of complements. The theory suggests four performance tests of complementarities, which can readily be seen with a cube diagram. For instance, Tambe et al. test for complementarities in the triple (x, y, z) , where x represents IT investments, y is decentralized work organization, and z is external orientation (meaning information systems are focused on customers, competitors, and suppliers, instead of on primarily internal data). There are eight potential systems, and the theory of complementarities predicts that they will be related to one another by the four inequalities depicted in Figure 2.¹⁰

4.2. Correlations and Demand Equations

The assumption that the adoption decisions are exogenous and uncorrelated is a strong one. In particular, managers usually will be consciously trying to maximize, or at least increase, performance, so when two practices are actually complementary, managers will seek to adopt them together. If the managers have perfect foresight and full control over both choice variables,

10. Additional inequalities may be inferred by comparing the performance of intermediate systems with the performance of the two fully complementary systems at $(0, 0, 0)$ and $(1, 1, 1)$.

Figure 1. Normalized market value $\ln(mv)$ as a function of information technology investment $\ln(i)$ and an index of organizational practices org for a sample of 372 firms. From Brynjolfsson et al. (2002).

Four tests of complementarities:

1. IT: $F(1,1,1) - F(0,1,1) > F(1,0,0) - F(0,0,0)$	Fail $p = 0.333$
2. WO: $F(1,1,1) - F(1,0,1) > F(0,1,0) - F(0,0,0)$	✓ $p = 0.043$
3. EXT: $F(1,1,1) - F(1,1,0) > F(0,0,1) - F(0,0,0)$	✓ $p = 0.007$
4. The system: $[F(1,1,1) - F(0,1,1)] + [F(1,1,1) - F(1,0,1)] + [F(1,1,1) - F(1,1,0)] -$ $[F(1,0,0) - F(0,0,0)] + [F(0,1,0) - F(0,0,0)] + [F(0,0,1) - F(0,0,0)] > 0$	✓ $p = 0.008$

Figure 2. Cube view of three-way complementarities. EXT, external orientation; IT, information technology; WO, decentralized work organization. From Tambe et al. (2012).

then in the absence of other exogenous forces, the complementary variables will always be adopted together. In this case, all observations (y_1, y_2) will be either $(0, 0)$ or $(1, 1)$; there will be no off-diagonal observations in the data. As a result, it will be impossible to identify values for $f(1, 0)$ or $f(0, 1)$, and we cannot estimate κ_p econometrically.

Similarly, market competition might reduce or eliminate the population of firms that attempts to implement inefficient combinations of practices. As with conscious choice by managers, this effect will reduce the share of off-diagonal observations and weaken the power of the performance test. Of course, in either of these cases, the very fact that the practices are correlated provides evidence of complementarities. This suggests a second test for complementarities using the correlation of practices:

$$\kappa_c \equiv \text{correlation}(y_1, y_2).$$

A larger value of κ_c provides more evidence against the null hypothesis of no complementarities. If other exogenous factors affect the choices, then this correlation should be made conditional on those factors.

In many cases, it can be useful to think of this test as estimating a factor demand equation: the demand for one practice, y_1 , will be higher when the levels of the other practice, y_2 , are higher, conditional on other observable characteristics. If y_2 is determined exogenously, then a multivariate regression will provide an estimate of κ_c . When y_2 is endogenous, then it may be possible to identify exogenous instrumental variables and use two-stage least squares.

Measuring the correlation, or clustering, of practices is perhaps the most common approach to testing for complementarities. It has the virtue that it does not require performance metrics, only observability of the practices themselves. Arora and Gambardella (1990) were the first to explicitly use this fact as a test for complementarities, and it was further analyzed by Holmström and Milgrom (1994). See also Arora (1996).

4.3. Boundedly Rational Decisionmaking: Random Error

Although the extreme cases of random and independent assignment of practices on one hand or perfectly correlated choices on the other hand are useful brackets, most real-world cases are likely to fall somewhere in between. In part, this is because decisionmakers may have imperfect information or bounded capabilities to assess the optimal levels of each practice. Furthermore, they may not be optimizing the same performance metric that the econometrician is measuring. If the choice of practices reflects both some degree of random error and of conscious choice, then both tests may be useful.

The correlation test $\kappa_c > 0$ has the most power when managers know about the relevant complementarities and are able to act effectively on that knowledge, so that errors in choosing practices are small. Conversely, the performance-based test $\kappa_p > 0$ is most powerful when the practices are randomly determined.

In practice, both tests are often useful. For instance, the Ichniowski et al. (1997) analysis presents data on both the clustering of practices and the performance effects of certain clusters. Similarly, the Bresnahan et al. (2002) analysis of IT and organizational practices included a series of 2×2 charts. The productivity differences relative to the base case of low IT and low

Table 2. Productivity differences for four combinations of information technology (IT) and new organizational practices (ORG)

Adoption of ORG	Adoption of IT	
	Low	High
High	.0258 (.0188) [N = 67]	.0643 (.0174) [N = 97]
Low	0 (n.a.) [N = 97]	.0130 (.0178) [N = 68]

Source: Adapted from Bresnahan et al. (2002).

Notes: n.a., not applicable. Standard errors are in parentheses. The number of observations is in brackets. The diagonal mentioned in the text runs from the lower left to the top right.

adoption of new organizational practices are consistent with complementarities as measured by the performance test ($\kappa_p \equiv f(1, 1) + f(0, 0) - f(1, 0) - f(0, 1) = 0.0255 > 0$), but the magnitude is not statistically significant (Table 2).¹¹ At the same time, the disproportionate share of observations on the diagonal (low-low, or high-high) cells is consistent with correlation test of complementarities and is statistically significant (Pearson chi-square test for association: $\chi^2 = 10.58$; $p < 0.001$).

Table 2 matches the organizational data to 1994 IT spending by the same firms. In contrast, when 1987 data are used, the performance test is significantly greater than zero, whereas the correlation test is positive but not statistically significant. One interpretation is that managers learned and adjusted their IT investments over the intervening 7 years, which is consistent with optimizing behavior and would affect the two complementarities tests as predicted.

4.4. Unobserved Heterogeneity

Problems created by unobserved heterogeneity are particularly salient when examining complementarities in organizations.

The adoption of practices will be a function of their costs and benefits, just as decisions about physical inputs are. However, although the prices of physical capital or labor are often observable, the costs of adopting organizational practices usually are not.

In general, the firm, but not the econometrician, may observe a broad set of exogenous variables. These might be, for example, managerial talent, worker attitudes, or beliefs about market conditions. When these cannot be explained by observables but still affect the marginal returns to adoption, then the econometric estimates of complementarities can be biased. The

11. Note that in Table 2, the output increase for the high-org/high-IT quadrant (.0643) is significantly greater than in the low-org/low-IT quadrant and is also greater than any of the other strategies. However, this does not by itself indicate complementarity, unless the output changes exceed the sum of changes in the off-diagonal quadrants.

standard econometrics of production functions and demand equations (e.g., see Berndt 1991) can provide useful guidance on potential biases, as can the broader literature on the effects of unobserved heterogeneity and endogeneity in regression estimates.

In particular, Athey and Stern (1998), drawing in part on the work on discrete choice and switching regressions (e.g., Heckman and MaCurdy 1986; Heckman and Honoré 1990) carefully analyze how unobserved heterogeneity can bias the performance and correlation tests for complementarities we described above. Here, we closely follow their approach to replicate key insights from their model and summarize some of their important results. We refer the interested reader to their very thorough paper for further detail.

For simplicity, assume firm t makes a discrete 0-or-1 choice for each practice, and the practices are endogenously determined by the firms' managers. As above, let y_1 and y_2 represent Practice 1 and Practice 2, respectively, for example,

y_1 represents a new computer system, and

y_2 is a training course.

Let $\mathbf{X}$ represent the practice-specific exogenous variables that, regardless of the other practices that the firm adopts, will affect the returns to that practice. For example, worker familiarity with computers will affect the returns to investing in the new computer system. An important assumption is that, regardless of what other practices the firm has in place, these practice-specific variables will affect the returns to adopting that practice.

In particular, the practice-specific return for each practice is

$\beta_1 \mathbf{X}_1$ if the firm adopts Practice 1, and

$\beta_2 \mathbf{X}_2$ if the firm adopts Practice 2.

Now we have described $\mathbf{X}$, the variables that affect the returns to the practices.

In addition, there also may be factors that affect adoption but not productivity. For example, training subsidies will make it more likely that the firm adopts training programs, but the subsidies themselves do not directly affect productivity. Let $\mathbf{W}$ represent these practice-specific exogenous variables that will affect adoption. Similar to the case for $\mathbf{X}$, an important assumption is that these are practice-specific variables, and they affect the adoption choice for the practice irrespective of what other elements are adopted.

4.4.1. Observability and Bias

Consider the case where the firm is aware of benefits or costs of adopting practices that the econometrician cannot observe. Thus, following Athey and Stern (1998), we further parse the elements of exogenous variation ($\mathbf{X}$, $\mathbf{W}$) each into an observed component and an unobserved component:

let $\mathbf{X}_j = (\mathbf{x}_j, \chi_j)$ for Practice j ($j = 1, 2$), and

let $\mathbf{W}_j = (\mathbf{w}_j, \omega_j)$ for Practice j ($j = 1, 2$).

Table 3. Examples of observable and unobservable exogenous variations in the adoption of computers

Variable	Observable	Unobservable
X	X_j (e.g., years of experience, education)	χ_j (e.g., home use of computers, whether software is user friendly)
W	w_j (e.g., state or federal tax laws to subsidize technology investment, regulation requiring use of a particular technology)	ω_j (e.g., beliefs about whether computer system will be adopted by other firms [if network effects are present], manager inclination to adopt fads)

Table 3 is an example of the observed components ($\mathbf{x}, \mathbf{w}$) and unobserved components (χ, ω) of exogenous variation for adopting Practice 1, a computer system.

The observable factors can be incorporated into the estimating equations. However, depending on the nature of the unobserved heterogeneity, econometric approaches may be biased to either overestimate or underestimate complementarity. Consider an estimate of a complementarity parameter from interaction effects using an ordinary least squares or two-stage least squares estimation of the organizational design production function. Assume that the interaction effects θ_{ij} are constant across firms,¹² where the first subscript indexes the level of the first practice (0 or 1), and the second subscript indexes the level of the second practice (also 0 or 1).

The total payoff for each of the four systems will now consist of three components:

1. the direct effect of Practice 1, if it is present;
2. the direct effect of Practice 2, if it is present; and
3. the pure interaction effect θ_{ij} for the relevant system.

Thus we have the following estimating equation:

$$f^t(i, j) = \beta_{1t}x_{1t}y_{1t} + \beta_{2t}x_{2t}y_{2t} + \theta_{ij} + \xi_t, \tag{11}$$

where x represents the observables, y is a dummy variable that is equal to 1 if the firm adopts the practice, and θ_{ij} is the pure interaction effect. We use t to index the firm, and ξ is a firm-specific error term. Equation (11) is similar to the approach of Ichniowski et al. (1997).

As Athey and Stern (1998) point out, we can further break up the error into the following terms:

$$\xi_t = \chi_{1t}y_{1t} + \chi_{2t}y_{2t} + \varepsilon_t, \tag{12}$$

12. In other words, assume that there is no systematic variation across firms in the performance effects of interactions. We discuss implications of relaxing this assumption in Section 4.4.4.

so that

$$f^t(0, 0) = \theta_{00} + \varepsilon_t, \text{ if the system} = (0, 0)$$

$$f^t(0, 1) = \theta_{01} + \beta_{2t}x_{2t} + \chi_2 + \varepsilon_t, \text{ if the system} = (0, 1)$$

$$f^t(1, 0) = \theta_{10} + \beta_{1t}x_{1t} + \chi_1 + \varepsilon_t, \text{ if the system} = (1, 0)$$

$$f^t(1, 1) = \theta_{11} + \beta_{1t}x_{1t} + \beta_{2t}x_{2t} = \chi_1 + \chi_2 + \varepsilon_t, \text{ if the system} = (1, 1).$$

The problem is that χ_1 and χ_2 are unobservable. For example, the ordinary least squares estimate of the payoff from adopting both practices together, $\hat{\theta}_{11}^{OLS}$, will have two bias terms (one each from χ_1 and χ_2).

Now recall the complementarity test discussed in Section 4.1:

$$\kappa_p \equiv f(1, 1) + f(0, 0) - f(1, 0) - f(0, 1).$$

The expected value of the test statistic will be

$$\begin{aligned} E[\hat{\kappa}^{OLS}] &= \kappa + E[\chi_1|ij = (1, 1)] + E[\chi_2|ij = (1, 1)] \\ &\quad - E[\chi_1|ij = (1, 0)] - E[\chi_2|ij = (0, 1)]. \end{aligned}$$

The last four terms add up to zero only if $\kappa_p = 0$ and χ_1 and χ_2 are uncorrelated or are equal to zero. Otherwise, there is bias, which we explore next.

4.4.2. Biases in the Performance Test

Under reasonable assumptions, the performance tests may reject the existence of complementarities even when they actually exist. Consider the following assumptions (Athey and Stern 1998: 18):

1. There are no unobserved exogenous drivers of adoption for the practices: $\omega_1 = \omega_2 = 0$.
2. χ_1 and χ_2 are uncorrelated.
3. The practices are truly complements: $\kappa_p > 0$.

Then we have $E[\hat{\kappa}_p^{OLS}] < \kappa_p$ and $E[\hat{\kappa}_p^{2SLS}] < \kappa_p$.

This result may seem a bit counterintuitive. Why should the existence of uncorrelated χ_1 and χ_2 bias the statistic downward, leading us to possibly reject complementarities when in actuality they exist?

To see the problem, write the test statistic as follows:

$$\begin{aligned} E[\hat{\kappa}_p^{OLS}] &= \kappa_p + E[\chi_1|ij = (1, 1)] - E[\chi_1|ij = (1, 0)] \\ &\quad + E[\chi_2|ij = (1, 1)] - E[\chi_2|ij = (0, 1)]. \end{aligned}$$

Consider the first term after κ_p . When a firm has adopted both practices, and the practices are truly complementary, then a manager is more likely to find it beneficial to adopt the new computer system, even if there is not much of an unobserved shock χ_1 . Now examine the second term. If there is no training, and the practices are complementary, then the manager is less likely to adopt the computer system unless there is a beneficial unobserved productivity shock χ_1 . Take an extreme case and suppose that, unless there is training, the econometrician has good reason to believe from the observed variables that the firm is worse off adopting computers than not adopting. Therefore, assuming that the manager is optimizing, if the firm adopts computers but not training, there must have been a large source of unobserved benefits to adopting computers that the manager was aware of, but the econometrician did not see. Therefore, $E[\chi_1|ij = (1, 0)] > E[\chi_1|ij = (1, 1)]$, and so $E[\chi_1|ij = (1, 1)] - E[\chi_1|ij = (1, 0)] < 0$. Using similar reasoning, $E[\chi_2|ij = (1, 0)] > E[\chi_2|ij = (1, 1)]$, and so $E[\chi_2|ij = (1, 1)] - E[\chi_2|ij = (0, 1)] < 0$.

Thus, when the manager is optimizing and faces practice-specific productivity shocks that are unobserved by the econometrician, then the sum of the four last terms is always negative, biasing down the test statistic.

As a practical example, this might be the case if spare computer capacity can be leased out at some firms, generating additional profits from computer purchases for those firms but not for others. Then some firms (those with leasing opportunities) will choose to purchase computers even when the complementary practice (training) is not present. In contrast, firms that already have a training system in place are more likely to find it profitable to purchase computers, even when they do not obtain any additional profits from leasing opportunities. If the econometrician does not observe these leasing opportunities, then the test statistic can be biased downward.

4.4.3. Biases in the Correlation Test

Now assume the following:

1. There are no unobserved exogenous drivers of adoption for the practices: $\omega_1 = \omega_2 = 0$.
2. χ_1 and χ_2 are positively correlated (not uncorrelated, as in Section 4.4.2).
3. The practices are truly independent: $\kappa_p = 0$.

Then we have

$$E[\hat{\kappa}_c^{OLS}] > 0 \quad \text{and} \quad E[\hat{\kappa}_c^{2SLS}] > \kappa.$$

That is, the researcher would find that there is a correlation between the practices, even though there are no complementarities between them.

With these assumptions, the unobserved returns to the new computer system could be high when the unobserved returns to training are also high. For example, it might be that firms in information-intensive industries have higher returns to computer investments than other firms have. Similarly, they might also experience greater benefits from training their workers. Then computer purchases would disproportionately occur if χ_1 is high, which is exactly when χ_2 is high as well, leading to greater training.

This example can be thought of as a basic case of bias stemming from omitted variables. Obviously, if the potential for such variables exists, the econometrician should make every effort to measure them (i.e., convert them from χ to $\mathbf{x}$) and explicitly include them in the regression.

4.4.4. *Systems of Equations and Instruments*

Organizational practices can be thought of as inputs to production, much like labor, capital, and materials. They have costs and generate output, when combined with the right set of matching practices. Accordingly, the potential biases in estimating equations for the effects of organizational practices have direct analogues in production functions and factor demand equations. Thus, we can look to those theories for tools to address these biases.

For instance, the bias in the performance equation, as discussed above, arises because the choice of practices is endogenously determined. Higher levels of one practice will lead to higher levels of a complementary practice. However, if all exogenous drivers $\mathbf{W}$ can be identified for the practices, then these drivers can be used as instruments, and a two-stage regression can be estimated. In essence, the econometrician first estimates a demand equation for $\mathbf{X}$, which includes all exogenous determinants of the practice level. If the instruments are valid, then this approach may eliminate the endogeneity problem and thereby eliminate the resulting bias from these particular unobservables in the performance equation.

If the econometrician has insight into the specific structure of the production function and the relationships among the variables, then a more structural model can be estimated. In particular, the performance and the demand equations can be simultaneously estimated as a system of equations with appropriate cross-equation restrictions (for a general discussion of this approach, see, e.g., Berndt 1991: 449–509).

4.4.5. *System-Specific Variables*

Just as there may be unobservables that are correlated with specific practices, there may also be unobservables that are correlated with specific systems of practices, even if they are not correlated with the practices themselves. Unfortunately, by positing a set of unobserved productivity shocks with a suitable pattern of correlations, one can derive any type of bias at all.

For instance, suppose firms that allocate budgets based on a centralized rule gain no benefit from investing in training when they also buy computers—then there is no true complementarity. However, suppose that they tend to invest in both practices or in neither one proportionately (because of the standardized budgeting rule, e.g., spending a fixed percentage of last year's sales on each new practice). In that case, one can see that if having the centralized rule happens to be correlated with greater output, for reasons having nothing to do with complementarities, then both complementarities test statistics will be biased toward finding complementarities. Firms will be more likely to adopt one practice when they adopt the other, and firms with higher performance will be more likely to adopt the practices together than separately.¹³ Of course,

13. In some cases, it may make sense to expand the system of practices that are considered potential complements to include such a third factor. For instance, it may be plausible that the correlation between a decisionmaking rule and certain clusters of practices is not due to chance, but rather reflects some complementarity between the practices and this type of decisionmaking itself. In that case, the interesting question may not be whether the complementarities exist, but rather what the mechanism is through which they work.

the opposite bias is equally easy to imagine. If the centralized budgeting rule is correlated with lower performance, then firms that adopt the practices together will have a negative productivity shock, biasing the performance test against finding complementarities even while the correlation test is biased toward finding them.

In most settings, with a little creativity and effort, one can imagine all manner of unobserved variables that add or subtract performance to certain clusters of practices or that create correlations among certain practices and yet are unrelated to direct complementarities. This fact underscores the importance of the econometrician having genuine domain knowledge of the particular set of practices being studied. In the abstract, with zero knowledge, any pattern of unobservable productivity shocks is theoretically possible, and thus, any type of bias is possible. Insofar as unobservables cannot, by definition, be measured, there cannot be a purely econometric solution to this concern. Instead, the researcher needs to gain sufficient expertise regarding the setting to be confident that all relevant variables are included in the model and that specific, plausible alternative explanations are duly considered and assessed. A convincing analysis will rarely, if ever, rely solely on econometric evidence.

4.5. Mitigating Unobserved Heterogeneity

Because unobserved heterogeneity can seriously undermine estimates of complementarities, it is important to address it. There are four principal approaches to mitigating the effects of unobserved heterogeneity: homogeneous populations, panel data, natural experiments, and designed experiments.

4.5.1. *Homogeneous Populations*

The researcher can remove as much unobserved variation as possible *ex ante* by focusing on homogeneous populations. This approach makes it possible to specify narrow production functions and performance metrics that are tightly linked to the underlying factor changes.

For example, Ichniowski et al. (1997) deliberately limited their analysis to organizations with nearly identical production processes and outputs to eliminate most sources of heterogeneity even before beginning their analysis. Bartel et al. (2004) and Ichniowski and Shaw (2003) provide good reviews of “insider econometrics,” which often employs this approach.

An important benefit of this approach is that it makes it possible to specify a narrow performance metric that is specifically adapted to the production process being studied. In this case, rather than look at overall market value, profits, or sales, each of which could be affected by a variety of outside, and often unobservable, factors, Ichniowski et al. (1997) measure the “uptime” of the production line. Based on visits and interviews at the production sites, they determined that the proportion of time that a line was actually running, as opposed to being down for some reason, almost uniquely determined its performance. Accordingly, focusing on this particular metric provided a sufficient statistic for performance without contamination from other factors. Subsequently, Bartel et al. (2007) took a similar approach in a longitudinal study of 212 plants in the valve manufacturing industry. They looked at several distinct performance metrics, each one matched to a predicted effect of a specific type of IT. They found evidence that IT increased productivity via its complementarities with certain business strategies (more customization and smaller batches), human capital, and new human resource practices.

Although this approach is very powerful, it is not without its weaknesses. First, it requires a suitably homogeneous population. Second, the very narrowness of the production function implies that the results may not be readily applicable to other settings. Finally, unobservables may still play a critical role. For instance, the choices of different work practices at different minimills may have reflected differential (perceived) costs of adoption, differential (perceived) benefits, or random error. Without knowing exactly what factors drove adoption, it is difficult to assess the strength of the evidence for complementarities. Furthermore, although the homogeneous population may reduce the unobserved heterogeneity, it is also likely to reduce the observed variation that drives the regressions of interest, so the signal-to-noise ratio may not be improved as much as hoped. As the late Zvi Griliches once remarked, when one slices the data more and more finely, one often discovers a fractal-like self-symmetry on smaller scales, leaving the ratio of observable and unobservable economic phenomena relatively unaffected.

4.5.2. Panel Data

Even though focusing on narrow production functions comes at the cost of generalizability, in some cases one can get the best of both worlds. One way to look at multiple industries while still controlling for heterogeneity to some extent is to use panel data. In particular, including fixed effects or taking long differences can remove potential biases from unobserved heterogeneity when the effects of the unobserved variables do not change over time. In this way, a much larger and more diverse sample can be studied.

An example of this strategy is the quantification of IT-related organizational capital for 272 American firms by Brynjolfsson et al. (2002). The firms were in a variety of industries, and each began with its own idiosyncratic combination of observable and unobservable characteristics. To address the unobservables, the authors estimated a specification with firm fixed effects. Thus, a firm with unusually high market value stemming from any unobservables that were invariant over time would not be credited with this high value when assessing the interaction of observable organizational practices and IT. A similar argument applied to their analysis of long differences. This specification subtracted out the historical levels of each of the variables and only examined changes in these variables.

A benefit of this approach is that it is possible to detect patterns that show up across numerous industries. This possibility increases the likelihood that similar patterns will hold outside the sample, and it makes it easier to make fairly general statements about characteristics of the economy as a whole. It also can make it easier to gather larger samples, because the units of observation are not constrained to be as similar *ex ante*.

However, there are also some important weaknesses. First, the fixed effects or long differences will not control for unobservables that change over time. Obviously, a change in one or more of these unobservables can bias the results if (i) it is correlated with the observed variables being studied and (ii) it has an effect on either the levels of the other potential complements (creating a spurious correlation or spurious lack thereof) or performance (affecting the productivity regressions). In particular, the same issue of unknown drivers recurs, as it did when using homogeneous populations.

Second, the production functions themselves remain heterogeneous. As a result, the same shock may affect the observed variables in different ways across different firms. For instance, suppose that there is strong complementarity among certain inputs in some firms, while those

same inputs are substitutes in other firms that have different production functions. The net result may be that, when the data are aggregated, none of the tests show evidence of complementarity.

The researcher can never eliminate either of these potential problems but can mitigate them by (i) including as many relevant drivers of performance and input demand in the set of observed variables as possible and (ii) explicitly identifying the shocks or drivers that lead to changes in their levels and distinguishing their effects in relevant subsamples of the data. The more sharply defined these exogenous shocks are, the less likely it is that they are coincident with an unobservable.

4.5.3. Natural Experiments

If the researcher can clearly identify an exogenous source of variation in the observable factors, then the potential role of unobserved drivers can be greatly reduced. The importance of explicitly identifying the sources of changes in the factors is often overlooked, but it should be an indispensable component of empirical research on complementarities.

There are several categories of change that can provide the requisite drivers of variation. For instance, legal and institutional changes are often ideal candidates to consider, because a change in a law or government policy can provide a precise date and specific geographic area or jurisdiction for which the change occurs. Given the power of the state, the costs of noncompliance can be extremely high, which also creates a sharp contrast before and after the change. The Athey and Stern (2002) study of the introduction of Enhanced 911 service is an excellent example of this type of exogenous variation. Advances in IT made it possible to identify the location of emergency callers. However, by government edict, the adoption was phased in county by county across the state of Pennsylvania, making it possible to identify the changes in complementary activities and several specific outcome measures before and after the adoption of the technology. Given the known government policy change, endogeneity and unobservables could be virtually ruled out as causing the adoption of the technology, making it much easier to make causal inferences about its effects. Each year, cities, states, nations, and other government entities introduce, modify, or repeal thousands of regulations and laws that can affect the relative costs and benefits of different organizational practices. Many such changes are promising candidates for exogenous drivers, although researchers must be cognizant that some legal changes themselves are endogenous to the organizational changes. For instance, differences in minimum wage laws may, in part, be influenced by the differences in the industry mix or organizational practices across state lines, or even changes in the relative importance—and political power—of different industries over time.

The introduction of management practices across plants by a multinational corporation can also provide a source of exogenous variation. For instance, the Bloom et al. (2007) study, as described earlier, uses data from a set of establishments in the United Kingdom and traces ownership of the parent company to the country where it is based. Because the plants in the study were from the same locality, the institutional differences, derived from the nationalities of their owners, provided a valuable source of identification for the observed differences in technology use and performance.

Technology and resource price shocks are particularly promising candidates. As noted in Section 2.2.4, the definition of complementarity in demand theory is that increasing the price of an input reduces the demand for complementary inputs. For example, an increase in the price of oil would be expected to decrease the demand for complements to oil, which might include energy-intensive methods of production and organizational practices. For instance, commuting by car and traveling by jet might be replaced by telecommuting and videoconferencing. In turn, such substitutions might affect the attractiveness of other organizational complements, such as the types of incentive systems used, the way tasks are allocated across jobs, and the criteria for hiring and training. A technology shock that reduced the costs of electronic interactions might have similar effects on telecommuting and videoconferencing and thereby on the associated complements. Accordingly, shocks to the price of oil or sudden innovations in technology are likely to be useful for identifying the reasons for changes in the other complements, especially if the shocks vary cross-sectionally in an observable way. For instance, a multibusiness firm that rolls out a new technology across the firm over a period of months or years can create a natural experiment, particularly if the rollout is randomized or at least uncorrelated with the variables of interest. The larger, more precisely timed, and more numerous the exogenous shocks are, the better, because they are then more likely to overwhelm other unobservable drivers of adoption.

In each of these cases, an exogenous shock can address the identification issue. Of course, the econometrician needs to make the case that the shock is truly exogenous.

4.5.4. *Designed Experiments*

Last but not least of the mitigations of unobserved heterogeneity are the increasing opportunities for economists to participate in designed experiments. Such experiments are, of course, the gold standard for research in the natural sciences. However, given that economists typically study organizations with large numbers of humans and millions or billions of dollars of assets, it has historically been beyond their power, or budgets, to run controlled experiments to test organizational hypotheses. However, the opportunities for such experiments are growing, and they are underexploited. In particular, more and more managers today have analytical backgrounds, springing from more formal training in quantitative methods in MBA and other educational programs. As a result, they are already carrying out controlled experiments to assess alternative policies in the course of their decisionmaking. This trend is especially prevalent in direct marketing and Internet retailing policies, but it also occurs in work practices and technology adoption. For instance, Gary Loveman, CEO of Harrah's, who has a doctorate in economics, regularly experiments with alternative incentive and promotion programs for employees and customers. Harrah's gathers copious data from these tests and uses them to design and implement new policies. Similarly, Amazon continuously experiments in both subtle and radical ways with its web design, pricing, delivery options, product selection, recommendation tools, and new features—individually and in combination with one another. At both companies, the richness and complexity of the choice set provide ample opportunities for identifying potential complementarities. Although these two firms are unusual in their commitment to experimentation, they are far from unique.

Historically, the costs of large-scale field experiments have discouraged economists from relying on them for data gathering. However, by using data from experiments already conducted

by business managers, or better yet, coordinating with them in advance to design more careful experiments, the cost issue can be overcome. When the manager is genuinely uncertain about the optimal policy combination, a well-designed experiment can pay for itself many times over, because the better-informed decisions following the experiment are more likely to be profitable than uninformed choice. Hence, managers can benefit as much, or more, from joint work with academic researchers as the academics can.

For example, Bhansali and Brynjolfsson (2007) worked with a large insurance firm to analyze the effects of a new electronic document management system on work practices, time use, and performance. The company had employees in locations across the country engaged in largely identical claims-processing work. They phased in the technology at different offices over time and allowed the researchers to gather data pre- and post-implementation, as well granting them access to historical data. The resulting quasi-experiment not only addressed many causality issues, but also made it possible to compare practices and productivity both across time and across different locations. As a result, the correlation of technology use with decreased routine work, increased cognitive work, and higher performance on several performance measures was much easier to interpret.

More recently, Bloom et al. (2009b, 2011) have conducted randomized control trials in textile firms in India. The treatment was to offer organizational consulting advice to a random sample of the firms. They found that the treated firms became more computerized and more decentralized in their decisionmaking, consistent with earlier findings about the complementarity of these practices. In turn, average productivity increased by about 10% after the treatment, reflecting improved quality and reduced inventories.

The growing success of the experimental approach in addressing issues of causality is underscored by the large number of field experiments reviewed in Lazear and Oyer (this volume).

5. Conclusion

5.1. Implications for Managers

Complementarities in organizations can be analyzed rigorously using theory and data, but they also have important practical relevance for managers and those who educate or advise them. For instance, the frameworks and approaches we review in this chapter can provide insights into

- choices about organizational practice,
- change management,
- competitive strategy,
- mergers and acquisitions, and
- leadership and culture.

Managers are deluged with examples of “best practice,” yet when they implement these same practices at their own firms, they rarely have as much success as the exemplar that they seek to imitate. Complementarities can help explain why. The success of a practice almost always depends on the system of complementary practices in which it is embedded. Thus, the concept of “best practice,” devoid of context, can be misleading. The same piece rate pay rules

that work so well at Lincoln Electric may end up undermining performance if implemented à la carte in another organization. Thus, before implementing a new incentive system, hiring practice, training program, or technology, managers should explicitly consider the existence or absence of the relevant complements. Of course, specifically identifying the relevant complements will often be nontrivial, but merely being aware of their relevance is a necessary first step.

A fruitful application of the theory of complementarities has been to change management. In particular, taking advantage of new technologies or other innovations typically requires substantial changes in a broad set of related business practices. Insights into the optimal pace, sequence, location, and even feasibility of change efforts can be provided by analyzing the situation from the perspective of complementarities. Although the mathematics of complementarities can be daunting, the underlying concepts are not hard for managers to grasp and manipulate. For instance, the Matrix of Change tool (Brynjolfsson et al. 1997) mentioned in Section 1 has been used by thousands of managers to make explicit organizational complementarities that might otherwise remain hidden. Appendix B provides a simple illustration.

Complementarities can also affect competitive strategy by creating lasting entry barriers and accompanying rents. As the Lincoln Electric case (Berg and Fast 1975) illustrates, best practices can be difficult to imitate if they rely on a web of interactions with other practices for success. As Milgrom and Roberts (1990) point out, this gives economic content and rigor to the concept of “core competence.” Ironically, as noted by Roberts (2004), organizations that succeed in implementing tightly coupled systems of highly complementary practices may have the greatest difficulty adopting new combination of practices when external factors warrant a change.

Complementarities among organizational practices create risks in mergers and acquisitions. The real value of many, perhaps most, businesses lies not in their tangible assets but in their intangible organizational capital. But this organizational capital can be fragile; the practices that are successful in one setting may not be so after being meshed with different practices in a merger or acquisition. Understanding the role of complementarities in organizations can make this management task less mysterious and more manageable.

Finally, leadership and culture might be thought of as far removed from quantitative analysis, and in many ways they are. However, an understanding of complementarities can illustrate why and when a clear leadership vision and strong organizational culture can be most beneficial. When practices are complementary, there are multiple equilibria. Coordinating on one of these equilibria, even if it is not the global optimum, will often be more successful than choosing practices in a decentralized and uncoordinated way. In contrast, optimizing individual practices on their own does not necessarily maximize total firm performance. This line of thinking suggests a clear role for leadership and culture. The task becomes even more important when conditions call for moving from one equilibrium to another one. Just as complementarities can create inertia to prevent change, they can also create momentum for a virtuous cycle of change—if the right set of practices is changed first.

Historically, the theory and analytical tools developed in economics and related disciplines have provided clear guidelines for managers who wish to use quantitative analysis instead of just heuristics and instincts to manage and price physical assets and technologies. The formal analysis of organizational complementarities promises to do the same for a much broader set of management challenges facing companies today.

5.2. An Agenda for Economists

There are at least three major frontiers for economic research on complementarities in organizations that overlap with one another: applications of existing theory, empirical assessments of complementarities, and extensions of the basic theory.

5.2.1. *Applications of Existing Theory*

In some ways, the agenda for economists seeking to advance the frontiers of complementarities research parallels the implications for managers. By identifying specific sets of complementary practices, we may shed light on a remarkably broad range of economic questions. For example:

- Can organizational complements to new technologies explain changes in productivity growth across geography, time, and industry?¹⁴
- Can such complements explain the growth in income inequality and the demand for certain types of labor or skills?
- Why are firms exiting certain industries and what do they have in common? What about entrants, including those with operations in other industries, as well as start-ups?
- To what extent do patterns of exports and imports, or regional trade, match the geographic distributions of complementary factors?
- How well can complementarities explain the specific set of activities retained in house and those outsourced or spun off? When can they explain mergers and acquisitions?

In addition, there may be some general implications of complementarities beyond those linked to specific practices. If one thinks of organizations as large clusters of complements, including many that are intangible or subtle, then the theory has several implications. For instance, when combined with game theory, complementarities can be a part of a theory of organizational inertia (e.g., Baron et al. 1996), explaining why and when change can be difficult. It can be very difficult to coordinate change on multiple practices when decisionmaking is decentralized, communication is imperfect, incentives do not match output, or all of the above.

A closely related question is the existence of persistent performance differences among seemingly similar firms (Gibbons 2006). Subtle complementarities can explain why apparently similar competitors do not obtain the same benefits from activities. If the complements are long lived, then the systematic performance differences can also be persistent.

Complementarities literally mean that the whole is greater than the sum of its parts, which suggests a role in valuing the organizational capital and other intangible assets of firms. Although neoclassical theory tends to model firms as production functions that simply combine various inputs to produce output, complementarities provide an explanation for why a going concern may be much more valuable than the same components *à la carte*. Similarly, by identifying and exploiting complementarities, the overall output of an economy can consistently exceed the weighted sum of its factor growth rates. In addition, the more heterogeneity there is among inputs, the more combinations are possible, and the greater the potential there is for complementarities.

14. For example, see Bresnahan and Trajtenberg (1995) and Basu et al. (2003).

Finally, the interplay of practices in sustaining a system of complements may shed light on corporate culture. Because of the multiplicity of equilibria that arise when systems have large numbers of potentially complementary practices, a general coordinating device, such as culture, can play an important role. For instance, it might be possible to extend the Kreps (1990) model of corporate culture by incorporating a more explicit role for complementarities.

5.2.2. *Empirical Assessments of Complementarities*

Most, if not all, applications discussed above lend themselves to empirical work. Embedding econometric work in a complementarities framework can make it easier to develop testable hypotheses.

Thus far, most empirical work on complementarities has relied on cross-sectional studies or relatively short panels. However, some of the most interesting issues raised by the theory pertain to changes in organizations over time. Thus, there is an opportunity for more work using longer panels and longitudinal data, with attention to entrants, exits, and persistence of performance differences.

Methodologically, some of the current frontiers for empirical work on complementarities include:

- panel data on relatively homogeneous populations and clear, exogenous drivers of variation in practices, or preferably changes in those practices;
- novel metrics of activity and performance, such as fine-grained, practice-specific inputs and outputs;
- structural modeling of systems of both the performance and demand equations, drawing on significant domain-specific knowledge of the setting, relevant practices, and likely interactions; and
- exploitation and even design of controlled field experiments to isolate the role of changing specific practices.

There has been significant progress in all these areas. However, the last one, controlled field experiments, may be the most important for eliminating the biases discussed in Section 4 and clearly quantifying complementarities. There are significant limits to how much can be learned solely by more sophisticated modeling. Fortunately, managers are increasingly receptive to the experimental approach. They are designing and implementing controlled experiments on their own and in cooperation with researchers. Part of this trend reflects the more academic and often quantitative training that managers have today and part reflects the relative flexibility of some new technologies, making controlled rollouts and careful monitoring of results easier. The success of the experimental approach in interactive marketing has made it more attractive as a way to improve organizational design choices as well.

5.2.3. *Extensions of the Basic Theory*

There are several ways the theory of complementarities can be extended. One interesting tack is to explore the dynamics of learning and growth in larger systems of complements. As the number of potential organizational complements increases, the number of potentially profitable systems to explore explodes combinatorially. This brings to the fore the issue of efficient search and

learning. Learning need not occur primarily or even at all on the level of an individual through conscious deliberation. It is also possible that learning occurs at the organizational level, perhaps through a quasi-evolutionary process. For instance, the influential paper by Cohen et al. (1972) argued that managerial decisions should not be thought of as being made rationally, but rather through the random matching of problems and solutions, as if being jostled about in a garbage can (see also Levinthal and March 1981).

In practice, innovative combinations of business practices are sometimes achieved by extensive trial and error. If the production process is complex, with many potentially relevant variables and interactions, it can be very difficult to identify the optimal combinations. Strong complementarities can significantly retard such a process by reducing the value of local experimentation, especially if the choices are indivisible and nonconcave. At the same time, the theory can provide guidance about ways to simplify the search process.

If this mechanism of tinkering is important, then except in environments that have been very stable for a long time, the population of firms will exhibit a variety of different strategies, including both successful and unsuccessful ones. As argued by Nelson and Winter (1982), successful systems may increase their share of the population of firms if they survive longer or attract more imitation. However, the most profitable combinations will not necessarily be the ones that dominate the population (e.g., see Cowperthwaite et al. 2008). There is recent evidence that design modularity can affect the nature and speed of this evolution by bundling together complementary components (MacCormack et al. 2007), and complementarities can create momentum as well as inertia (Milgrom et al. 1991), but a comprehensive theory remains to be developed.

In conclusion, there is a plethora of opportunities for further research using the tools and insights of complementarities in organizations. Such research may shed light on some of the longstanding puzzles and challenges that have confronted economists and others who study organizations.

Appendix B: Example of the Matrix of Change

When Merrill Lynch's brokerage business was confronted with competition from online brokers, the company contemplated changing over to an all-electronic approach. Although the technology itself was relatively straightforward, it was clear that the associated complementary changes that would also need to be made would be traumatic. In addition to physical stores, the existing brokerage business had several other important characteristics: assignment of a personal broker to each client; relatively high fees; use of the human broker to mediate trades; provision of investment recommendations; heavy investment in an in-house research staff; and focus on a

Figure B1. Matrix of Change analysis for the transition from traditional brokerage to online brokerage.

relatively limited, high net worth client base. Every one of these characteristics was eliminated in the reigning approach to electronic trading, and a new set of practices was implemented.

The Matrix of Change analysis showed that the old practices formed a coherent system of mutual complements. The new system also was dominated by complementary interactions. However, interactions between the old and new practices were rarely complementary and more often conflicted with one another. The Matrix of Change tool illustrated these effects by denoting complementary interactions with “+”, and conflicts with “-” as described in Figure B1.

The complementarities in the old system suggest it would have a great deal of inertia, and the conflicts in the transition matrix suggest that an organization that tried to run with a mixture of old and new practices would be relatively inefficient. Hence, the change effort would likely be difficult, and there were relatively few synergies between the old and new systems. Finally, it

was clear that the new system was itself fairly coherent, but perhaps not quite as much so as the old system. These insights, while drawing on complementarities theory, can be visualized easily in the Matrix of Change without a formal economic or mathematical analysis.

Economic Theories of Incentives in Organizations

Robert Gibbons and John Roberts

1. Motivation in Organizations

Managed organizations serve both to coordinate the decisions and actions of individuals and groups and to motivate these people to perform the needed activities. This chapter considers the nature of motivation problems in organizations and summarizes theories of the means to address these problems, focusing on the literature in economics but drawing ideas and observations from such fields as economic sociology and accounting where possible.

Both in well-functioning competitive markets and under efficient Coasian bargaining, the motivation problem is fully solved. But familiar sources of contracting problems—precontractual private information leading to adverse selection, observability problems leading to moral hazard, or contractual incompleteness from whatever cause—mean that neither the market nor bargaining always works perfectly. In these circumstances, other ways to solve the coordination and motivation problems should be considered (Arrow 1974; see also Roberts 2004). Managed organizations are a prominent alternative.

Motivation can be an issue in organizations because self-interested behavior by the organization's members may not produce a Pareto-efficient outcome for the group as a whole. The problem is one of externalities: the members of an organization typically do not bear all the costs and benefits of the actions they take and the decisions they make in the organization.

Of course, the distribution of costs and benefits within an organization is not exogenous. For example, it can be altered by contracts. More generally, managed organizations have many means to affect incentives and behavior—every aspect of the organization's design can in principle be used (Roberts 2004). First, attracting, engaging, and retaining the right set of people can be important. People who enjoy their work and are skilled at it or who believe in what the organization is trying to accomplish are likely to be more highly motivated. Giving individuals appropriate training can also help motivation, because well-trained employees are more confident that they will succeed and that their efforts will be rewarded. The formal organizational

Figure 1. Coase (1937) meets Heckman (1979). Reprinted from *Journal of Economic Behavior and Organization*, vol. 58, no. 2, Robert Gibbons, “Four Formal(izable) Theories of the Firm?” pp. 200–245, copyright © 2005, with permission from Elsevier.

architecture, including such matters as the allocation of decision rights, the definition of subunits, the financing and governance structure, and the boundaries of the organization, can have a strong effect on behavior. So too can the routines, processes, and procedures through which information is gathered and shared, people and resources are allocated, performance is monitored and rewarded, and work is done. Additionally, the culture of the organization is perhaps particularly important. In particular, the shared values in the organization and the social norms that guide behavior are both important sources of motivation. Finally, the firm’s strategy can be an element of motivation (Roberts and Saloner, this volume).

As generations of sociologists and management scholars have documented, however, organizations often—perhaps typically—do a pretty bad job of motivating their members. Workers shirk. Mid-level employees, seeking advancement, manipulate information and practice politics at the expense of performance. Cautious bureaucrats avoid taking risks that are clearly worthwhile for the organization. Managers sacrifice long-term performance in the pursuit of short-term results. Top executives pursue personal gain at the cost of wrecking the organizations they head. Why is this? Why do managed organizations perform so poorly?

The answer comes from recognizing that firms will not be immune to forces that wreck markets. As Williamson put it, for example, “substantially the same factors that are ultimately responsible for market failures also explain failures of internal organization” (1973: 316) and, hence, “distortion-free internal exchange is a fiction and is not to be regarded as the relevant organizational alternative in circumstances where market exchange predictably experiences non-trivial frictions” (1975: 125).

In short, markets work well (and perhaps better than managed organizations) in circumstances where contracting is not particularly problematic. But as contracting difficulties increase, the performance of market solutions falls, *as does that of managed organizations*. But the latter, with the broad array of levers they have to affect motivation, are less disadvantaged than markets are when contracting is beset by great difficulties. Thus, managed organizations are observed precisely when there are significant contracting problems, and these cannot be easily overcome. Gibbons (2005) summarizes this argument with Figure 1.

The figure illustrates not only Coase's (1937) hypothesis (that firms exist only where they perform better than markets would, which is to the right of the dotted vertical line in this figure), but also its unremarked corollary: that the firms we then observe will be less efficient than the markets we observe, even though the observed firms will be more efficient than markets would be, so the former comparison is biased by sample-selection issues like those addressed in Heckman (1979).

From the perspective of organizational design, the solution to motivation problems is to shape the organization to bring a closer alignment of interests between the organization and its members and thereby increase the efficiency of the choices they make. In this task, the designer in a firm can have access to all the elements of organizational design, and in many contexts all these elements should be used. In particular, motivation is not just a matter of monetary incentives, as important as these are in some cases. Rewards can be dollars, but they can also be other sorts of resources, as well as personal satisfaction or social approval and status. Furthermore, although the motivation problem arises fundamentally at the level of the individual, it may be attacked at more aggregated levels, such as teams, departments, or divisions.

This chapter connects to many others in this volume that treat related issues, often in greater depth. For example, chapters in this volume by Baron and Kreps, Camerer and Weber, Hermalin ("Leadership and Corporate Culture"), Ichniowski and Shaw, Lazear and Oyer, Malcomson, and Waldman all address people aspects of organization relative to incentive and motivation issues. In addition, chapters by Bresnahan and Levin, Garicano and Van Zandt, Hansmann, Mookherjee, Roberts and Saloner, and Segal and Whinston address architectural issues, some of which are driven by motivation concerns. Issues relevant to organizational routines, processes, and procedures are addressed in chapters by Bolton and Dewatripont, Gertner and Scharfstein, Gibbons and Henderson, Gibbons et al., and Roberts and Saloner, as well as in the chapters already cited in connection with the people part of organization. Finally, Hermalin's chapter ("Leadership and Corporate Culture") addresses some issues connected to culture as a motivation and control device.

Despite our conviction that motivation is a lot more than contracts and money, given the coverage of these other chapters, this chapter will largely focus on the use of monetary incentives. Further, it is concerned almost exclusively with the economic theories behind these incentives. The logic is that other chapters deal with different aspects of motivation and discuss the managerial implications and economic evidence.

We begin with a primer on basic agency theory: we develop in some detail the models of single-person, static agency contracts designed to induce "effort," even though much of this material will be familiar to many or most readers of this volume. We then examine contracts with multiple agents and dynamic contracting. Next we consider relational contracts and then situations with no contracts, where career concerns are paramount. We then move to more recent work, particularly the use of other aspects of organization as tools for motivation, motivating actions other than "effort," and economic (optimizing) models of various behavioral phenomena related to motivation in organizations.

2. Formal Performance Contracts

Most economic research on incentives has focused on pay for performance. Here we start with static models of performance contracts between a principal and a single agent. We then move to multiperson contracts and dynamic issues in contracting.

2.1. Static Principal-Agent Models

Much of the economic analysis of motivating people in organizations is couched in terms of principal-agent models, where explicit formal contracts link financial rewards to contractible signals that give information about the agent's unobservable behavior. (If the agent's behavior is contractible, there is no real problem: specify what you want done, and pay if and only if it is done.) Although we reiterate that motivation in organizations is in fact a much broader and more complex phenomenon, we start our discussion with this sort of agency model, with cash compensation used to motivate a behavior that can be labeled "effort."

The basic setup is that there are two actors, a principal (conventionally female) and an agent (conventionally male). The agent may take some action a that affects the welfare of both parties. Often this action is called "effort," but it might be any of a variety of things, including making investments, evaluating options, or abjuring theft of the principal's wealth. The action has a private, convex cost $C(a)$ for the agent,¹ and it generates benefits y for the principal (these may be random). Higher values of a lead (probabilistically) to higher levels of y . There are also contractible signals x carrying information about the chosen level of a , so pay could depend on the signal.² The principal decides whether to use the agent and designs a contract promising payments $w = w(x)$ to the agent. This contract is then accepted or rejected, depending on how it compares to the options the agent faces if he rejects the contract. If the contract is accepted, then the agent chooses his action to maximize his expected utility under the contract, recognizing how his choice will affect his pay. Then the signals x are observed, the benefits y are realized, and the principal pays $w(x)$ to the agent in accordance with the contract. The principal thus receives $y - w(x)$, the realized payoff less the payment to the agent, and the agent receives $w(x) - C(a)$, the payment less the cost of action.

There are three main approaches to creating an incentive problem in this context: (1) risk aversion for the agent combined with noisy signals, (2) manipulable signals of the agent's effort, and (3) exogenous limits on the amounts that the agent can be paid. We focus on the first two; the third raises fewer fundamental issues than the first two, so we only sketch the basic idea.

2.1.1. Risk Aversion and Noisy Measures

The workhorse model during the 1980s and early 1990s assumed that the agent is risk averse and the signals about behavior are noisy. For example, the signals might be imperfect observations of the agent's actual choices, or they could be the outcomes of his efforts, where these are also affected by unobserved random factors. In this case, rewarding the agent based on the signals puts randomness into his income. In particular, making the rewards vary more with the signals, which would normally occur if the incentives were made stronger, increases the amount of risk the agent bears. The optimal contract then trades off the cost of inefficient risk-bearing against the benefits of inducing the desired behavior less its cost to the agent. The result is

1. Note that it is not necessary to assume that costs are always strictly increasing. There may be some level of effort that the Agent would supply without explicit incentives, because the job was enjoyable or important to him. But if effort is productive at the margin in creating value, efficiency would argue for inducing more than this level of effort that comes for free.

2. In the early models in the agency literature, the signal and the benefit are not distinguished from one another, so $y = x$.

typically that the agent bears excessive risk and delivers too little effort relative to the first best that would be achieved were it not for the contractibility problems. However, obtaining clear predictions about the shape of the performance contract beyond this basic one proved very difficult without putting strong assumptions on the preferences and the information structures, although important results were obtained regarding the information structure. For example, Holmström's sufficient-statistic condition (Holmström 1979; see also Shavell 1979) states that if we have a signal x of the agent's effort and another signal z becomes available, then z should enter the performance contract if and only if x is not a sufficient statistic for (x, z) . And, as another result about the information structure, Milgrom (1981) showed that, for the case where the signal x is identical to the benefit y , the contract $w(y)$ is monotone if the conditional distribution $f(y|a)$ has the monotone likelihood ratio property.

Given the difficulties of working with a general model, the highly tractable linear-exponential-normal (LEN) specification of the agency model has become widely used. (As we discuss below, Holmström and Milgrom (1987) provided microfoundations for this model, but here we simply assume that contracts are linear.) Suppose the agent's utility for income w and effort a is

$$U(w, a) = -\exp(-r[w - C(a)]),$$

where r is the agent's coefficient of absolute risk aversion. The expected benefit to the principal is $P(a)$, and the observed signal (performance measure) is $x = a + \varepsilon$ where ε is a normally distributed noise term with zero mean and variance σ^2 . The contract is assumed to take the form $w = s + bx$. Because the principal is risk neutral, her problem is to optimize her expected payoff, $P(a) - (s + ba)$, with respect to s , b , and a , subject to the agent being willing to select the indicated value of a when faced with the corresponding values of s and b and to his weakly preferring to enter the relationship than pursue his outside options.

In this context, the agent's choice can be determined from maximizing his certainty equivalent, which is $E(s + bx) - C(a) - \frac{1}{2}r \text{Var}(s + bx)$, where Var denotes the variance. Substituting gives $s + ba - C(a) - \frac{1}{2}rb^2\sigma^2$. Thus, his choice satisfies $b = C'(a^*)$, whence $da/db = 1/C''(a^*)$. These results and the fact that the agent can be held to the value of his outside option by the choice of s without affecting his effort choice lead to an expression for the principal's payoff in terms of b . Then maximizing leads to the key conclusion of this model: the optimal value of b is given by³

$$b^* = \frac{P'}{1 + r\sigma^2 C''}.$$

This result makes intuitive sense. Because P' , r , σ^2 , and C'' are positive, b^* is between zero (full insurance) and P' (full incentives). Furthermore, b^* is smaller if the marginal productivity of effort is lower (P' is lower), the agent is more risk averse (r is higher), there is more noise in the performance measure (σ^2 is higher), or the agent's effort choice is less responsive to increased incentives (C'' is higher). If the agent is risk neutral or if there is no noise in the signal, then the optimal incentive payment is equal to the marginal productivity of effort in creating benefits. If

3. For a full derivation of these results, see Milgrom and Roberts (1992).

y and x were the same, then the expected benefit would be $P(a) = a$, and the optimal value of b would be $1/(1 + r\sigma^2 C'')$.

Simple extensions of the basic LEN model generate versions of some of the classic results of agency theory. For example, allowing a second noisy signal z that is unrelated to a but may be correlated with x permits deriving a particular version of Holmström's Informativeness Criterion (1979) in a clean and revealing form: The optimal value of b_z in the contract $w = s + b_x x + b_z z$ is $b_z = -\rho b_x / \sigma_z^2$, where ρ is the correlation between z and x . Thus, if x and z are uncorrelated, so z gives no information about the value of ε and thus about the choice of a , then z should not be used in the optimal incentive contract. If there is information in z about a , then it should be used. Further, if x and z are positively (negatively) correlated, then a high (low) z suggests that ε was high (low). Thus, a given level of x is less (more) favorable information about the agent's choice, and so his reward is reduced (increased). The weight put on z is inversely related to its variance, so that a poor measure does not get much weight. And the greater the weight put on x , the more that z is used to offset the increased variance in the pay. Similarly, allowing the variance of the measurement error in x to be decreased at a cost leads to a conclusion that the intensity of incentives b and the precision of the performance measure $1/\sigma^2$ are complements, so anything favoring increasing one favors increasing the other too.

A key extension of the basic model allows for multiple kinds of effort, say a_1 and a_2 . In the case where these compete for the agent's time and attention—for example, $C(a_1, a_2) = \frac{1}{2}(a_1 + a_2)^2$ —each sort of activity must be compensated equally at the margin if it is to be provided at all. Yet if noise in the measures on the two differ, then the formula above cannot yield $b_1 = b_2$. So if the principal desires the agent to undertake positive levels of both actions (multitasking), then the choice of the incentive intensities is constrained. The result is that muted incentives are optimally offered even for well-measured actions when multitasking is desired. In fact, the optimal common b may be lower than that which would be given to motivate only the worse-measured action in isolation. These arguments have been used to explain why activities that it might seem could be rewarded with strong incentives are in fact not, for fear of driving out other desired activities. They also have been used to investigate elements of job design (see Section 5.2).

This model has been widely used in applied work, but in fact its fit with the empirical evidence is mixed. In particular, the model suggests that strong (respectively, weak) incentives should be observed where there is little (much) noise in the performance measures, yet this is not obviously the case. For example, Prendergast (2002) documented that it is not uncommon to use stronger incentives when there is more uncertainty—at least for certain industries and occupations.

One explanation for this observation is that there might be a second form of noise that is omitted from the formal model but is important in real contracting environments. In particular, in addition to the noise in the performance measure, the marginal productivity of effort might be random (Zábojník 1996; Raith 2008; Rantankari 2008b). In this context Rantakari (2008b) identified four distinct mechanisms through which this production uncertainty could affect the optimal intensity of incentives by affecting the value of effort to the principal and the agent's choice. Any of these could generate a positive relationship between the aggregate amount of uncertainty and the intensity of incentives.

2.1.2. Manipulable Performance Measures

A second approach to capturing conflicts of interest in an agency framework is based on the available performance measures' being manipulable by the agent through actions that do not benefit the principal.⁴ The first models in this spirit were Holmström and Milgrom (1991) and Baker (1992). The tractable framework we present here was developed by Feltham and Xie (1994); see Datar et al. (2001) and Baker (2002) for enrichments and applications. This approach is becoming increasingly influential, for several reasons: it captures the idea that one might get what one pays for, it avoids the necessity of assuming risk aversion and uncertainty (which are important in some real-world environments but absent in others), and it is tractable (like the LEN model discussed above) and so lends itself to further applications.

The basic idea is that the benefits to the principal, y , may differ systematically from the signal, x , in how they respond to the agent's choices, and that it may be possible to contract only on x and not on y . Then the problem would be that paying on x would motivate the agent to produce x , and that may be very different from what the principal values, namely, higher levels of y : you get what you pay for. Yet it may still be worthwhile to offer a contract on x , so long as she gets some extra y in return.

For example, if the benefit y were simply an invertible function of the performance measure x , then there would be no problem: simply calculate the optimal contract to induce y and then translate into a contract stated in terms of x . But even in more complicated cases, where x and y are not so aligned, there can be value in contracts on x . The agent will respond to the incentives to affect x , but these can be designed to provide useful incentives for y . For example, suppose that $y = a + \varepsilon$ and $x = a + \phi$. Note that the two different noise terms mean that the benefits and the performance measure are not in a one-to-one relation. Still, a contract based on x creates incentives to increase x , and the induced action increases y .

More generally, as long as effort is one dimensional and the noise is additive (as in the LEN model), the performance measure x and the benefit to the principal y are essentially aligned, because the principal can induce any choice of a she might want. Thus there are essentially two ways to create an incentive problem. The first was identified by Baker (1992): if the marginal products of a in creating x and in creating y are not perfectly correlated (e.g., when the noise is multiplicative), it may be impossible to induce some levels of effort that the principal might want. The second, to which we now turn, involves multidimensional effort.

So now suppose that there are two kinds of actions that the agent can take, a_1 and a_2 . To keep things simple, assume that costs are separable:

$$C(a_1, a_2) = \frac{1}{2} (a_1^2 + a_2^2).$$

In this multitask environment, if $y = a_1 + a_2 + \varepsilon$ and $x = a_1 + \phi$, then a contract based on x creates incentives for a_1 but cannot create incentives for a_2 . Yet increasing a_2 from zero is costless to a first approximation and has a first-order positive effect in increasing y . Alternatively, if $y = a_1 + \varepsilon$ and $x = a_1 + a_2 + \phi$, then a contract based on x creates an incentive for the agent

4. Parts of this section draw on Gibbons (2010) with permission from the *Annual Review of Economics*, Volume 2, © 2010 by Annual Reviews, <http://www.annualreviews.org>.

to take action a_2 , even though a_2 is irrelevant to the principal's return, y . This action is pure social waste, and if the agent is being held to his outside option, the cost will be borne entirely by the principal. Finally, in an extreme case, such as $y = a_1 + \varepsilon$ and $x = a_2 + \varepsilon$, a contract based on x will create no value at all. (Note that, in this example, y and x will be perfectly correlated because of the common noise term ε . However, in line with Baker (1992), the marginal products are completely uncorrelated.)

Generalizing these examples, suppose that the technology of production is $y = f_1 a_1 + f_2 a_2 + \varepsilon$, the technology of performance measurement is $x = g_1 a_1 + g_2 a_2 + \phi$, the contract is $w = s + bx$, and the payoffs are $y - w$ to the principal and $w - C(a_1, a_2)$ to the agent.⁵ The first-best actions, which maximize $E(y) - C(a_1, a_2)$, are thus $a_1^{FB} = f_1$ and $a_2^{FB} = f_2$. With contracts based on only x , however, we will see that the agent typically cannot be induced to take these first-best actions.

The timing is as before. The principal offers the agent a compensation contract, $w = s + bx$.⁶ The agent accepts the contract or rejects it in favor of an alternative opportunity with payoff U_0 . The agent chooses his actions (a_1, a_2) . These are not observed by the principal. Unobserved random events (ε, ϕ) that are beyond the agent's control occur. Measured performance (x) is observed by the principal and the agent (and by a court, if necessary). The agent receives the compensation specified by the contract, and the principal realizes her return net of the payment.

The risk-neutral agent chooses a_1 and a_2 to maximize $E(w) - c(a_1, a_2)$, so the chosen actions under the contract are $a_1^*(b) = g_1 b$ and $a_2^*(b) = g_2 b$. Thus, to induce the first-best actions $a_1^{FB} = f_1$ and $a_2^{FB} = f_2$, the principal would like to choose b to satisfy $g_1 b = f_1$ and $g_2 b = f_2$. However, this is impossible unless $f_1 g_2 = f_2 g_1$ (in which case, in expectation, x and y are just multiples of each other, and the optimal contract is the first-best one adjusted for the multiplicative effect). When $f_1 g_2 \neq f_2 g_1$, the optimal contract for the principal is given by setting s to hold the agent to utility U_0 and setting

$$b^* = \frac{f_1 g_1 + f_2 g_2}{g_1^2 + g_2^2} = \frac{\|f\|}{\|g\|} \cos(\theta),$$

where θ is the angle between the vectors $f = (f_1, f_2)$ and $g = (g_1, g_2)$.

There are two important features of b^* : scaling and alignment, reflected by $\|f\|/\|g\|$ and $\cos(\theta)$, respectively. Scaling is intuitive but not very interesting. For example, if $f_i = \lambda g_i$, $i = 1, 2$, so that the two vectors are just multiples of each other, then the first best is achieved by $b^* = 1/\lambda$, which scales the rewards to reflect the actual value of effort in generating y . More generally, if g_1 and g_2 are both much larger (smaller) than f_1 and f_2 , then the efficient contract puts a small (large) bonus rate on x , as shown by $\|f\|/\|g\|$. Alignment, however, is the key to the model. As one example, if the f and g vectors lie almost on top of each other (regardless of their lengths), then the incentives created by paying on x are quite valuable for increasing y , and b^* is relatively large. In contrast, if the f and g vectors are almost orthogonal to each other, then the incentives created by paying on x are almost useless for increasing y , and b^* is near zero.

5. As noted earlier, there is no need to assume risk aversion as there was in the classic setup.

6. To motivate the assumption of linear contracts, imagine that $x \in [0, 1]$ and $Pr(x = 1) = g_1 a_1 + g_2 a_2$, where f_1, f_2, g_1 , and g_2 are sufficiently small. In general, however, linear contracts are not optimal.

More generally, the efficient contract has a larger bonus rate b when f and g are more closely aligned, as measured by $\cos(\theta)$.

One further example may be illuminating in this regard. Suppose $f = (1, 1)$, and consider different possible values for g where $\|f\| = \|g\| = 2^{1/2}$. Then, from the formula above, $b^* = (g_1 + g_2)/2$. Consequently the agent maximizes $[(g_1 + g_2)(g_1 a_1 + g_2 a_2) - a_1^2 - a_2^2]/2$, yielding $a_i = g_i(g_1 + g_2)/2$, $i = 1, 2$. Now consider how the effort choices change as g_1 increases and g_2 decreases to keep $\|g\| = 2^{1/2}$. Let $g_1 = \lambda g_2$, where we vary λ . Then one can calculate that $a_1 = \lambda(1 + \lambda)/(1 + \lambda^2)$ and $a_2 = (1 + \lambda)/(1 + \lambda^2)$. At $\lambda = 1$, $a_1 = a_2 = 1$. As λ increases from unity, a_2 falls, while a_1 initially rises and then falls. As λ goes to infinity, so (g_1, g_2) approaches $(2^{1/2}, 0)$, a_1 decreases to 1, and a_2 goes to zero.

Examples of such misaligned measures abound. Often, rewards within firms are based on accounting numbers, even though the firm's owners care not about these, but instead about long-run profitability. The latter, however, is difficult to measure and thus is problematic for contracting, while the accounting measures are only loosely connected to profitability (particularly as they are not forward looking) and can be manipulated in a variety of ways (the timing of revenue recognition, choosing different financing options, etc.). Similarly, sales people are often compensated for revenues, not profitability, and this leads them to focus their efforts on revenue maximization, not profits. Likewise, teachers are measured against student achievement on standardized tests in a few subjects rather than on overall learning, and this motivates them to teach to these tests at the expense of other important aspects of their job. In each case, the agent's behavior is twisted away from generating what the principal actually values.

2.1.3. *Wealth Constraints*

If there is a minimum amount that the agent has to be paid in any circumstance (say, $w \geq 0$), then this alone may create a contracting problem, even when both parties are risk neutral. For example, suppose $y \in \{0, 1\}$ and $Pr(y = 1) = a$, where $C(a) = a^2$ and $a \leq 1$. First best involves $a^{FB} = \frac{1}{2}$, yielding total utility $\frac{1}{4}$. The first-best effort can be induced by setting $b_1 = b_0 + 1$ in a contract that pays b_1 if $y = 1$ and b_0 if $y = 0$.⁷ In this case, the agent's expected utility is $b_0 + \frac{1}{4}$. Now suppose the agent must receive a nonnegative payment in any event, so that $b_0 \geq 0$. This means he must receive an expected utility of $\frac{1}{4}$ if the first best is to be induced, leaving nothing for the principal. As a consequence, the principal will find it optimal to induce less than first best effort.

More generally, motivation here ideally involves both carrot and stick (positive and negative payments, depending on results). The stick is used to ensure that the agent does not earn any rents, so the principal will seek to maximize the total surplus. If negative payments are not available, then motivating efficient effort takes a big carrot, because there must be a large enough difference in pay across possible outcomes to provide motivation. Then, unless the agent's outside options are very attractive, he will earn rents. Thus, the principal will look to maximize her share of the surplus, rather than the total surplus, and this leads her to induce less effort than would be efficient.

7. The contract could also include a payment that is independent of the level of y without affecting the conclusion.

Sappington (1983) combined wealth constraints with postcontractual private information in an interesting fashion. He supposes that the risk-neutral agent becomes privately informed about a productivity parameter after the contract has been agreed. Higher values of the parameter correspond to lower values of the agent's total and marginal costs of achieving any expected level of output. Sappington shows in this context that the optimal contract induces efficient effort choice only in the highest productivity states. In all others, the amount of effort elicited is less than efficient in order to reduce the rents that the agent receives.

Wealth constraints also play a role in efficiency-wage models (e.g., Shapiro and Stiglitz 1984; Akerlof and Yellen 1986). In these, the principal pays the agent enough that he enjoys returns on the job in excess of the value of his outside option. Thus, if he loses his job, he will suffer a discrete utility loss, and the threat of being fired if caught shirking in a random inspection motivates him to work. More frequent or more accurate tests increase the probability of catching slackers and reduce the amount that the agent must lose if fired in order to motivate him.

If the agent were not wealth constrained, he could be charged for the job up front, and the excess returns would be reduced to being quasi-rents, with no rents being earned by the agent. However, if he is wealth constrained, then the returns are actual rents—returns in excess of his opportunity costs. Consequently, the cost to the principal of motivating effort is increased, as it was above, and again this may reduce the amount of effort demanded to inefficient levels.

2.1.4. Choosing the Principal

In many settings, the roles of principal and agent are not a matter of choice, in one or both of two senses: who does the work and who gets the returns?⁸ Regarding the former, sometimes only the agent has the skills or knowledge needed to carry out the productive activity. In other settings, however, it is possible to allocate at least some of the tasks to either the principal or the agent. Because several other chapters in this volume—including Bolton and Dewatripont, Garicano and Van Zandt, Gibbons et al., Mookherjee, and Roberts and Saloner—discuss various aspects of this delegation problem, we sidestep it here.

Even when it is preordained who does what work, however, there is still the question of who gets the returns (and then contracts with the other, if useful). As with who does the work, sometimes who receives the returns from an activity is preordained (e.g., in the relation of a patient and surgeon). In other cases, however, the returns could be alienated from one party and transferred to the other, so we can then analyze which party should receive the returns. We now briefly discuss this issue, both to address a loose end from Section 2.1.2 and to illustrate the larger “incentive system” approach we describe in Section 5, where multiple instruments are available and are used in combination to address a given incentive problem.

In the classic case of the risk-aversion model of Section 2.1.1, where $y = x$, an incentive contract $w = s + by$, where $b = 1$ (and $s < 0$), transfers the full returns of his effort to the agent. This contract would create first-best effort incentives, but the agent would also bear all the risk in y . This would involve inefficient distribution of the risk, because the agent is risk averse while the principal's risk-bearing ability is wastefully unused. In particular, because this

8. Parts of this section draw on Gibbons (2010) with permission from the *Annual Review of Economics*, Volume 2, © 2010 by Annual Reviews, <http://www.annualreviews.org>.

contract was feasible but not optimal in Section 2.1.1, we know that this method of selling the agent the firm is not optimal.

We could also imagine situations in which it is possible to transfer the right to receive the payoff y , even if y itself is not contractible. For example, perhaps this return accrues automatically to whomever owns a particular asset, and transfer of the asset would transfer the return. In the classic model, this runs into the same problem: it is optimal to share the risk in y . Thus, once the transfer of title has been made, the resulting allocation of the risky return is inefficient. If possible, the parties would benefit by signing a risk-sharing contract. This is not possible if y is not contractible, so the inefficiency remains. If it were possible to share the risk, however, doing so would reduce the effort incentives facing the former agent. Accounting for this would result in contract terms that reproduce the distribution of returns (and effort) under the original optimal agency contract.

We next consider these issues in the manipulable-measures model from Section 2.1.2. A core aspect of this model is that y is not directly contractible and $x \neq y$, so it is not possible to sell the agent the firm in the first sense discussed above, by means of an incentive contract $w = s + by$ with $b = 1$ and $s < 0$. However, the agent is risk neutral, so literally selling the agent the right to receive the benefits y (the second approach above) would now create first-best incentives for the agent, because there would be no reason to write any contract with the (former) principal. To prevent this argument from eliminating the applicability of the manipulable-measures model, we now enrich that model to explain why the principal should not sell the agent the right to receive y . Simply put, the reason will be that, in a richer setting where both the principal and the agent take actions to increase firm value, the agent should be the actor whose performance measure is less easily manipulable (so that the principal can contract with the agent without too much loss from the “get what you pay for” problem).

Formally, suppose there are two actors ($i = 1, 2$), each of whom can take both a productive action (a^i) and a manipulative action (m^i). The actors’ collective contribution to firm value is $y = a^1 + a^2$, the available performance measures are $x^i = a^i + g_2^i m^i$, and each actor’s cost function is $C(a^i, m^i) = ((a^i)^2 + (m^i)^2)/2$. Thus, each $f^i = (1, 0)$, while $g^i = (1, g_2^i)$. Suppose actor i is the principal and signs the incentive contract $w = s + b^j x^j$ with actor j . An optimal contract can then be derived from the logic of the manipulable-measures model:

$$b^{j*} = \frac{1}{1 + (g_2^j)^2} = \frac{\|f\|}{\|g^j\|} \cos(\theta^j).$$

Because the principal receives y (and the actors’ productive actions are additively separable in producing y), the principal has first-best incentives. Higher values of g_2^j (equivalently, lower values of $\cos(\theta^j)$) reduce the optimal b^j , the corresponding induced effort, and the final payoff. The expected payoff to the two parties is therefore maximized by avoiding having to contract with the actor whose performance measure is more manipulable: actor j should be the principal if $g_2^i < g_2^j$.

Finally, in the wealth-constraints model, the agent simply lacks the resources to buy the firm. Further, if negative values of y are possible, then even loans from the original owner will not work, because bankruptcy provisions shield the agent from having to repay the loan.

2.2. Contracting with Multiple Agents

Of course, it is rare that a principal would be dealing with a single agent if we think about a firm. What difference does it make when there are multiple agents?

The multi-agent problem perhaps closest to the single-agent analyses in Section 2.1 is Holmström's (1982) model of relative performance evaluation. Imagine that each agent's effort affects only that agent's output (e.g., $y_i = a_i + \varepsilon_i$), but the agents' noise terms are subject to common shocks (e.g., $\varepsilon_i = \theta + \mu_i$). Holmström's Informativeness Principle (1979) then implies that, because there is statistical information in one agent's results about other agents' noise terms, the pay of the latter should depend on the former's performance. For example, the performance of other firms facing similar market conditions ought to be informative about the extent to which a CEO's good performance was a matter of effort or instead due to luck in that market conditions were good.

The evidence on the extent of such use of relative performance evaluation for CEOs is mixed (Murphy 1999). To the extent that it is not used, it may be because of multitasking concerns: for example, relative performance evaluation might encourage collusion among CEOs to keep effort and performance low. In other contexts, beyond CEOs, concerns with sabotage of others' efforts, collusion among the workers, shopping for a "good" reference group, and mismanagement of positive spillovers among different agents' work could all discourage the use of relative performance evaluation (Gibbons and Murphy 1990). Still, some forms of relative performance evaluation seem widespread in various contexts. A prominent example is tournaments.

In a tournament, the performances of multiple agents are ranked, and higher rewards are given to those with higher ranks. For example, with two agents, the principal prespecifies wages w_H and $w_L < w_H$, and the agent with the higher output receives w_H ; see Lazear and Rosen (1981) for an early treatment. The relative-performance aspect of a tournament filters out common shocks, such as if $y_i = a_i + \theta + \mu_i$, but tournaments also provide incentives in the absence of common shocks, such as if $y_i = a_i + \mu_i$. Furthermore, tournaments can provide incentives when only ordinal rather than cardinal performance information is available. Finally, the fact that a tournament's wages can be not only prespecified but also prepaid (into, e.g., an escrow account, awaiting distribution to the appropriate agents) is one way to address a possible commitment problem where the principal is tempted not to pay high wages resulting from high output under a contract, such as $w = s + by$; see Malcomson (1984). Lazear and Oyer (this volume) and Waldman (this volume) describe more recent work on tournaments. See also the use of tournament models in the dynamic settings discussed in Section 2.3 and in the context of promotions in Section 5.4.

Other analyses of multi-agent incentive problems place greater emphasis on team production, free riding, and one agent helping another. As a first step in this direction, Holmström and Milgrom (1990) assumed that a team works together for a boss but then decides how to share the rewards paid to them. An example might be a fruit-picking team in California agriculture. The key insight here is that if the team shares output optimally (as in Wilson's (1968) theory of syndicates) and the team can avoid the free-rider problem, then it is as if the boss were contracting with a single individual whose risk tolerance is the sum of the risk tolerances of the team. This means stronger incentives than under individual contracting.

Rather than assuming that a team can avoid the free-rider problem, other papers have asked whether and when this might occur. The first results are due to Holmström (1982), who

analyzed an N -person partnership with individual actions x_i , where all that can be observed is total output $y = f(x_1, \dots, x_N)$ and so payments must be $s_i(y)$. Note that here there is not (yet) a principal; there are just the N partners. Holmström showed it is impossible for the partnership to achieve Pareto-optimal output as a Nash equilibrium of the game where all the agents choose their input levels simultaneously if we insist that all the output be distributed: for all y , $\sum s_i(y) = y$. The essential logic is the free-rider problem. On average, an agent can get only y/N , so on average, individuals will each equate their marginal productivity divided by N to their marginal cost of input. But y is, in essence, a public good, so optimality requires that each individual's marginal cost be equated to the full marginal productivity.

In Holmström's model, one way to restore the possibility of achieving optimality in Nash equilibrium is by agreeing to throw away output if the Pareto-optimal level is not achieved, but the team may have difficulty committing to throwing away resources in this way. To avoid this commitment problem, one could introduce an $N + 1$ st party who absorbs the team output if it differs from the Pareto-optimal level, but labeling this $N + 1$ st party (who plays only this budget-breaking role) the principal does not easily match common conceptions of the roles of a boss. In particular, she does well only when the others fail.

More optimistically, Che and Yoo (2001) analyzed when and how a pair of workers might overcome the free-rider problem by mutual monitoring in a repeated game if each can observe the other's performance. Assume that the workers' production functions are independent, so that independent pay-for-performance rather than a group bonus would be optimal in a static model. Che and Yoo showed, however, that in a repeated game, the principal optimally chooses a group bonus for the pair of workers, exactly because the free-rider problem then threatens to make the workers' continuing relationship inefficient if cooperation between them breaks down. See Section 3 for more on such relational contracts, often constructed vertically between principal and agent, rather than horizontally between workers as here.

Continuing to consider horizontal effects between workers, it may be that formal contracts other than a group bonus may also support cooperation between workers (either by reducing the reneging temptation today or, as in Che and Yoo, by increasing the punishment if reneging were to occur). In particular, the observed practice of allocating a fraction of ownership of the firm to the workers might function this way. And, moving from instrumental to behavioral theories, allocating a fraction of the firm's ownership to workers may also change "mindsets," so agents "think like owners," although it is hard to see why they would think like more than $1/N$ th owners absent some peer pressure. See Section 7.2 for more on peer pressure.

There are also analyses of one worker's incentive to help other workers. For example, Itoh (1991) modeled a situation in which workers decide both how much effort to devote to their own responsibilities and how much to help co-workers and thereby increase co-workers' measured performance. If the principal wants the agents to focus on their own jobs, she offers pay based only on individual performance, which induces the agents to choose not to help one another. However, if she pays each agent on both his and the other's output, she will induce team production. Itoh shows that either may be optimal. In particular, team pay is optimal if the two sorts of effort are strategic complements, so getting more help from the other induces an agent to work harder at his own job.

Finally, there are a class of problems involving a multilevel hierarchy with a third party (the supervisor) between the principal and agent. For a wide-ranging discussion of models of incentives in hierarchies, see Mookherjee (this volume).

2.3. Dynamics

The preceding sections were largely concerned with one-shot contracting situations. However, many relationships extend over time, especially in organizations, and incentive contracts can have intertemporal aspects. For example, in a single contract, there may be opportunities to respond to new information as it arrives—including but not limited to interim performance evaluation. Also, over time, there can be either a sequence of short-term contracts or a long-term contract. We now discuss these issues in turn.

2.3.1. *Responding to New Information*

One of the strong assumptions in a one-shot model, including those discussed above, is that nobody learns anything until the end of the transaction. At the other extreme, there are continuous-time models in which the principal and agent are constantly observing how things are going (see Section 2.3.3 for more on this). As a first step between these two extremes, in this section we consider some of the issues that arise when new information becomes available during the course of the contract. Sometimes such information may be valuable. At other times, the additional information may be harmful. This is especially likely if the parties lack commitment power, but it can also arise in other contexts.

A prominent example involves interim performance evaluation in a context where the agent takes repeated actions and the principal gets information before the second action is taken. Here, feedback may or may not be useful. To see this, consider two different models where the agent acts repeatedly and the principal, but not the agent, observes the results of each action before the next is taken. On the one hand is the model in Fuchs (2007), which is discussed in more detail in Section 3. In this model, the principal wants the agent to take the same action in every period. Given that the desired behavior is unchanging, there is no value to providing the agent with performance information. In fact, providing such information just increases the number of incentive constraints that must be met, and so makes the principal worse off (without benefiting the agent). On the other hand, in Manso (2011), which is discussed further in Section 6.2, the principal sometimes wants the agent to change his action, depending on the results of early actions. In this case, feedback is necessary.

Ederer (2010) explored the costs and benefits of providing feedback and finds that several competing effects can arise. Specifically, in a sequence of two tournaments, if effort and ability are complements, feedback can inform workers about their relative position in the tournament (evaluation effect) as well as their relative productivity (motivation effect), and it can also create signal-jamming incentives to exert effort prior to the performance evaluation. These effects suggest a trade-off in giving feedback between evaluation and motivation. Ederer suggests that this finding is in accordance with behavioral research and actual practices.

In addition to providing the information, the principal might also act on it. We mention two papers in this vein. First, Crémer (1995) showed that it can be costly for the principal if she cannot commit not to gather information. In his model, the principal can find out whether a bad outcome was the result of low effort or bad luck. This possibility makes it infeasible to carry out threats, such as “I will fire you if output is low.” This weakens the incentives that can be provided, and in fact the principal would be better off if she did not have access to the information. In Meyer (1992) the principal’s reaction to new information can be contractually specified. She showed that, in a sequence of two tournaments where the principal’s goal is to

maximize the sum of the agents' efforts over time, it is efficient to commit *ex ante* to biasing the second-round tournament in favor of the first-round winner. Such a bias reduces second-round effort, but it also increases first-round effort. Furthermore, these effects are second and first order, respectively, so the optimal incentive scheme produces a fast track (i.e., those who win early are more likely to win later as well).

2.3.2. *The Ratchet Effect*

Although it is sometimes feasible for the parties to specify in advance how they will respond to new information, it seems at least as common for such responses to be noncontractible.⁹ This is either because the response is never contractible (e.g., the agent's action, in a setting with repeated actions), or because the response is not yet contractible (e.g., the contract the principal will offer next period, in a setting where the principal can commit within but not between periods).

A classic example of the latter is the ratchet effect, where the firm reduces its piece rate if it learns that a job can be done more easily than was thought at first. Anticipating such a reduction, workers restrict output, working slowly to prevent the firm from discerning the true pace at which the job could be done. Mathewson (1931) and Roy (1952) offered rich descriptions of both the ratchet effect and output restriction.

To explore these qualitative accounts analytically, it seems natural to consider an environment in which the workers have private information about the job's difficulty and a worker's effort cannot be monitored. Gibbons (1987) showed that, in this environment, if the firm cannot commit to maintain the piece rate and the worker cannot commit to remain with the firm, then both the ratchet effect and output restriction are unavoidable: there is no equilibrium compensation scheme that induces efficient effort.

Lazear (1986) analyzed a similar model but assumed that the worker is bound to the firm. In this case, a sufficiently steep slope in the initial incentive contract induces the worker to put forth efficient effort today (i.e., there is no output restriction), even though the worker understands that the rate will ratchet tomorrow. Under Gibbons's assumption that the worker is not bound to the firm, in contrast, such a steep slope would cause the worker to "bust the rate" (i.e., maximize earnings, producing more than is efficient) today and quit tomorrow.

Kanemoto and MacLeod (1991) and Carmichael and MacLeod (2000) studied mechanisms that allow firms to avoid the ratchet effect (and so avoid output restriction as well). Kanemoto and MacLeod analyzed the case where the worker's output conveys information about the worker's ability, rather than about the job's difficulty, as in Lazear (1986) and Gibbons (1987). In the Kanemoto-MacLeod model, competition for the worker's services from the market of prospective employers effectively allows the firm to commit. Carmichael and MacLeod explored repeated-game models in which the future value of the ongoing relationship may allow the firm to commit. For example, they described mutual-monitoring arrangements among British cotton spinners in the nineteenth century, in which piece rates were publicly posted and sanctions were administered (by other firms!) against firms that cut rates.

9. Parts of this section are reprinted with permission from Gibbons (1997), © 1997 Cambridge University Press.

2.3.3. Long-Term Contracts

The ratchet effect (and its associated output restriction) arises because firms are assumed to be able commit to only short-term contracts. In such situations, the ability to commit to future piece rates by means of a multiperiod contract could be very valuable. However, the world changes over time (e.g., new techniques of production may warrant new piece rates), sometimes in ways that cannot be included in a contract *ex ante*, so long-term contracts may at least need to be renegotiated and might not even be feasible.

In a sufficiently stationary setting, however, long-term contracts may be feasible but not necessary, in the sense that a sequence of short-term contracts may be just as efficient as the optimal long-term contract. Holmström and Milgrom (1987) provided the first result in this spirit, by reinterpreting the classic model from Section 2.1.1: instead of assuming that the agent takes a single action a that influences a single output y , Holmström and Milgrom assumed that the agent takes a sequence of actions a_t , each of which produces its own output y_t , where all past outputs are observed before the next action is taken. For the case where $y_t \in \{0, 1\}$, we can interpret output in the classic model as the sum of the individual outputs here, $y = \sum y_t$. For example, the actions and outputs a_t and y_t might happen every day, and y in the classic model might refer to aggregate output during one year (with, say, T days in the year).

One of Holmström and Milgrom's insights is that if a contract based on aggregate output, $w(y)$, is nonlinear in y , then the agent will face different incentives for a_t depending on what prior outputs have been realized (y_τ for $\tau < t$). But if there is no reason for the agent's incentives to vary (or, more strongly, if the principal would like the agent to take the same action in each period), then there are two equivalent ways to proceed. First, the parties could sign a contract $w(y) = S + By$ that is linear in aggregate output. Second, the parties could sign a sequence of single-period contracts $w_t(y_t) = s + by_t$, with the same values of s and b in each period. Given such assumptions as exponential utility (so that there are no income effects), each of these approaches creates constant incentives for the agent. Moreover, the two approaches create the same constant incentive if $B = b$, and they deliver the same certainty equivalent to the agent if $S = Ts$.

In fact, we take three points from Holmström and Milgrom (1987). The first is the one we started this section with: in a sufficiently stationary setting, a sequence of short-term contracts may be just as efficient as the optimal long-term contract. Fudenberg et al. (1990) explored the domain over which this result holds. They showed that if the following conditions all hold, then a sequence of short-term contracts can achieve everything a long-term contract could: (1) all public information can be used in contracting, (2) the agent can save and borrow on the same terms as the principal, (3) technology and preferences are common knowledge between the agent and principal at each time of contracting, and (4) the utility possibility frontier generated by the set of all incentive-compatible contracts is always downward sloping. Condition (1) means insurance opportunities are not lost, (2) means the agent can do any consumption smoothing on his own and does not need to use the principal to do it by means of the contract, (3) avoids adverse selection when contracting (including private information about unobserved actions), and (4) ensures that an efficient contract can achieve any utility level for the agent that is relevant. These conditions seem quite restrictive, suggesting that long-term contracts should often be valuable. It is therefore important to think about why long-term contracts are not more common (or, where they exist, are often simple rather than detailed).

The second point we take from Holmström and Milgrom (1987) is that, given several assumptions, the optimal contract for the year not only is linear in aggregate output but also has exactly the optimal slope b^* from the LEN model in Section 2.1.1. This is the sense in which Holmström and Milgrom (1987) provided microfoundations for the LEN model. This interpretation of the linear contracts in the LEN model has been offered in many subsequent static models, perhaps beginning with Holmström and Milgrom (1991).

Finally, the third point we take from Holmström and Milgrom (1987) is that long-term contracts may fruitfully be modeled in continuous time. That is, in models with discrete time periods, optimal multiperiod performance contracts tend to be very complicated, and it is typically hard to get clean results, let alone explicit solutions (for an early contribution, see Rogerson 1985). However, in recent years, continuous-time models of agency have been developed and have proven to be remarkably tractable, and Holmström and Milgrom (1987) initiated this approach. Informally, one can think of the agent acting more and more frequently, so that each period is very small. Formally, the agent selects at each instant over a finite horizon the drift $\mu(t)$ of a one-dimensional Brownian motion. He has exponential utility for income less the cost of effort and consumes only at date T , the end of the relationship. It turns out that the best the principal can do is to induce a constant drift (effort) over time and to pay the agent a linear function of final profits. Even if the agent controls a multidimensional process, the result holds if the principal can observe only a one-dimensional function of the outcomes.

More recently, some papers have explored other continuous time formulations (for references, see Edmans et al. 2012). For example, Sannikov (2008) offered an infinite-horizon, continuous-time agency model where the agent again controls the drift of a Brownian motion by his efforts, but in contrast to Holmström and Milgrom (1987), his supply of effort is subject to income effects, and consumption occurs at each instant. Sannikov is able to obtain a closed-form solution for this problem. DeMarzo and Sannikov (2006) used the techniques of Sannikov (2008) to study an agency problem where the agent may divert corporate resources to his private use. As well, Edmans et al. (2012) analyzed a very rich model, allowing not just for effort provision by the agent (thought of as a CEO), but also manipulation of earnings that shifts returns across periods at a cost to the firm (e.g., inflating current returns at a real long-run cost) and private, unobserved borrowing and saving by the agent that could undo the contract's terms. There can be stochastic linkages across periods as well. Again, the authors obtain an explicit expression for the optimal contract. Further, they are able to show that it can in fact be implemented in a simple manner using a cash and equity compensation whose mix is altered over time in a "dynamic incentive account" in which the agent's expected pay is escrowed.

3. Relational Incentive Contracts: Informal Instruments

In Section 2 we examined formal performance contracts—those that can rely on court enforcement. We turn now to relational contracts—those that use performance measures that cannot be verified by third parties.¹⁰ Because they use such performance measures, relational contracts

10. Parts of this section draw on Gibbons (2010) with permission from the *Annual Review of Economics*, Volume 2, © 2010 by Annual Reviews, <http://www.annualreviews.org>.

must be self-enforcing: the parties need to find it in their interest to adhere to the mutually understood terms.

A classic example involves Lincoln Electric (Fast and Berg 1975), where a piece-rate formula ties part of a worker's pay to objective measures of the worker's output, but typically about half of a worker's pay is a bonus based on the supervisor's subjective assessment of the worker's cooperation, innovation, dependability, and so on. Workers expect supervisors to judge them fairly and the firm to pay the bonus earned because they are in a long-term relationship, which allows misbehavior today to be punished in future dealings.

Our treatment of relational contracts is short. See Malcomson (this volume) for an entire chapter on such models, Baron and Kreps (this volume) for a nuanced application of these ideas to employment relationships, and Gibbons and Henderson (this volume) for some of the difficulties in reaching mutually understood terms. Also, it is important to note that relational contracts may not always be efficiency enhancing. For example, recall Roy's (1952) description of output restriction in response to the ratchet effect, where the firm's ability to collect information and implement change was limited by an informal agreement among the workers that was enforced by ostracism and physical punishment.

To formalize the idea of relational incentive contracts, we sketch Bull's (1987) model, as interpreted by Baker et al. (1994), in which the relational contract is an equilibrium of a repeated game between a principal and an agent. In each period, the agent chooses an unobservable action, a , that stochastically determines the agent's total contribution, y . For simplicity, suppose that y is either High ($y = H$) or Low ($y = L < H$), and that $\text{Prob}(y = H|a) = a$, where $a \in [0, 1]$. If total compensation is w , the principal's payoff is $y - w$, and the agent's is $w - C(a)$, where $C(0) = 0$ and $C' \rightarrow \infty$ as $a \rightarrow 1$.

Now suppose y cannot be objectively measured in a way that is verifiable in a court of law, but that it can be assessed by both parties. Further, assume for now that their assessments are identical. In particular, let the compensation consist of a base salary, s , whose payment can be court enforced, and a bonus, B , which the principal promises to pay if the parties' common assessment is $y = H$. Note that the bonus is in fact discretionary, because no court can enforce the promise. The timing of events in each period is as follows. First, the principal offers the agent a compensation package. Second, the agent either accepts the compensation package (in which case s is paid) or rejects it in favor of an alternative employment opportunity with payoff U_0 . Third, if the agent accepts, then the agent chooses an action at cost $C(a)$, but the principal does not observe the agent's action. Fourth, the principal and the agent observe the realization of y (but a court cannot). Finally, if $y = H$, then the principal chooses whether to pay the agent the bonus B specified in the relational contract.

In a single-period employment relationship, the principal would choose not to pay a bonus, so the agent (anticipating the principal's decision) would choose not to supply effort, and so the agent's contribution would be $y = L$. Anticipating this, the most the principal would offer is a salary $s = L$. Then, if $L < U_0$, the agent would choose not to work for the principal.

But things can be different in an ongoing relationship. Formally, consider an infinitely repeated game in which both parties discount future payoffs at rate r . We focus on equilibria in which the principal and the agent play trigger strategies (roughly speaking, the parties begin by cooperating and then continue to cooperate unless one side defects, in which case they refuse to cooperate forever after).

If the agent believes the principal will pay the bonus B , then the agent's optimal action, $a^*(B)$, satisfies $C'(a) = B$. If the principal offers the minimum salary that the agent will accept, then the principal's expected profit per period is

$$L + a^*(B) \cdot (H - L) - C(a^*(B)) - U_0 \equiv V(B) - U_0,$$

where $V(B)$ is the expected gross surplus (output minus cost) from the effort induced by the bonus B .

But should the agent believe that the principal will pay the bonus B if the outcome is H , as she is supposed to? If the principal does not pay the bonus, then her payoff is $H - s$ this period but zero thereafter, whereas if the principal does pay the bonus, then her payoff is $H - s - B$ this period but equal to the expected profit from the relationship thereafter. Thus, the principal should pay the bonus if and only if

$$(H - s - B) + \frac{1}{r}[V(B) - U_0] \geq (H - s) + \frac{1}{r} \cdot 0,$$

or $B \leq [V(B) - U_0]/r$. In words, the renege temptation must be smaller than the present value of the net surplus from the relationship. If enough value is created in the relationship, then incentives for positive effort can be provided.

This basic model of relational incentive contracts has been enriched by MacLeod and Malcolmson (1989) and Levin (2003), who established a number of key features of the set of optimal contracts and characterized the range of economic outcomes consistent with equilibrium. It has also been used as an ingredient in models of the combined use of formal and relational contracting (see the beginning of Section 5) and to study empowerment (Baker et al. 1999), partnerships (Doornik 2006), job design (Schöttner 2008), supervision (Thiele 2012), and other incentive issues in organizations. In addition, there has been some progress in relaxing the strong information assumptions in this basic model (where everything is commonly known or observed except the agent's effort), with interesting implications for the dynamics of relational contracts, some of which we now discuss.

One natural change in this basic model is to move from *discretionary* bonuses (where the parties both see the agent's output, but the court does not, so the principal can decide whether to pay a bonus after the agent produces high output) to *subjective* bonuses (where only the principal sees the agent's output, so the principal can claim that output was low and no bonus should be paid). Levin (2003), MacLeod (2003), and Fuchs (2007) have analyzed such subjective bonuses.

In a static model, MacLeod (2003) noted that truth telling by the principal requires that the principal's payment be independent of her report about the agent's output. From this, it follows that with a budget-balanced contract (i.e., one where everything paid by the principal is received by the agent), the agent's pay is independent of the principal's report, and so he cannot be induced to supply any effort. MacLeod characterized the optimal contract, and he interpreted the necessary instances of "money burning" (i.e., states of the world in which the principal pays more than the agent receives) as inefficient conflict that occurs on the equilibrium path (specifically, after the principal reports low output by the agent). MacLeod's static model simply allows any amount of money burning (say, as though a third party were available to receive the difference between what the principal pays and the agent receives).

In contrast, in a repeated-game model, Levin (2003) endogenized the upper bound on how much expected future inefficiency the parties can tolerate and still maintain their relationship today. Under the “full-review” assumption that the principal gives the agent a performance review (i.e., truthfully reveals the agent’s output) each period, Levin shows that the optimal relational contract takes a threshold form: for sufficiently high output, the agent receives a bonus and the relationship continues; for output below the threshold, there is no bonus and the relationship ends.

Finally, Fuchs (2007) shows that, by releasing more information to the agent, the full-review policy cannot help and might hurt in implementing the optimal relational contract. This is because releasing more information about past performance gives the agent more histories on which he can condition his effort decision this period and thus increases the number of incentive constraints the contract must meet. A superior approach is to keep the agent in the dark for blocks of 7 periods, after which the principal provides performance information. Even better, the principal could withhold performance information for the entire relationship, meaning that the optimal contract is a termination contract: the agent receives a constant wage each period until the principal decides to fire him.¹¹

A second natural way to enrich the basic model of relational incentive contracting is to add private information not about outcomes but instead about payoffs—such as the agent’s cost function or the principal’s discount factor. MacLeod and Malcomson (1988) and Halac (2012a) have analyzed such models where the party’s type is permanent, and Li and Matouschek (2012) and Halac (2012b) have analyzed models with a transient type. We discuss each of these now.

In MacLeod and Malcomson’s (1988) model, workers know their own abilities (but firms do not), and it is efficient for higher ability workers to exert more effort. The result is akin to heats in a track meet. In the first round, only the least-able workers fail to qualify for the second round (i.e., fail to get promoted); all other workers work just hard enough to qualify. Of those promoted, the least able fail to qualify for the third round (i.e., a second promotion), and the others work just hard enough to qualify. Eventually, the workers’ ability distribution is broken into intervals, corresponding to the groups of workers who have chosen to stop on each rung of this endogenous promotion ladder. Having reached its steady-state rung on the ladder, each such group then works hard enough to avoid demotion but finds it not worthwhile to work hard enough to induce further promotion. This gradual learning, in which different types settle into different steady states for the remainder of the repeated game, is a prominent theme in the literature. See Gibbons and Henderson (this volume) for descriptions of how Chassang (2010) and Halac (2012a) also fit this description. In Li and Matouschek (2012) and Halac (2012b), where types are transitory, it is not surprising that learning does not cause different types to settle into different steady states for the remainder of the game, but even one-period types can nonetheless cause longer run inefficiencies. Again, see Gibbons and Henderson (this volume) for details.

11. Fong and Li (2010) build on Fuchs’s logic to show that an intermediary who can induce intertemporal garbling of performance information (producing a garbled public signal instead of either the principal or the agent observing true output) can improve relational contracting compared to the full information about performance in the basic model.

4. No Contracts: Career Concerns

The models in Sections 2 and 3 analyzed formal and then relational contracts. In this section, we take the next step and analyze situations with no contracts.¹² Workers can still have incentives, now from career concerns: the worker's current performance affects the market's belief about the worker's ability, and hence the worker's future compensation. Fama (1980) argued informally that such career concerns might make incentive contracts unnecessary. In line with Fama's intuition, career concerns may have a positive effect when the issue is motivating effort (although, even in this case, effort may be too high or too low), but career concerns can also have a very bad effect when trying to motivate other forms of behavior, such as risk taking (see Section 6.2).

The first formal investigation of Fama's idea is Holmström's (1982/1999) model, in which an agent's output in any period depends not only on the agent's effort but also on his ability plus random noise: $y_t = a_t + \eta + \varepsilon_t$. Both ability η , which is persistent, and the noise in each period, ε_t , are normally distributed random variables. Firms and the agent are initially uncertain about the agent's ability and so use observed performance y_t to update their beliefs. As in the relational-contracting model in Section 3, the agent's output here is observable but not verifiable. Nonetheless, competition among prospective employers (all of whom see the agent's output) makes the agent's future wages depend on firms' updated beliefs about his ability, so he has an incentive to perform well today to try to influence these beliefs.

Holmström showed that, in the absence of incentive contracts, career concerns do provide incentives but produce an inefficient (but intuitive) pattern of effort over time: agents typically work too hard (relative to the efficient first best) in early years (while the market is still assessing the agent's ability and he has a long time to reap the rewards of improving the market's belief) and not hard enough in later years (when the market's belief is hard to budge and the agent has little time to go). The idea is that by working harder than might be optimal under full information, the agent can hope to make employers believe he is more productive than he actually is. However, in equilibrium the employers recognize this incentive and account for it in their inferences. Yet the agent is stuck trying too hard, because if he does not, his low output will be seen as evidence that he is especially untalented.

With its additive production function and normal uncertainty, Holmström's model is tractable enough to allow analyses of short, long, and infinite horizons (as well as of the case where the agent's ability changes as a random walk over time). Dewatripont et al. (1999a) took a complementary approach, allowing both for multidimensional actions (multitasking) and signals and for different distributions relating signals, actions, ability, and noise. Given these generalizations, their analysis allows only two periods. Their focus is on how information structures familiar from standard agency theory (e.g., Holmström's (1979) sufficient statistic result) influence equilibrium effort in this context. In Dewatripont et al. (1999b), they applied a career-concerns model to governmental agencies, where budgetary and political limitations may curtail the use of explicit performance pay, and career concerns may consequently be more

12. Parts of this section draw on Gibbons, "Incentives between Firms (and Within)," *Management Science* 51(1), 2005, pp. 2–17, by permission from the Institute for Operations Research and the Management Sciences, 7240 Parkway Drive, Suite 300, Hanover, MD 21076, USA.

salient, but observers may be less able to interpret output signals than in some private sector contexts.

MacLeod and Malcomson (1988) analyzed something like career concerns in a model where workers now know their own abilities (but firms still do not) and it is efficient for higher ability workers to exert more effort (unlike the additive production function above). The result is akin to heats in a track meet. In the first round, only the least-able workers fail to qualify for the second round (i.e., fail to get promoted); all other workers work just hard enough to qualify. Of those in the second round, the least able fail to qualify for the third, and the others work just hard enough to qualify. Eventually, the ability distribution is broken into intervals, corresponding to the groups of workers who failed to qualify for each round. Having reached its steady-state level, each such group then works hard enough to avoid demotion but finds it not worthwhile to work hard enough to induce further promotion.

5. Beyond Contracts: Incentive Systems

Having discussed (and seen the limitations of) formal contracts, relational contracts, and no contracts in providing incentives, we now consider other ways to improve incentives when each of these is of only limited use by employing several motivating devices at once.

One approach is to mix formal contracts with relational contracts and/or career concerns. For example, Baker et al. (1994) examined the interplay between formal and relational contracts, showing that they could be complements in providing incentives (if the formal contract alone would be quite ineffective) but more typically are substitutes. Indeed, if the formal contracts are imperfect but nonetheless too effective, they can make relational contracts impossible, even where relational contracts alone would be more effective than these imperfect formal contracts. Other models in this vein have been explored by Pearce and Stacchetti (1998), Che and Yoo (2001), Kvaløy and Olsen (2006), Rayo (2007), and Battigalli and Maggi (2008); see Malcomson (this volume) for a discussion. The common theme of these models is that formal and relational contracts not only co-exist but also interact. Roughly speaking, the idea is to choose the formal contract to minimize the renegeing temptation created by the relational contract (which typically means choosing a different formal contract than would be optimal if the parties had access to formal contracts only).

Similarly, Gibbons and Murphy (1992) added single-period formal contracts to Holmström's (1982/1999) career-concerns model. Because career-concern incentives decline as the agent approaches retirement, the slope of the optimal incentive contract increases, keeping total incentives (roughly) constant. Gibbons and Murphy presented evidence on CEO compensation consistent with this prediction, and Gompers and Lerner (1999) did likewise for venture capitalists. Meyer and Vickers (1997) also allowed single-period formal contracts in addition to career concerns, but they added the possibility of relative performance evaluation in a model where the principal employs one agent but can observe the output of another. Formal contracts depend only on the agent's own output, but the career-concerns mechanism (updating beliefs about the agent's ability) is allowed to depend on past performances by both agents and hence can involve relative performance evaluation. Meyer and Vickers showed that relative performance evaluation in the career-concerns mechanism can help or hurt welfare—unlike in the classic agency model, where relative performance evaluation always improves incentives (see

Section 2.2). They suggest that their result may help interpret the mixed evidence on relative performance evaluation noted above.

Our focus in this section, however, is on using other features of the organizational design (besides pay for performance) to affect incentives, rather than merely blending the three approaches from Sections 2–4. By using these new instruments appropriately, the principal and agent may be able to create an improved solution to their incentive problem. In particular, the features of organizational design we consider sometimes have their own effect on the agent's incentives, but often also function by allowing the parties to utilize formal or relational contracts differently, thereby improving the overall results. In short, the overarching theme of this section is that no single instrument is likely to create perfect (or perhaps even tolerable) incentives, so multiple instruments are likely to be used in combination as an incentive system (Holmström and Milgrom 1994). Indeed, although we break this section's discussion into several parts, the spirit of the argument is not only that each of these can be combined with formal or relational contracts, but also that some or even all of these organizational features often can be usefully combined with one another. The organizational features we discuss are employees versus independent contractors; job design; empowerment; promotion; selection; and strategy, vision, and leadership.

5.1. The Agent as Employee or Contractor

If the identity of the principal has been established along the lines discussed in Section 2.1.4, it remains to determine whether the agent should be an employee or an independent contractor for the principal.¹³ Inspired by Holmström and Milgrom (1991), we now enrich the manipulable-measures model from Section 2.1.2 by assuming that there is a machine that the agent uses in producing y . The resale value of the machine (after it is used in production) is $v = h_1 a_1 + h_2 a_2 + \xi$. As with y , we assume that v is not contractible, so contracts continue to depend on only x . If the principal owns the machine (so the agent is an employee), then the principal's payoff is $y + v - w$ and the agent's is $w - c$. Alternatively, if the agent owns the machine (so the agent is a contractor), then the principal's payoff is $y - w$ and the agent's is $w + v - c$. In short, the parties now have two instruments to influence the agent's incentives—the formal incentive contract and ownership of the asset—and they need not use these instruments independently; to the contrary, we expect different formal contracts to be optimal depending on who owns the asset.

As stark illustrations of this incentive-system model, consider the following pair of examples.

Example 1: $y = a_1$, $v = a_2$, and $x = a_1$.

Example 2: $y = a_1$, $v = a_2$, and $x = a_1 + a_2$.

In Example 1, the parties are better off having the agent own the machine, because if the principal owns it, there is no way to provide incentives for the agent to enhance the machine's resale value (through action a_2). In Example 2, the reverse is true. In fact, in these simple examples, with the wrong choice of asset ownership the parties create a "get what you pay for" problem, but with the right choice the parties can then write incentive contracts that induce the first-best actions.

13. Parts of this section draw on Gibbons (2010) with permission from the *Annual Review of Economics*, Volume 2, © 2010 by Annual Reviews, <http://www.annualreviews.org>.

5.2. Job Design

Next, we return to the suggestion from the end of Section 2.1.1, that there may be better and worse ways to group tasks, for purposes of performance measurement and formal incentive contracting. Consider a multitask LEN model where there are four different tasks and the cost of effort for either of two agents is

$$C(a_1, a_2, a_3, a_4) = \frac{1}{2}(a_1 + a_2 + a_3 + a_4)^2$$

if at most two of the a_i variables are positive and infinity otherwise. Thus, each agent can undertake at most two tasks and the marginal cost of effort on any task is increasing in the amount of effort that the agent devotes to other tasks. Assume contracts are of the form

$$w = s + \sum_{i=1}^4 b_i x_i,$$

where $x_i = a_i + \varepsilon_i$. Because of the cost function, if the b_i values differ for any tasks the agent is asked to perform, only the most highly rewarded type of effort will be provided.

Now suppose the variances on the measures differ, with $\sigma_1 > \sigma_2 > \sigma_3 > \sigma_4$, and suppose that each agent can do only two tasks and all four tasks are desired by the principal. How should the tasks be allocated? The answer is that one agent should take tasks 1 and 2, the poorly measured ones, and the other should take 3 and 4. The agent taking the poorly measured tasks will receive quite muted incentives (small b), and the other agent will receive stronger incentives. This choice is better than mixing the tasks and having both agents necessarily receive the weak incentives that would then be optimal. Thus, as with the decision to make the agent an employee or a contractor, the decision about bundling tasks into jobs affects the formal incentive contracts that are then optimal.

Using a model based on Meyer and Vickers (1997), Meyer et al. (1996) asked whether this lesson about job design in a static model continues to hold in a dynamic model with limited commitment. Parallel to the Meyer and Vickers finding that relative performance evaluation (which has an unambiguously positive effect in a static model) can help or hurt welfare in a dynamic model with limited commitment, here Meyer et al. found that the optimal bundling of tasks may no longer be high versus low variance. Corts (2007) considered the job-design problem with two tasks, two customers for which these must be carried out, and two agents. He showed that it may be better to make both agents accountable for both tasks for both customers. The reason is that the team arrangement gives two measures on each agent, and this can be advantageous if the multitasking problem is severe and the risk costs are low. Even so, the basic incentive-systems point continues to hold: choosing the bundling of tasks appropriately allows the parties to choose a different formal incentive contract and improve their overall results.

5.3. Empowerment

The allocation of decision authority can have strong motivational effects. For example, in the early 1990s, large amounts of authority were delegated to front-line managers at BP, the energy company. They spoke of how motivating having this authority was, to feel that they had control and were responsible for a piece of business (Roberts 2004).

Usually, economic models aimed at this phenomenon assume that there are private benefits that the agent can enjoy if he is in charge (e.g., Aghion and Tirole 1997). As in Van den Steen (2010), an alternative modeling allows that the principal and agent may fundamentally disagree about which decision will lead to a good outcome, but that both principal and agent may gain if a good outcome occurs. If the agent believes the decision is more likely to be right if he makes it than if the principal does, then the agent will be more motivated to work hard (to develop decision-relevant information or to implement the chosen course of action successfully) if he can choose the decision.

If empowerment creates incentives (as did ownership of the machine when the agent is a contractor in Section 5.1), then one would expect different formal incentive contracts to be optimal, depending on whether decision rights were or were not delegated to the agent. As noted in Section 2.1, Prendergast (2002) developed a model in this spirit. See Bolton and Dewatripont (this volume), Gibbons et al. (this volume), and Mookherjee (this volume) for more on these and other aspects of delegation and empowerment.

5.4. Promotion

The up-or-out systems used in law firms, consultancies, and other professional service firms can induce exceptional levels of effort among junior members of the firms. See Kahn and Huberman (1988) and Waldman (1990) on the incentives created by such up-or-out contracts.

The tournament model sketched in Section 2.2 is another way to analyze the incentives created by the prospect of promotion. One drawback of using the tournament model (or up-or-out contracts) to study promotions is that, taken literally, the model implies that there are no incentives after being promoted. Of course, the model could be enriched to allow, say, formal incentive contracts, which could indeed be used to create incentives for agents who have been promoted. But in this enriched model, one should also ask why incentives before promotion are created by the prospect of promotion rather than by formal incentive contracts. See Baker et al. (1988) for an early exploration of these issues.

Another way to analyze incentives after a first promotion is to suppose that a second promotion is then possible. If there are fewer jobs at each successive level of the hierarchy, and pay rises with hierarchical level, then competition for promotion creates a tournament at each level. See Rosen (1986) for a first model of such elimination tournaments.

Finally, as we discuss in Section 6.1, Prendergast (1993) has shown how promotion policies can affect incentives for other desired behaviors (besides effort), such as the acquisition of firm-specific human capital. See Lazear and Oyer (this volume) and Waldman (this volume) for more on these and other aspects of promotions.

5.5. Selection

Offering performance pay can attract some agents while encouraging others to look elsewhere. In this sense, incentive pay may cause selection, and the productivity effects of this selection could be as important as the productivity effects of the incentives themselves. See Lazear (1986) for theory and Lazear (2000) for evidence.

Of course, the argument can also work in the other direction: having caused a narrow group of workers to select into the firm, the parties may then be able to use different formal or relational

contracts than would have been optimal for a broader population of workers. For example, in Sappington's (1983) model with limited liability and private information from Section 2.1.3, different contracts would be optimal if selection led to different supports of the agent's private information (and the same would be true in Laffont and Tirole (1986) and the models that followed).

5.6. Strategy, Vision, and Leadership

Various papers have suggested ways in which a firm's commitment to a strategy (or a vision or leadership style) can motivate employees. For example, defining a strategy as a specification of the lines of business in which the firm will operate, Rotemberg and Saloner (1994) developed a model in which a narrower portfolio of businesses makes it easier to execute useful incentive contracts. In this model, the agent supplies effort toward generating new projects, and the principal commits to a payment to the agent if a new project is implemented, but the principal retains control over whether projects are implemented (and so makes this decision based on the net benefits from implementing the project less compensating the agent). Tension arises if the agent generates a new project with value less than the compensation promised if a project is implemented, because the principal then prefers not to implement the project; anticipating this, the agent's incentives for effort then fall. If a narrow portfolio of businesses is more likely to generate "home-run" innovations or nothing (i.e., a broader portfolio generates more projects of intermediate value, perhaps because a given project has weaker synergies across a broader portfolio of businesses), then this tension arises less often if the firm pursues a narrow strategy. (See the discussion of Prendergast (1993) in Section 6.1 for a similar mechanism applied to workers' investments in firm-specific human capital and firms' subsequent decisions about whether to promote workers to higher paying jobs.)

Other approaches are similar in spirit but operate through other mechanisms, more along the lines of the differing beliefs mentioned in Section 5.3 on empowerment. For example, Rotemberg and Saloner (2000) called a top manager "visionary" if she is known to be biased toward a particular course of action. Knowing that a manager is visionary gives workers stronger incentives to invest in projects that are consistent with the manager's vision, because the workers are confident that such projects will indeed be implemented; see Van den Steen (2005) for more along this line.

Finally, Hermalin (1998) explored a signaling model of leading by example, where a leader has private information about the productivity of her own and followers' efforts, and observing high effort by the leader causes the followers to conclude that their productivity is high and so to work hard. See Camerer and Weber (this volume), Hermalin ("Leadership and Corporate Culture," this volume), and Roberts and Saloner (this volume) for more on strategy, vision, and leadership.

5.7. The Organizational Architecture

Sections 2–4 discussed performance incentives created by formal, relational, and no contracts, whereas this section has shifted attention to instruments besides pay-for-performance for creating incentives. Having discussed various instruments internal to the firm—such as job design,

empowerment, promotions, selection, and leadership—we now conclude this section by considering one last instrument: the formal architecture of the firm itself. Although we briefly mention a variety of aspects of the architecture that can affect effort incentives, most of our attention is on the boundaries of the firm.

Many aspects of organizational architecture are discussed in other chapters of this volume. These include the horizontal and vertical boundaries of the firm (Bresnahan and Levin; Ménard; Roberts and Saloner), its ownership structure (Hansmann), its corporate governance system (Hermalin, “Corporate Governance”), its internal structure of hierarchy and authority (Bolton and Dewatripont; Gibbons et al.; Mookherjee; Roberts and Saloner), and its decisionmaking systems (Gertner and Scharfstein; Gibbons et al.). As argued in Roberts (2004), each of these can have implications for incentives.

For example, the owners of a traditional partnership facing unlimited liability might be expected to exert quite different efforts toward mutual monitoring than they would if they were owner-managers of a limited liability corporation. The make-up of the board of directors and its compensation can certainly affect their incentives for oversight of the executives and thus the latter’s behavior. We have already considered an example of the effect of the internal structure and allocation of decision rights in Section 5.3. And, as noted in Jensen (1986), the choice of debt or equity financing can significantly affect managerial behavior.

In Section 5.1’s analysis of whether the agent should be an employee or an independent contractor, we have already touched on the idea that the boundary of the firm (there construed as the payoff right attached to asset ownership) might be a useful complement to formal incentive contracting. Here we sketch further applications of this idea, motivated by Holmström’s (1999) view that the firm is a “subeconomy” in which the principal can set the rules. For example, the principal can allow the agent to contract with outside parties at will, within limits, or not at all.

The following simple model shows that the boundary of the firm can matter for creating incentives even in the absence of formal incentive contracts. This model follows Grossman and Hart (1986) in emphasizing the role of property rights in creating hold-up, but it incorporates a multitask aspect from Holmström and Milgrom (1991) to produce an intuitive trade-off. Our discussion is informal; see Aghion and Tirole (1994), Holmström (1999), and Baker et al. (2002) for related formal models.

Consider an upstream biotech unit that can produce drug candidates for two downstream pharmaceutical firms—say, Merck and Pfizer. If one of the pharmas (say, Merck) owns the biotech, then Merck can forbid the unit to sell drug candidates to Pfizer. In addition, suppose that when Merck owns the biotech unit, the unit also cannot bargain with Merck, in the sense that Merck owns any drug candidates that the unit produces. In these circumstances, Merck may seek to create incentives for the biotech unit, perhaps through a formal contract, but we have seen that this can be exceedingly difficult to do well.

An alternative is to spin off the biotech unit as its own separate firm. The downside (from Merck’s perspective) is that the biotech is now free to bargain with and sell to Pfizer. The upside, however, is that the biotech’s opportunity to hold up Merck (i.e., to present a competing offer from Pfizer for a given drug candidate) may create useful incentives for the biotech (again, from Merck’s perspective). For example, suppose that the actions the biotech can take to create a drug candidate that is valuable to Pfizer also make that candidate valuable to Merck. In this case, the prospect of holding up Merck creates strong and useful incentives for the biotech

during the creation of the drug candidate. As an opposite example, however, suppose that actions that make the candidate more valuable to Pfizer instead reduce its value to Merck. In this case, the prospect of holding up Merck may create equally strong incentives for the biotech, but now these incentives are destructive rather than useful from Merck's perspective. In the former case, hold-up may be Merck's friend, and spinning off the biotech may be optimal; in the latter case, hold-up is disastrous for Merck, and they might be better advised to retain the biotech unit inside Merck, in spite of difficulties in then creating incentives for the unit.

This argument is another application of the fundamental insight from Grossman and Hart (1986): a benefit of nonintegration is that it creates strong incentives. Holmström's (1999) complementary insight is that when these high-powered incentives from nonintegration are misdirected, the low-powered incentives from integration may be preferred.

6. Beyond Effort

Most of the preceding discussion has focused on the problem of inducing the agent to supply what we have called "effort": an action that is costly for the agent, benefits the principal, and cannot be directly stipulated by contract. But there are many other actions, besides effort, that may have these three attributes, and there are still other noncontractible actions that may be beneficial to the agent and costly to the principal.

In this section we briefly discuss several such actions: investing in firm-specific skill; risk taking; information acquisition, communication, and decisionmaking; obedience; and influence activities. Similar to the organizational instruments discussed in Section 5, the contexts discussed here place less weight on formal or relational contracting than do the traditional agency models described in Sections 2 and 3. The distinction we draw between this section and the previous one, however, is that here we focus on models with enough context to make clear that the problems (and organizational responses) are not as simple as inducing effort from the agent to create output for the principal.

6.1. Investing in Firm-Specific Skill

Becker (1962) analyzed investment in firm-specific human capital in a world with complete contracting.¹⁴ In this world, workers' investments are verifiable by a court, so it is easy to induce efficient investment: simply have the firm reimburse the agent for the costs of his time and effort if he has acquired the requisite skills. Suppose, however, that a court cannot verify whether the investments have been made properly. The incentive problem is then two-sided: the parties need incentives that both induce the workers to invest and induce the firm to pay workers once they have invested. Put differently, the problem is that the firm will hold up the workers, refusing to pay once the investment cost is sunk, and the workers, foreseeing this, will not invest.

14. Parts of this section draw on Gibbons, "Incentives between Firms (and Within)," *Management Science* 51(1), 2005, pp. 2–17, by permission from the Institute for Operations Research and the Management Sciences, 7240 Parkway Drive, Suite 300, Hanover, MD 21076, USA.

Prendergast (1993) has shown that a firm's promise to promote skilled workers can sometimes overcome this two-sided incentive problem.¹⁵ Formally, let the agent's skill level be L if he has not invested in the requisite skills and $H > L$ if he has invested. The agent incurs an opportunity cost of c to improve his skill from L to H .

Having now described dozens of models above in which the agent's output is at best imperfectly contractible (if at all), we note here that the agent's skill is likely to be at least as difficult to contract on as his output is, because skill is a determinant of future output. For simplicity, Prendergast assumes that the agent's skill level is not contractible, even imperfectly so. However, imagine that the principal has two tasks to which the agent could be assigned. Call these tasks "easy" and "difficult," meaning that the agent's skills are more important in the production process for the difficult (D) task than for the easy (E) one. More specifically, suppose that an agent with skill s ($= L$ or H) assigned to task p ($= E$ or D) has productivity v_{sp} satisfying: (1) an agent who has not invested is more productive when assigned to task E ($v_{LE} > v_{LD}$); (2) one who has invested is more productive when assigned to the difficult task ($v_{HD} > v_{HE}$); and (3) training is efficient, because the productivity difference with optimal job assignments exceeds the investment cost ($v_{HD} - v_{LE} > c$).

Suppose that job assignments are verifiable by the court, so the principal can commit to paying a high wage (w_D) to the agent if the agent is assigned to the difficult task and a low wage ($w_E < w_D$) if the agent is assigned to the easy task. If the agent believes that investing will lead to assignment to the difficult task, then he will invest if $w_D - w_E > c$. The principal, for her part, will choose to assign a skilled agent to the difficult task if $v_{HD} - w_D > v_{HE} - w_E$. Unfortunately, these two conditions may be incompatible, even if investment is efficient: the agent's and principal's incentive conditions require $v_{HD} - v_{HE} > w_D - w_E > c$, but the assumption that investment is efficient guarantees only that $v_{HD} - v_{LE} > c$, not that $v_{HD} - v_{HE} > c$.

In short, the firm's promise to promote skilled workers creates a tension between needing a large enough difference in wages to induce the agent to invest, but a small enough difference to induce the principal to assign a skilled agent to the difficult task. If the change in value created from assigning a skilled agent efficiently is sufficiently large ($v_{HD} - v_{HE} > c$), then there exists a difference in wages that meets both these constraints. But if the two tasks satisfy $v_{HD} - v_{HE} < c$, then the promise of promotion cannot simultaneously provide an incentive for the agent to invest and an incentive for the principal to reward investment.¹⁶

The promise of promotion in Prendergast's (1993) model illustrates a contract different from the formal contracts analyzed in Section 2. Here, the agent's compensation is based on the principal's decision (the job assignment) rather than on the outcome that the agent's action produces (the skill level). Incentives for the agent then arise from how the principal's

15. See Lazear and Oyer (this volume) and Waldman (this volume) for more on skill development and promotions.

16. Recall from Section 5.6 that the Rotemberg and Saloner (1994) model of narrow business strategies has an analogous tension. Following Rotemberg and Saloner's idea that the firm might choose (at an opportunity cost) a narrow instead of a broad business strategy, where the former resolves the tension in their model but the latter does not, one could imagine by analogy in Prendergast's model that the firm might choose (at an opportunity cost) job technologies where $v_{HD} - v_{HE} > c$ instead of not.

decision (d) depends on the outcome the agent produces (v). If the principal's decision and the agent's outcome create value $y(d, v)$ for the principal, and the agent's compensation contract is $w(d)$, then the principal's optimal decision $d^*(v)$ maximizes $y(d, v) - w(d)$. In Prendergast's model, the agent chooses v directly, so one can express the agent's problem as choosing v to maximize $w(d^*(v)) - c(v)$; in a richer model, the agent might choose an action a that generates a stochastic outcome with distribution $f(v|a)$.

Obviously, this indirect approach to creating incentives for the agent would fail if $d^*(v)$ were a constant (e.g., if the principal never promoted the agent). This is one way that incentives for effort differ from incentives for developing skill: if "effort" means that the agent's total contribution is already realized (e.g., $y(d, v) = v - d$), then the principal has no incentive to make a decision that depends on the agent's outcome, whereas if "skill" means that (at least some of) the agent's total contribution depends on the principal's decision (e.g., $y(d, v) = dv$), then $d^*(v)$ may create useful incentives for the agent.¹⁷

6.2. Risk Taking and Experimentation

Agents are frequently asked to make choices among risky alternatives. This can be problematic if the agent is risk averse, his compensation depends on the results of his choice, and his risk attitudes differ from those of the principal. The obvious solution—disconnect his pay from the results of his choice—would work if he could demonstrate to the principal the basis for his choice. But such a demonstration is not possible, and if the principal wants to motivate the agent to exert unobservable effort to learn about the choice, then an agency problem arises of getting the agent to exert effort on research and then make a choice the principal would like.

Lambert (1986) studied this problem. A risk-averse agent is charged with selecting between a safe investment yielding y_0 for sure or a risky investment yielding either y_L or y_H , where $y_H > y_0 > y_L$. The prior probability that the risky investment yields y_H is 0.5, but at a cost c the agent can learn the actual probability p of success, which is distributed uniformly on $[0, 1]$. The risk-neutral principal would like the risky investment chosen if $py_H + (1 - p)y_L > y_0$. However, she does not observe p , and Lambert assumes that if the agent does observe p , he cannot communicate it credibly to the principal.

Given payments w_i , $i = L, 0, H$, from the principal in each of the three possible outcomes that yield U_L , U_0 , and U_H , respectively, the agent will select the risky investment if either he has not learned p and $(U_H + U_L)/2 > U_0$ or he has learned p and $pU_H + (1 - p)U_L > U_0$. In the latter case, this leads him to adopt a cutoff value r such that he chooses the risky investment only if $p > r$. Thus, if he learns p , his expected utility is $rU_0 + [(1 - r^2)U_H + (1 - r)^2U_L]/2$, so he will invest in learning p if this expected utility, evaluated at the optimal value of r (which depends on the utility levels) exceeds $\max\{U_0, (U_H + U_L)/2\}$ by at least his cost of effort, c . This in turn requires $U_H > U_0 > U_L$: risk is imposed on the agent to get him to work, as in

17. The implementation literature in contract theory has asked whether there exists a contract $w(d)$ that induces the principal to implement a desired decision rule $d^*(v)$ in a world where v is uncertain, exogenous, and noncontractible; see Moore and Repullo (1988), for example. Prendergast's (1993) model can be seen as endogenizing v , by introducing the agent and allowing him to choose v to maximize $w(d) - c(v)$. See Aghion et al. (1994) for more abstract progress along Prendergast's line.

the standard models. However, unlike the standard models, increasing the amount of risk the agent faces does not necessarily increase his incentives, because at some point the risk he faces is so great that he becomes better off not working and always selecting the safe investment.

In Lambert's (1986) model, at the optimal contract, the agent does not always choose the principal's preferred project. Note that this conflict of interest involves which project should be selected after the agent observes the value of p . But the compensation contract not only seeks to align interest in this regard but also to motivate the agent to invest in learning p . Consequently, the contract trades off the costs of motivating the agent to work against the benefits of having him adopt a project-selection strategy that the principal likes.

Manso (2011) offered a different take on motivating appropriate risk taking. He considered a problem where the risk-averse agent has three choices in each period: shirk; try the established way of carrying out his responsibilities, which has a known probability of success; or try a new way, which has an unknown probability of success. Each option carries a positive probability of success and of failure, but the new way is, in expectation, inferior to the old. Further, both yield more value, net of the agent's cost of effort, than does shirking. In a single period, therefore, the principal would want to motivate the agent not to shirk and to follow the standard procedure. However, suppose that if the new way is tried and it succeeds, then the updated posterior on its probability of further success exceeds the known probability of success of the established way. In this case, in a two-period setting, the principal may want the agent to experiment with the new way, with the intention of adopting it in the second period if it is a success and otherwise reverting to using the old way.

Motivating the agent to adopt the established way involves a contract design that is absolutely standard from the literature on unobservable costly effort. In contrast, motivating experimentation necessitates muted first-period incentives, because success is more likely if the agent adopts the established way, and so observing success is bad news about the choice he made. In fact, it may even be necessary to reward first-period failure if the agent finds it easier to do things the old way. However, second-period rewards have to be quite large to deter shirking.

6.3. Information Acquisition, Communication, and Decisionmaking

The Lambert (1986) and Manso (2011) papers on risk taking begin to illustrate three larger issues that are related to incentives in organizations but often are quite different from the idea in the classic agency model that the goal is to induce something like effort from the agent: information acquisition, communication, and decisionmaking. These topics are discussed in detail in Bolton and Dewatripont (this volume) and Gibbons et al. (this volume), so we treat them only briefly here.

Information acquisition can be like effort in that it is costly to the agent. This cost is direct in Lambert (1986) and somewhat indirect in Manso (2011), where it is subsumed in the cost of effort. However, unlike effort, information itself does not typically produce a benefit for the principal. Instead, a decision is taken on the basis of the information, and then the principal receives the benefits.

In some contexts, information may be "hard," in that the agent cannot distort it. For example, Athey and Roberts (2001) made such an assumption in modeling whether to give control of investment decisions to a third party rather than leave them with the parties that originated the

opportunities. There are few interesting incentive issues in communicating hard information of this sort. However, one could also imagine that, even though the information cannot be distorted, it can be withheld, with the agent falsely claiming that he is uninformed. This gives rise to richer strategic communication possibilities. And moving to “soft” information that can be directly misrepresented raises especially rich opportunities for strategic communication.

The baseline model of strategic communication of soft information is the Crawford and Sobel (1982) analysis of cheap talk. The agent is informed (for free) about a state of the world. The principal wants to make her decision match the state, but the agent wants the decision to differ systematically from the actual value of the state by a constant amount, b . The rewards to both parties depend only on how the decision is tailored to the state. Crawford and Sobel showed that it is impossible to induce complete revelation of the agent’s information.

It is also possible that the decisions might be delegated to the agent, as can happen in Dessein (2002). Recent papers by Alonso et al. (2008) and Rantakari (2008a) have built models of adaptation and coordination of decisions in multiproduct firms based on cheap talk. The issue is whether decisions should be taken centrally or in a delegated fashion by the agents, where in either case there is strategic communication. Friebe and Raith (2010) have generated a theory of the multiproduct firm based on the possibility of resource reallocations within the firm where communication is strategic and productive effort must be induced.

Finally, an important line of work embeds career concerns in models of project development and selection—see, for example, Holmström and Ricart i Costa (1986), Scharfstein and Stein (1990), and Zwiebel (1995). In these papers, career concerns, which were shown to be good for inducing effort, have a very negative impact. The idea is basically Mark Twain’s: “Better to keep your mouth shut and appear stupid than to open it and remove all doubt.” In Holmström and Ricart i Costa (in the case without incentive contracts), for example, a manager forgoes a profitable investment, because the result of the investment would reveal information about his ability to choose investments. Similarly, Scharfstein and Stein (1990) and Zwiebel (1995) show that managers will exhibit “herd behavior,” choosing the investment chosen by others even when their own information shows that another investment has a higher expected return.

6.4. Obedience

Superiors’ giving orders and subordinates’ deciding whether to obey is a characteristic of most organizations. The basic agency model can be thought of in these terms, with the principal telling the agent to exert the amount of effort that he finds optimal under the contract, given that the principal cannot directly see whether the agent has obeyed her instructions. Yet this model does not seem to be all there is to the matter (or even much of it). In particular, there is no actual need (or value) in those models to issue an order: the agent can work out what he wants to do, and if the principal designed the contract correctly, he will do what the principal intended.

A few recent papers have addressed the obedience issue directly. For example, Van den Steen (2010) considered situations where the principal and agent differ fundamentally in their beliefs about how the agent should carry out a task or address a problem (i.e., they have differing prior beliefs about the best way to do whatever it is that the agent is supposed to do). In such a context, rewarding the agent for success will motivate him to do things the way he thinks

is best, which may well be counter to what the principal wants and believes is best. Because the principal thinks the best course of action is to follow her beliefs, she should not reward the agent much for success. This phenomenon leads to a hierarchic, superior-and-subordinate relationship. The principal hires the agent and tells him what to do. If he obeys, which may mean making a choice contrary to what he thinks is most likely to succeed, he receives an efficiency wage that does not vary with the results of his effort and that makes him strictly better off than had he refused the offer to work for the principal. If he disobeys, he is fired. To improve the incentives of each party, the principal should own any assets being used in the relationship, because then the agent, if fired, has a weaker position, while the principal may more easily replace him. This improves the agent's incentives to obey and the principal's to carry through with the termination threat. Thus, several characteristic features of firms emerge endogenously: authority of one party over the other, minimal explicit incentives, and ownership of assets by the hierarchic superior. If moral hazard on effort is an issue, then there is performance pay, but it is muted.

Marino et al. (2010) considered a private-benefit model of authority and disobedience based on the model of Aghion and Tirole (1997).¹⁸ They studied a two-period problem. As usual in models derived from Aghion and Tirole, the principal and agent may have differing benefits from particular decisions. In Marino et al., the agent receives information for free, whereas the principal's efforts to become informed about the returns to different decisions are costly and uncertain. The payoffs to different decisions are such that the principal will want to leave decisions to the agent unless she has become informed. The principal may choose to direct the agent to make a particular choice, but she will do so only if she is informed. Nevertheless, he may choose to disobey and take his preferred option. Following disobedience in the first period, the principal may fire the agent and hire another to complete the project.

In the model by Marino et. al., the agent will disobey if his returns from making the choice he prefers are high enough and the cost of being fired is low enough. If the principal expects her orders to be ignored, she will not invest in becoming informed, and the decision is effectively delegated. In contrast, an agent whose preferred choice is different from the principal's may obey in the first period if the costs of doing so are low and the costs of being fired are high. (Then he disobeys for sure in the second period, because the principal has no recourse.) Expecting at least partial obedience, the principal may invest in becoming informed and so may hold the authority herself. Thus, external labor-market conditions and the ease of firing affect the functioning of the firm and the allocation of authority (whether the principal decides to become informed). For example, because it is easy to fire in the private sector, harder in the public sector, and virtually impossible under tenure schemes, orders are common in business and typically obeyed, they are given but often ignored in government, and nobody orders tenured faculty to do anything.¹⁹ Moreover, disobedience may occur in equilibrium (unlike in Van den Steen 2010).

18. The Aghion-Tirole model is discussed in Bolton and Dewatripont (this volume) and Gibbons et al. (this volume).

19. This observation is credited to George Shultz, former CEO of Bechtel, U.S. secretary of state, and dean of the Chicago Business School.

6.5. Influence Activities

Most of the preceding discussion has focused on the problem of inducing the agent to take actions that are costly for the agent, beneficial for the principal, and cannot be directly stipulated by contract. But there are other actions that may be almost the reverse: beneficial to the agent and costly to the principal, but still noncontractible.

Milgrom and Roberts (1988) suggested that organizational decisions often have distributional effects that are separate from their efficiency effects. For example, someone must be assigned to Paris, Texas, and someone to Paris, France. It may not matter at all to overall performance who is assigned where, but the candidates may care a lot. Each then may seek to influence the decision in his preferred direction. This effort may involve all sorts of politicking, including misrepresentation, sabotage, or side payments of various sorts. Milgrom and Roberts argued that these influence activities can be costly in several ways: resources are expended that bring no corresponding social benefits, decisions are potentially twisted, and the organization may alter its routines and processes to discourage attempts at influence.

Meyer et al. (1992) developed a model of how organizational design can reduce the incentives for influence activities. In their setting, lobbying occurs from the prospect of organizational decline. To reduce wasteful lobbying, it may be more efficient to spin off declining units.

Powell (2012) offered another formal model of these ideas, in the spirit of Holmström's (1982/1999) career-concerns model. In Powell's framework, there are two parties and two decisions. Before these decisions can be made, the parties decide who will be empowered to make each decision, but once this allocation of decision authority is set, contracting difficulties prevent renegotiation. If the other party is to make a decision, then the disempowered party may have incentives to try to affect the decision by undertaking (unobserved) influence activities that are in the spirit of signal jamming.

Given an arbitrary allocation of decision rights, Powell solved for the equilibrium level of influence. In equilibrium, the party making a decision will correctly anticipate the amount of influence the other party is undertaking and, using that correct estimate, will back out the effect of the influence and make the decision that is best for him. So the influence does not distort decisions, but it does occur and impose costs.

The optimal allocation of decision rights maximizes the sum of utilities given that the parties will choose their levels of influence in the equilibrium fashion. This may be either divided control, with each controlling one decision (which involves lower costs, because the costs of influence are convex and so it is better to have the total amount of influence split between the two parties) or unified control, with both decisions being made by the party who cares more about the outcome.

Powell then examined some suggestions made by Milgrom and Roberts (1988) for limiting influence activities and mitigating influence costs. In particular, a "closed-door" policy is modeled as unified control, with no public signal being observed (because the parties agreed not to hire the needed staff, loaded their calendars so they were too busy, and limited their meetings). This policy eliminates the disempowered party's incentive to attempt influence, but it also deprives the party in control of useful information. However, if the initial uncertainty was not great, then not a lot has been lost, and the closed-door policy may be preferred to the alternative of playing the game as originally specified.

Also, if there is a lot of disagreement about how to tailor decisions to the state of the world, then again it may become worthwhile to adopt the closed-door policy. Then a selection story like that in Figure 1 (from Section 1) applies: as disagreement increases, both the open- and closed-door policies do worse, but the closed door does relatively better at high levels of disagreement. Thus, the rigid, apparently bad management practice of limiting communication obtains when circumstances are bad, and observed firms with these practices are worse performers than those that are observed adhering to open-door policies. However, the closed-door firms perform better in the environments they inhabit than would firms with apparently “better” management practices.

7. Behavioral Economic Theories of Incentives

Most of the preceding discussion focused on egoists who find their work burdensome (at least at the margin). However, such phenomena as intrinsic motivation, altruism, reciprocity, gift exchange, status, self-image, and self-justification have figured prominently in discussions of incentives in sociology, psychology, and management. Partly in response to these ideas, an active intersection between organizational economics and behavioral economics has arisen in what might be called “behavioral incentive theory.” As an introduction to evidence on this issue, see Fehr and Falk (2002) and Bandiera et al. (2005, 2007). Recently, there is an emerging theoretical literature, including Bénabou and Tirole (2003, 2006), Besley and Ghatak (2005), Prendergast (2007), Sliwka (2007), and Ellingsen and Johannesson (2008). Here we briefly mention some highlights of this literature. See also Baron and Kreps (this volume) for discussion and references to the literatures in sociology and psychology.

7.1. Intrinsic Motivation

One of the most striking differences between standard economics and more behavioral fields involves the phenomenon of intrinsic motivation—the idea that people are inherently motivated to do a good job—and the possibility that providing explicit incentives for something may reduce intrinsic motivation enough to be counterproductive, actually reducing overall motivation. There is evidence that extrinsic incentives can reduce intrinsic motivation (see, e.g., the summary in Bénabou and Tirole 2003), but at the same time, there is also evidence on the economists’ side that extrinsic incentives can be productive (Lazear 2000). The issue is how to reconcile these observations.

The paper by Bénabou and Tirole (2003) is a notable first attempt to do so while sticking to the usual economic assumptions of rational egoistic behavior. The analysis here relies on the principal being privately informed about the difficulty of the task being set for the agent, on his productivity at the task, or the match of the two. Explicit rewards may lead the agent to infer that the principal’s information is negative. This inference may then result in reduced effort, but need not, and may have differing short- and long-run effects.

Bénabou and Tirole (2006) departed from standard models of preferences in attempting both to understand the interplay of intrinsic and extrinsic motivation and also the fact that people often appear to be motivated by how others will view them or by how their self-image will be affected. Bénabou and Tirole offered a theory that combines heterogeneity in the extent of

individuals' altruism and greed with a concern for social reputation or self-respect to investigate decisionmaking with pro- or antisocial effects. Much of their analysis is aimed at a wider social context than motivation in organizations, but parts of it are directly relevant to our concerns.

The heart of the model is that parties' actual behavior is driven by three separate motives, which Bénabou and Tirole labeled intrinsic, extrinsic, and reputational incentives. Decision-makers and others may both care about the actual mix of motives behind any decision, but the drivers of decisions are not observable, so motivation must be inferred from choices and the context.

In this framework, offering extrinsic incentives clouds inferences about the motives behind apparent good deeds: Did the good behavior arise because the party is well intentioned or even altruistic, or was it motivated by the explicit rewards? This signal-extraction problem can result in fewer good deeds when there are explicit rewards for them, and, in particular, it may be that discretely more are supplied when there is no outside reward at all. So if the culture of an organization places value on those who are motivated to act in the common good, the provision of explicit incentives may be counterproductive.

In addition, Bénabou and Tirole noted that there is a trade-off regarding making contributions memorable, as through "employee of the month" programs. Public recognition of good behavior increases the incentives for signaling by acting nicely, but it also clouds the inference because of the possibility that the action was motivated by the hope of recognition. They also note that the inferences that are drawn from a person's actions depend on others' actions, which creates spillovers and multiple equilibria corresponding to different norms of behavior, and they investigate the nature and determinants of these spillovers.

7.2. Peer Effects

That people work together, rather than as isolated individuals, potentially affects the motivation problem. For example, peer pressure, mutual monitoring, and group norms are often suggested as important determinants of behavior.

Kandel and Lazear (1992) presented a simple model of these phenomena. Output is a function F of the efforts e_i of N identical individuals, who share the output equally. Thus, for $N > 1$, there is the free-rider problem discussed in Section 2.2, because each individual gets only $1/N$ of the extra output F_i generated by extra effort but bears the entire additional costs, $C'(e_i)$. Kandel and Lazear then introduced a peer pressure function $P(e_i; e_{-i}, a_1, \dots, a_N)$, where e_{-i} is the effort level of the parties other than i , and the a_j are other actions that may effect the pressure. The payoff to i is now $F/N - C - P$. If P is decreasing in its first argument (working harder leads to less peer pressure), then the level of effort will increase, improving efficiency.

Kandel and Lazear then investigated the P function, discussing how it might arise; the roles of norms and guilt if efforts are not observable; those of mutual monitoring, shame, and social punishment if the parties can observe one another's choices; and the problems of motivating the group's members to carry out punishments if these are costly.

Recent empirical work has pointed to several other peer effects. Ichino and Maggi (2000) studied regional differences in shirking in a large Italian bank and found that these are related to peer effects: otherwise similar individuals shirk more in work environments where others are shirking more. Hamilton et al. (2003) found that some workers apparently like working in teams,

even when doing so lowers their incomes, because in the team they are linked to less-productive workers. Mas and Moretti (2009) found that supermarket workers' productivity is higher if they can be seen at work by high-productivity co-workers. Card et al. (2011) reported that learning of co-workers' pay has asymmetric effects on those above and below the group median. Lower paid workers reported lowered satisfaction with their pay and jobs and an increased likelihood of seeking a new employer, but there was no effect among those paid more than the median. Modeling such effects, particularly in a unified fashion, would be interesting.

7.3. Altruism, Fairness, Reciprocity, and Gift Exchange

Some people sometimes seem to care about the welfare of some others. People also sometimes care about whether outcomes are fair or just. The norm of reciprocity—do unto others as they have done to you—is widely documented and manifests itself, in particular, in the exchange of gifts. Here we briefly discuss some of the economic research relating to these ideas.

Rotemberg (1994) studied what might cause workers to become altruistic toward one another and whether the firm can benefit from such feelings. Rotemberg assumes that individuals are initially entirely selfish but can choose to become altruistic toward specific individuals. He argued that if different individuals' actions are strategic complements, then becoming known to be an altruist will be advantageous, because it will affect others' expectations about one's future behavior and thereby make their future behavior more favorable. Rotemberg then suggested that altruism should be expected to arise when employees work as a team and are rewarded on aggregate team output. In addition, when a group leader is charged with setting the pace of work, it is advantageous for her to be altruistic toward the workers, because they will be more trusting of her.

Building on Rotemberg (1994), Dur and Sol (2010) have explored how workers' altruistic feelings toward one another might interact with the compensation contracts optimally offered. Suppose workers care about their incomes; the costs of effort and of the time they devote to being nice to one another; and the others' welfare, provided the others have been nice to them. If pay is not purely on individual output but involves some element of either relative performance evaluation or group pay, then workers will be better off if they induce altruism toward themselves in their colleagues by being nice. When the contract has team incentives, an agent's provision of attention induces the other agent to exert more effort, which benefits the agent. Likewise, when the contract has relative incentives, the agent's provision of attention induces the other agents to exert less effort, which again benefits the first agent.

Akerlof (1982) brought economists' attention to the idea from the behavioral sciences that the employment relationship could involve a gift exchange. In particular, the firm in this context offers pay in excess of market levels, and in return the employees work at a level above that which the firm demands. Akerlof suggested this behavior arises because workers come to care for the firm as an institution, so the norm of reciprocity is activated. Presumably the same behavior would obtain if they care about their boss as an individual.

Experimental evidence lends some support to this approach. For example, Fehr et al. (1997) ran an experiment where one party, the firm, offers a wage to several potential workers, who each accept or reject it. Then one acceptor is chosen at random, and the chosen one makes a choice of costly effort from an interval $[e_L, e_H]$, where $C(e_L) = C'(e_L) = 0$, and C is strictly increasing and convex above e_L . Assume the value of effort is such that e_H maximizes the returns to effort

less its cost. The predictions of standard economic theory would be that the worker will always choose e_L , the cost minimizing effort level. Then the firm will offer a wage of zero, and all the gains from trade accrue to the firm. What happens in the laboratory, however, is that firms offer significantly positive wages, and workers respond with effort levels well above e_L . Further, wage offers and effort choices are positively correlated. More recent field observation has produced rather mixed results on gift exchange, however (see Englemaier and Leider 2011). Some of these observations can be reconciled through a field experiment conducted by Englemaier and Leider, where they observed that the worker's choice to provide more than perfunctory effort depended on whether the boss's reward was responsive to the worker's efforts. If the worker could not return the favor, then the gift wage was not offered.

Fehr and Schmidt (1999) suggested a theory of fairness that generates, inter alia, gift-exchange behavior. The essence of their theory is that the utility to an individual of an amount x when others are getting x_n , $n = 1, \dots, N$, is

$$Nx - \alpha \sum_{n=1}^N \max[x_n - x, 0] - \beta \sum_{n=1}^N \max[x - x_n, 0],$$

where $\alpha \geq \beta \geq 0$ and $0 \leq \beta \leq 1$. Thus, the individual suffers a loss of utility of α for each dollar of income anyone has in excess of what he has, and a smaller loss of β for every dollar he has more than any other person. So the individual cares about inequality, but only relative to himself.

Fehr and Schmidt (1999) then argued that a firm that offers a low wage to a person with these sorts of preferences will induce low effort, because by reducing effort, the worker can reduce the inequality between the firm's returns and his own. Note that this is not a factor in final goods markets, where buyers typically have no such recourse. Fehr and Schmidt also showed that their theory explains a variety of other findings. A notable one is why fairness seems to be a force in "divide the dollar," ultimatum games, where (contrary to the predictions of standard theory) players reject offers that they deem too low, even though they (and the player making the offer) then get zero, and yet fairness is not an issue in competitive market games where several parties compete to sell an item to a single party and the play very closely matches the competitive equilibrium where the buyer gets all the gains from trade.

8. Conclusion

We have surveyed economic theories of the basic incentive problem of getting an agent to take an unobserved, costly action from which the principal benefits. Much of this is well known among economists, but there are pieces that may be less familiar. Our intent was to provide a common source to which those reading the other chapters of this volume could refer, for the ideas in this chapter reappear throughout this volume.

Property Rights

Ilya Segal and Michael D. Whinston

1. Introduction

Every organization, whether a firm, a nonprofit organization, or a society, must confront two basic problems. The first is the creation of incentives for efficient behavior among its members. The second is the efficient allocation among those members of the resources available to and produced by the organization. These problems are closely related, because the rule for allocating resources generally affects individuals' incentives.

Organizations have many ways of trying to achieve these goals. Sometimes they use contracts. These may explicitly specify behavior or attempt to indirectly encourage desirable behavior through incentive pay. At other times they allocate decision rights to parties and leave them considerable discretion. In this chapter, we focus on one particular instrument: the allocation of property rights over assets.

The basic concept of a property right is relatively simple: A property right gives the owner of an asset the right to the use and benefits of the asset, and the right to exclude others from them. It also, typically, gives the owner the freedom to transfer these rights to others. Roman law referred to these elements as *usus* (the right to use), *abusus* (the right to encumber or transfer), and *fructus* (the right to the fruits). The American jurist Oliver Wendell Holmes put it this way:

But what are the rights of ownership? They are substantially the same as those incident to possession. Within the limits prescribed by policy, the owner is allowed to exercise his natural

We thank Robert Gibbons and John Roberts, the volume editors; Bengt Holmström; and seminar participants at Arizona State, Cambridge, Institut D'Economie Industrielle, London School of Economics, Northwestern, Oxford, University College London, a meeting of the NBER Working Group in Organizational Economics devoted to reviewing early drafts of chapters from this handbook, and the Boston University conference on "New Directions in Organization Theory" for helpful comments. Segal thanks the Toulouse Network for Information Technology and the National Science Foundation for financial support. Whinston thanks the Toulouse Network for Information Technology, the Leverhulme Trust, and the National Science Foundation for financial support as well as Nuffield College and Oxford University's Department of Economics for their hospitality.

powers over the subject matter uninterfered with, and is more or less protected in excluding other people from such interference. The owner is allowed to exclude all, and is accountable to no one but him. [Holmes 1881: 246; quoted in Grossman and Hart 1986: 694]

Thus, property rights over an asset can be defined as a bundle of decision rights involving the asset (also called “entitlements” in the legal literature), which provide rights to take certain actions (“rights of access”) and to prevent others from taking certain actions (“rights of exclusion”), including the right to take the profit generated by use of the asset and to prevent others from doing so (often called “profit rights” or “cash flow rights” in the literature).¹

This chapter surveys some theories of the optimal allocation of property rights. The problem of optimal allocation of property rights differs from the classical economic problem of optimal allocation of goods in an important way. As suggested by the above definitions, a central feature of property rights is that although they may influence economic allocations, many of the details of the allocation are left for future specification by the agents, either unilaterally or by negotiation with one another. For example, *usus* leaves it up to the owner to decide how exactly the asset should be used. *Abusus* leaves it to the owner in negotiation with other agents to decide who the asset should be transferred to and on what terms. In this sense, property rights are simple (or “incomplete”) contracts that specify some aspects of the status quo but leave discretion for economic agents to fill in the gaps. This incompleteness is, of course, inevitable in the real world, because it may be difficult to list all possible deployments of an asset in advance or all relevant variables on which the deployment should be contingent, and specifying such a contingent rule would be very costly. As a result, as Grossman and Hart (1986) note, property rights confer *residual rights of control* to the owner of an asset: the owner is entitled to the use and fruits of the asset except insofar as she has contractually agreed to limits on those rights (say, by transferring them to others).

To fix ideas and foreshadow the models discussed in this chapter, consider the following framework in which property rights may influence subsequent economic outcomes:

Stage 1. An allocation of property rights $\hat{x} \in \hat{X}$ is chosen.

Stage 2. Agents individually choose some noncontractible actions $a \in A$.

Stage 3. Uncertainty $\theta \in \Theta$ is realized.

Stage 4. Agents can renegotiate the initial property rights allocation, specifying a new outcome $x \in X$, where $\hat{X} \subseteq X$ (outcomes that are in X but not in $\hat{X}$ cannot be specified contractually ex ante, but they are contractible ex post). Should the agents not reach an

1. In practice, however, complications can arise in the notion of a property right. First, these rights of ownership are not always bundled together. Consider the following examples: (i) some stockholders of a firm may own a share of its profits but may not have the right to vote on the use of the firm's assets; (ii) an individual may possess the right to use an asset but may not have the right to exclude others from using this asset (e.g., a community garden or lake); and (iii) an owner may not possess the right to transfer ownership rights to others, as with the prohibition against slavery. In addition, property rights are in practice often held collectively. For example, no single shareholder in a firm may be able to use the firm's assets as he sees fit. Yet a majority of the shareholders, should they reach an agreement, can do so.

Table 1. Alternative assumptions about bargaining and actions

Bargaining efficiency	Noncontractible actions?	
	No	Yes
Efficient bargaining	Coasian benchmark	Section 3 (hold-up models)
No bargaining	Simple allocation benchmark	Section 2 (Tragedy of the Commons, adaptation, and incentives models)
Imperfect bargaining	Section 4 (asymmetric information or bilateral contracting)	

agreement, the initial property rights remain unchanged, so that $x = \hat{x}$.² Each agent i 's utility is $v_i(x, a, \theta) + t_i$, where t_i is a monetary transfer.³

The framework encompasses many models of property rights in the literature. These differ in which of the variables are actually present (Are there noncontractible actions a ? Are there decisions that are noncontractible ex ante but contractible ex post?) and the nature of the ex post negotiation process (Is bargaining perfectly efficient? Is it imperfect due to asymmetric information about θ or due to agreements involving only subsets of the agents?). They also differ in how property rights matter. In some models, property rights are rights to asset returns (*fructus*) that directly affect payoffs $v_i(\cdot)$ and are possibly valued differently by different agents. In others, property rights are “control rights” that determine who takes noncontractible actions (*usus*) but leave payoffs as a function of the chosen actions unchanged (e.g., all payoffs may be inalienable private benefits). To formally capture the latter case in the above framework, we can allow each agent to take the action in question but have only the action choice of the asset's owner (as determined by $\hat{x}$) matter for payoffs (see Remark 1 in Section 2.2).

Table 1 organizes these various possibilities according to whether noncontractible actions are present and to the efficiency of ex post bargaining. In the simplest settings, the effect of property rights $\hat{x}$ is simply to allocate assets to agents, who derive a direct private benefit from them, and there are neither noncontractible actions a nor ex post negotiations. In this case, an optimal property rights allocation is very simple: it gives assets to the agents who value them most in expectation. That is, $\hat{x}$ is set to maximize $E[\sum_i v_i(\hat{x}, \theta)]$. Thus, setting optimal property rights in this case is just like choosing an optimal allocation of goods in an exchange economy. (Of course, if externalities are present, so agents care about others' possession of assets in addition to their own, then this must be taken account of in determining the optimal allocation.) We call these settings cases of “simple allocation.”

The case of simple allocation, however, fails to capture property rights' role as an incomplete contract, because it does not envision any activities after the initial property rights allocation is

2. As an example, suppose the only ex ante contractible decision is the ownership of assets, denoted $z \in Z$, while ex post the parties also can contract on decisions $q \in Q$ (e.g., cooperation in the use of the assets). Then, letting $q^\circ \in Q$ denote the default that arises when no ex post agreement is reached, we have $\hat{X} = Z \times \{q^\circ\}$, while $X = Z \times Q$.

3. This framework could be enriched in many respects without altering the fundamental conclusions. For example, after stage 4 the agents may be able to choose noncontractible noncooperative actions, in which case the functions $v_i(x, a, \theta)$ incorporate Nash equilibrium choices of such actions.

specified. Of greater interest for the study of organizations are settings in which agents engage in such activities.

One simple benchmark of this type arises when all decisions can be efficiently bargained over and contractually specified *ex post*. That is, no noncontractible actions a exist, and *ex post* bargaining yields a surplus-maximizing outcome in X for every state θ . In this case, as the celebrated Coase Theorem (Coase 1960) points out, the initial specification of property rights $\hat{x}$ is irrelevant for efficiency of the final outcome, which is always first best, and affects only the distribution of the first-best surplus among the agents.⁴

In this chapter, we focus on models in which, in contrast to the Coase Theorem, the initial allocation of property rights matters, but their optimal allocation amounts to more than a case of simple allocation. In these cases, depicted in the remaining entries of Table 1, either the agents choose noncontractible actions a , or *ex post* bargaining occurs but is imperfect.

We begin in Section 2 by examining settings in which agents choose noncontractible actions a , but no bargaining occurs (see Table 1). Thus, the setting is essentially static, and an optimal property rights allocation must take account of the effect of the property rights allocation on agents' choices of noncontractible actions. Discussions of property rights in such static settings—in the guise of the famous tragedy of the commons—were the first writings in the economics literature to consider how property rights can improve economic efficiency. Static settings appear in the more recent literature in what Gibbons (2005) has called “adaptation models” of the firm (e.g., Hart and Holmström 2010; Baker et al. 2011), as well as in incentive models, such as Holmström and Milgrom (1991, 1994).⁵ We examine when (and how) the first best can be achieved in such settings, as well as the nature of distortions and second-best property rights when the first best cannot be achieved. Throughout, we emphasize the role of property rights in ameliorating inefficiencies caused by externalities.

In Section 3, we extend Section 2's model of noncontractible actions by introducing perfect *ex post* renegotiation (although some results also hold with imperfect renegotiation). In this context, the noncontractible actions are typically interpreted as long-term investments that are subject to hold-up in the subsequent bargaining. These hold-up models, whose use for examining the optimal allocation of property rights began with the seminal contribution of Grossman and Hart (1986), have been a workhorse of much of organizational economics over the past 25 years.⁶ We discuss the nature of optimal property rights in these settings, including how they depend on the nature of agents' investments, the characteristics of assets, and the form of bargaining. We show how the analysis of hold-up models can make use of the insights from

4. Note, however, that when utilities are not quasi-linear (there are wealth effects), final outcomes will typically depend on the property rights specified in stage 1. Still, the final outcome will be on the *ex post* Pareto frontier. In this chapter, we ignore wealth effects. For the role of property rights in the presence of wealth effects or credit constraints, see, for example, Legros and Newman (1996) and Segal and Whinston (2012a). Note also that in this case, initial property rights may have *ex ante* efficiency consequences due to risk-sharing considerations.

5. Gibbons uses the term “adaptation” in reference to Simon (1951), in which authority is granted *ex ante* to one individual (the “boss”) to make a decision following the resolution of some uncertainty. This fits into our framework in Section 2 by viewing that individual's action a as the choice of a decision rule describing his *ex post* action as a function of the state θ .

6. They have also been used extensively in other fields, such as industrial organization and corporate finance.

Section 2 by applying them to a new form of externalities—bargaining externalities. We also discuss the use of more complicated mechanisms than simple property rights, which relates to discussions of the foundations of incomplete contracts.

In Section 4, we suppose instead that renegotiation does occur but is imperfect. We examine two reasons for imperfect renegotiation and their implications for optimal property rights. We first suppose that θ is not public information—pieces of it are observed privately by different agents. With such asymmetric information, renegotiation may be hindered by agents' incentives to misrepresent θ , incentives that can depend on the initial property rights. We then suppose that the impediment to bargaining is that the agents cannot all get together and write a grand contract. Rather, contracting is bilateral, which can create externalities on other parties. These models can be viewed as possible formalizations of Williamson's (1971) focus on integration as a means of affecting ex post haggling costs.⁷

Our discussion of optimal property rights that follows can be viewed either as prescriptive (normative) or descriptive (positive). If perfect (coasian) bargaining regarding property rights occurs at the ex ante stage 1 (even if bargaining is imperfect at the ex post stage 4), then the parties will arrive at an optimal initial property rights allocation.⁸ However, the same factors that may cause imperfections in negotiation at the ex post stage (e.g., private information or the inability to write grand contracts) may also be present at the ex ante stage, in which case the parties may fail to achieve an optimal allocation of property rights on their own.⁹ In such cases, legal rules can improve efficiency by setting the optimal property rights allocation as the default.

Even though our chapter focuses on property rights, the variable $\hat{x}$ in our framework could in principle represent not only an allocation of property rights but also any other kind of ex ante contractible choices facing the organization. These could include, for example, the allocation of decision rights that are not linked to assets, as in Aghion et al. (2004) or Baker et al. (2008). It could also include compensation schemes, as in Holmström and Milgrom (1991, 1994). That said, the results we discuss here depend on the assumed properties of $v_i(\cdot)$, which depend on the interpretation of $\hat{x}$. For example, in the literature on hold-up models, which we discuss in Section 3, Hart and Moore (1990) assume that increases in $\hat{x}$ (greater ownership of assets) increase the marginal returns to a (investments), which is motivated by their interpretation of $\hat{x}$ as asset ownership and a as an investment in asset-specific human capital.

Finally, the scope of our discussion is limited by space considerations, and we omit a number of topics that could naturally fall within a survey of the effects of property rights on organizations. For example, in Section 2's discussion of static settings, we do not consider a set of interesting recent papers in which agents' actions include communication, and this communication affects how the holders of property or decision rights choose to exercise their rights based

7. Gibbons (2005) instead formalizes ex post haggling costs as arising from influence costs. Influence cost models are closest to the static models we consider in Section 2, although with the presence of learning and the addition of signal jamming as a noncontractible action.

8. Although, unlike in the Coase Theorem, the outcome need not be first best—it may be second best, given subsequent contracting imperfections.

9. An additional reason ex ante bargaining may be imperfect is that agents may not know who all the relevant parties are at the ex ante stage.

on their information (e.g., Aghion and Tirole 1997; Alonso et al. 2008; Rantakari 2008). We also discuss in only a limited way the interaction between property rights and other incentive instruments (e.g., Holmström and Milgrom 1991, 1994). The effects of property rights with relational contracts (as in Baker et al. 2002) are also not considered. We also do not discuss the extensive, but less formal, literature on transaction cost economics. However, these topics are covered in chapters in this volume by Bolton and Dewatripont, Gertner and Scharfstein, Gibbons and Henderson, Malcolmson, and Tadelis and Williamson.

2. Static Models of Property Rights, Externalities, and Efficiency

The importance of property rights for incentives has been recognized since at least Aristotle:

That which is common to the greatest number has the least care bestowed upon it. Everyone thinks chiefly of his own, hardly at all of the common interest; and only when he is himself concerned as an individual. [Aristotle (1885 translation), *Politics*, Book II, Chapter III, 1261b]

A popular nineteenth-century text conveyed the point as follows:

Suppose that the earth yielded spontaneously all that is now produced by cultivation; still without the institution of property it could not be enjoyed; the fruit would be gathered before it was ripe, animals killed before they came to maturity; for who would protect what was not his own . . . ? [Marcet 1819: 60–61; quoted in Baumol and Oates 1988: 28]

As these quotes suggest, the incentives created by property rights are important when behavior can generate externalities (for a more recent discussion of this point, see Demsetz 1967). When this is so, efficiency may call for allocating an asset to an individual or individuals who do not derive the greatest benefit from it, to induce desirable behavior. In this section, we explore this trade-off in a simple static setting. We first illustrate these effects in a classic model of property rights, the tragedy of the commons, and then derive some more general results about the efficiency effects of property rights. These results turn out to apply as well to a variety of dynamic settings, as we will see in Section 3.

2.1. An Example: The Tragedy of the Commons

We begin by considering the classic tragedy of the commons, updated with a modern organizational spin. Suppose there are two managers, denoted $i = 1, 2$, who each try to meet their clients' consulting needs. There is a single asset, a data center. Access to the data center enables a manager to better serve his clients. Each manager i can exert some effort to meeting client needs, denoted by $a_i \in [0, \bar{a}_i] \subseteq \mathbb{R}$. Access to the data center, determined by the specification of property rights, is captured by the variables $(\hat{x}_1, \hat{x}_2) \in \{0, 1\}^2$. Manager i has access to the data center if $\hat{x}_i = 1$, and does not if $\hat{x}_i = 0$. Private ownership gives the owner access to the data center and the ability to exclude all others from access to it, and given the negative externalities we assume below, the owner always exercises this right of exclusion. So private ownership by manager 1

results in $(\hat{x}_1, \hat{x}_2) = (1, 0)$; private ownership by manager 2 leads to $(\hat{x}_1, \hat{x}_2) = (0, 1)$. In contrast, with common ownership, both managers have the right to use the data center and neither has a right to exclude the other, so $(\hat{x}_1, \hat{x}_2) = (1, 1)$.

Given access $(\hat{x}_1, \hat{x}_2)$ and efforts (a_1, a_2) , manager i 's payoff is given by the function

$$\hat{x}_i V_i(a_i, \hat{x}_{-i} a_{-i}) - C_i(a_i),$$

where $V_i(\cdot) \geq 0$ is the gross benefit that manager i receives if he has access to the data center, and $C_i(\cdot)$ is his cost of effort, normalized so that $C_i(0) = 0$. The function $V_i(\cdot)$ is nonincreasing in its second argument, reflecting the fact that when manager $-i$ has access to the data center (so $\hat{x}_{-i} = 1$), her increased use may lower manager i 's payoff.¹⁰ We assume that these benefits are private, so that they cannot be transferred through a contract and that each manager's effort is noncontractible. Thus, ownership is the only thing that is contractible. Finally, because of the urgency of the clients' needs, access to the data center cannot be renegotiated.¹¹

Because a manager generates an externality only if he exerts effort, there is always a first-best outcome in which both managers have access to the data center. Indeed, if $V_i(0, a_{-i}) > 0$ for all a_{-i} and $i = 1, 2$, using the data center without effort generates a strictly positive payoff for a manager regardless of the other manager's level of effort, which implies that all first-best outcomes involve giving both managers access. When benefits and costs are differentiable, (interior) efficient effort levels (a_1^*, a_2^*) then satisfy $\partial V_i(a_i^*, a_{-i}^*)/\partial a_i + \partial V_{-i}(a_{-i}^*, a_i^*)/\partial a_i = C_i'(a_i^*)$ for $i = 1, 2$. In contrast, (interior) equilibrium effort levels with common ownership (a_1°, a_2°) satisfy $\partial V_i(a_i^\circ, a_{-i}^\circ)/\partial a_i = C_i'(a_i^\circ)$ for $i = 1, 2$, because the managers ignore the external effects of their actions. If $V_i(\cdot)$ is independent of a_{-i} for $i = 1, 2$, so that externalities are absent, the equilibrium is efficient. This would be the case if there were no congestion (e.g., a large enough data center). But if $\partial V_{-i}(\cdot)/\partial a_i < 0$, then any interior equilibrium is inefficient.

In some cases, there is also a first-best outcome in which only one manager has access to the data center. This occurs, for example, when $a_2^* = 0$ and $V_2(0, a_1) = 0$ for all a_1 . This case can arise when manager 2's cost of effort is very high and she derives no benefits from the data center without exerting effort. Because there are no externalities under private ownership, private ownership by manager 1 then achieves the first best.

Which property rights allocation maximizes aggregate surplus when the first best requires giving access to both managers, but externalities are present? In that case, the optimal (second-best) property rights allocation involves a trade-off: common ownership allows both managers to benefit from the data center but introduces externalities, while private ownership denies the benefit to one manager but avoids externalities. As an illustration, consider a situation with symmetric managers, where $V_i(a_i, \hat{x}_{-i} a_{-i}) = v(a_i) - e(\hat{x}_{-i} a_{-i})$ with $e(0) = 0$, and

10. Note that $V_i(0, a_{-i})$ may be positive and that the externality arises in this example only from manager $-i$'s effort, not her access per se. We can imagine that certain low-urgency uses of the data center, such as billing, are not generated by managerial effort, create no externalities, and provide a benefit for serving clients that is independent of congestion effects. In contrast, urgent uses are generated by a manager's effort and both create and are subject to congestion externalities.

11. A manager's value of access could be uncertain ex ante. Because we assume that the urgency of the tasks precludes renegotiation of access ex post, we can think of V_i as manager i 's expected payoff.

$C_i(a_i) = c(a_i)$ for $i = 1, 2$. In that case, common ownership is optimal if and only if $v(a^\circ) - c(a^\circ) \geq 2e(a^\circ)$, that is, if the direct benefit of granting a second manager access exceeds the externalities that this access creates.

2.2. A General Static Model

We now consider what can be said more generally about the optimal allocation of property rights in a static setting.¹² Suppose there is a set N of N agents, each of whom chooses an action $a_i \in A_i$. The profile of actions is $a = (a_1, \dots, a_N) \in A = \prod_i A_i$. Before actions are chosen, a property rights allocation $\hat{x} \in \hat{X}$ is specified (e.g., $\hat{x}$ may be a vector of zeros and ones, indicating, for each asset and individual, whether the individual has access to the asset). Agent i has quasi-linear utility of the form $U_i(\hat{x}, a) + t_i$.¹³

The aggregate surplus given property rights $\hat{x}$ and action profile a is therefore $S(\hat{x}, a) = \sum_i U_i(\hat{x}, a)$, and the first-best outcomes are denoted

$$O^* = \arg \max_{\hat{x} \in \hat{X}, a \in A} S(\hat{x}, a).$$

It is also useful to define the efficient actions given some fixed property rights $\hat{x} \in \hat{X}$ as $A^*(\hat{x}) = \arg \max_{a \in A} S(\hat{x}, a)$ and the efficient allocation of property rights given some fixed actions $a \in A$ as $\hat{X}^*(a) = \arg \max_{\hat{x} \in \hat{X}} S(\hat{x}, a)$. If actions were fixed at a , so that incentive effects were not an issue, the optimal property rights would be an element of $\hat{X}^*(a)$, reflecting the principle that the individual or individuals who most value access to an asset should have it. We also let $\hat{X}^* = \left\{ \hat{x} \in \hat{X} : (\hat{x}, a) \in O^* \text{ for some } a \in A \right\}$ be the property rights allocations that can arise in a first-best outcome.

Given an allocation of property rights $\hat{x}$, the agents choose their actions noncooperatively to maximize their individual payoffs. The resulting Nash equilibrium set is

$$A^\circ(\hat{x}) = \left\{ a \in A : a_i \in \arg \max_{a'_i \in A_i} U_i(\hat{x}, a'_i, a_{-i}) \quad \text{for all } i \right\}. \quad (1)$$

We will be interested in studying the second-best optimal assignment of property rights, which takes into account not only the property rights' direct effect on payoffs but also their effect on agents' actions.

Remark 1 In some cases property rights specify control rights, which give agents the rights to take certain actions. As mentioned in Section 1, the model can formally capture these cases in the following way. Suppose there are K actions to be chosen: $\alpha = (\alpha_1, \dots, \alpha_K)$, where

12. The model we examine here is a version of the model studied in Segal and Whinston (2012a), specialized to transferable utilities and (later) to one-dimensional actions.

13. In terms of the framework in Section 1, the important assumption here is that there is no bargaining in stage 4. Although, strictly speaking, the model introduced here has no uncertainty θ , we can think of the functions $U_i(\cdot)$ as specifying expected payoffs (averaging over realizations of θ).

$\alpha_k \in \mathcal{A}_k$ for each $k = 1, \dots, K$, which result in payoffs $\mathcal{U}_i(\hat{x}, \alpha)$ to each agent i . A property rights allocation specifies $\hat{x}_{ik} \in \{0, 1\}$ for each agent i and each action k , with $\hat{x}_{ik} = 1$ when agent i has the right to choose action k , and $\sum_i \hat{x}_{ik} = 1$ for each k . To incorporate this setting in our general framework, we endow all agents i with the same action set $A_i = \prod_{k \in K} \mathcal{A}_k$ and let $a_i = (a_{i1}, \dots, a_{iK}) \in A_i$ describe the agent's plan for all the actions, with the actual implemented actions being $\alpha(\hat{x}, a) = (\sum_i \hat{x}_{ik} a_{ik})_{k=1}^K$. The resulting payoffs take the form $U_i(\hat{x}, a) = \mathcal{U}_i(\hat{x}, \alpha(\hat{x}, a))$. When property rights do not affect these payoffs directly but only through implemented actions α [i.e., when we can write $U_i(\hat{x}, a) = \mathcal{U}_i(\alpha(\hat{x}, a))$], we will call them "pure control rights."

The model includes the tragedy of the commons as a special case. The following two examples, drawn from the recent literature, also illustrate the model. In the first, property rights affect only payoffs. In the second, property rights affect not only payoffs but also who takes certain actions, as in Remark 1.

Example 1 (agency model) Consider a principal-agent setting in which two individuals pursue a project. Individual P is the principal and takes no actions, while individual A is the agent and has a noncontractible action choice $a \in A$. As in Demski and Sappington (1991) and Holmström and Milgrom (1991), there is an indivisible asset that may be owned by either the principal or the agent, and we let $\hat{x} \in \{0, 1\}$ denote the agent's ownership share. We let $V_i(a)$ denote the asset's value to individual i , for $i = A, P$. The project also generates inalienable returns to the principal equal to $Y(a)$, while the agent's private cost of taking action a is $C(a)$. (This private "cost" may include private benefits as well as costs and so may be negative.) In some applications the agent's actions move Y and each V_i in the same direction (e.g., Y and V_i are the project's current and future profits, respectively, both of which are enhanced by greater agent effort); in other cases they move in opposite directions (e.g., increasing current project returns depletes the asset). Because these returns are private, ownership of the asset is the only thing that is contractible and is the only mechanism for providing incentives.¹⁴ The principal's payoff is

$$U_P(\hat{x}, a) = Y(a) + (1 - \hat{x})V_P(a),$$

while the agent's is

$$U_A(\hat{x}, a) = \hat{x}V_A(a) - C(a).$$

In one well-studied case, the parties' different values for the asset are attributed entirely to their differing risk aversion and the randomness of the asset's returns. Namely, if individual i has constant absolute risk aversion with coefficient $r_i \geq 0$, and the asset's returns are normally

14. In Holmström and Milgrom (1991), returns $Y(a)$ are also verifiable, so incentive schemes can be based on them as well.

distributed with mean $\mu(a)$ and variance $\sigma^2(a)$, then her certainty equivalent asset value equals $V_i(a) = \mu(a) - \frac{1}{2}r_i\sigma^2(a)$.¹⁵

In this example, efficiency calls for the individual i with the higher value $V_i(a)$ to own the asset. However, note that incentive effects may call for a different asset ownership $\hat{x}$, because ownership may affect the agent's action: $A^\circ(\hat{x}) = \arg \max_{a \in A} [\hat{x} V_A(a) - C(a)]$.

Example 2 (coordination model of firm scope) This example is based on Hart and Holmström (2010). In this setting, property rights allocate control rights as in Remark 1 but also affect payoffs directly. For each of two production units indexed by k an action in $\{0, 1\}$ is to be chosen, with action 1 being the “coordination” action and action 0 being the “noncoordination” action. There are three agents and two possible property rights considered: nonintegration, in which the action for each unit $k = 1, 2$ is chosen by agent $k = 1, 2$ (the unit's manager-owner), and integration, in which both actions are chosen by agent 3 (the owner of the integrated firm). If the coordination action is chosen for both units, the coordinated outcome $c = 1$ results, and otherwise the noncoordinated outcome $c = 0$ results.

To fit this setting into the general framework, as in Remark 1, we let the action set of manager 3 be $A_3 = \{0, 1\}^2$, where $a_{3k} \in \{0, 1\}$ is her planned action for unit $k = 1, 2$, and let the action set for each agent $i = 1, 2$ be $A_i = \{0, 1\}$, with $a_i \in \{0, 1\}$ being his planned action for his unit i . Letting $\hat{x} \in \{0, 1\}$, where $\hat{x} = 1$ stands for integration and $\hat{x} = 0$ for nonintegration, the resulting outcome is $c(\hat{x}, a) = (1 - \hat{x}) a_1 a_2 + \hat{x} a_{31} a_{32}$.

Hart and Holmström (2010) assume that in addition to control rights over unit k , its owner receives its alienable profit flows $v_k(c)$. In addition, each unit manager $i = 1, 2$ receives private benefits $w_i(c)$ from his unit. Coordination is assumed to reduce the unit managers' private benefits, so $w_i(1) \leq w_i(0)$ for $i = 1, 2$. These assumptions yield the following payoffs:

$$U_i(\hat{x}, a) = (1 - \hat{x}) v_i(c(\hat{x}, a)) + w_i(c(\hat{x}, a)) \quad \text{for } i = 1, 2,$$

$$U_3(\hat{x}, a) = \hat{x} [v_1(c(\hat{x}, a)) + v_2(c(\hat{x}, a))].$$

The total surplus in this setting is

$$S(\hat{x}, a) = v_1(c(\hat{x}, a)) + v_2(c(\hat{x}, a)) + w_1(c(\hat{x}, a)) + w_2(c(\hat{x}, a)).$$

Note that because property rights here allocate control rights and cash rights that are valued equally by all agents, their effect on the total surplus is entirely through the implemented actions.¹⁶

15. Many papers study the case with risk aversion in which the asset is divisible, so that $\hat{x} \in [0, 1]$. Then fractional ownership is typically optimal, with $\hat{x}$ interpreted as the strength of the agent's incentives. Although our analysis extends straightforwardly to this case, for simplicity, we restrict attention to an indivisible asset.

16. Unlike in our discussion, Hart and Holmström (2010) assume that an agent i may feel “aggrieved” when he gets less than his maximal possible payoff, and that such aggrievement causes agent i to lower agent j 's payoff through “shading,” which induces a loss for agent j proportional to the level of aggrievement. Under non-integration, for example, the payoff for each manager $i = 1, 2$ is then $\hat{U}_i(0, a) = U_i(0, a) - \theta[\max_{\hat{a}} U_{-i}(0, \hat{a}) - U_{-i}(0, a)] = U_i(0, a) + \theta U_{-i}(0, a) - \theta \max_{\hat{a}} U_{-i}(0, \hat{a})$ for some $\theta > 0$.

Examples 1 and 2 illustrate what might be called cases of “pure cash rights” and “pure control rights.” Pure cash rights allocate the benefits of an asset valued identically by all agents. Pure control rights, as defined in Remark 1, alter who takes actions without changing agents’ payoffs conditional on the implemented actions. In Example 1, property rights are pure cash rights when the two agents have equal values for the asset ($V_A(a) = V_P(a)$ for all a). In Example 2, property rights are a hybrid of pure cash rights and pure control rights. Note that in cases of pure cash rights and pure control rights, the first best can be achieved for any property rights allocation provided that the appropriate actions are implemented: formally, $\hat{X}^* = \hat{X}$. In fact, for pure cash rights, $\hat{X}^*(a) = \hat{X}$ for all $a \in A$, whereas for pure control rights, this is true for all $a \in A$ in which all agents specify the same plan for each action. These properties play a role in some of our characterizations of optimal property rights.

2.3. Achieving Efficiency

We begin with a result identifying conditions under which a first-best outcome can be achieved. The basic idea is that efficiency can be sustained in equilibrium if there is a first-best outcome without harmful externalities.

Definition 1 *There are no harmful externalities at $(\hat{x}, a) \in \hat{X} \times A$ if*

$$U_i(\hat{x}, a) \leq U_i(\hat{x}, a_i, a'_{-i}) \quad \text{for all } i \text{ and all } a'_{-i}.$$

Proposition 1 *If there are no harmful externalities at some first-best outcome $(\hat{x}^*, a^*) \in O^*$, then $a^* \in A^\circ(\hat{x}^*) \subseteq A^*(\hat{x}^*)$; that is, given property rights $\hat{x}^*$, action profile a^* is sustained in a Nash equilibrium, and every Nash equilibrium action profile a° is efficient (and thus $(\hat{x}^*, a^\circ) \in O^*$).¹⁷*

Proof For all j and $a_j \in A_j$,

$$\begin{aligned} U_j(\hat{x}^*, a^*) &= S(\hat{x}^*, a^*) - \sum_{i \neq j} U_i(\hat{x}^*, a^*) \\ &\geq S(\hat{x}^*, a_j, a_{-j}^*) - \sum_{i \neq j} U_i(\hat{x}^*, a_j, a_{-j}^*) \\ &= U_j(\hat{x}^*, a_j, a_{-j}^*), \end{aligned}$$

where the inequality holds because $a^* \in A^*(\hat{x}^*)$ and any externalities are nonharmful. Hence, $a^* \in A^\circ(\hat{x}^*)$.

17. It is clear from the proof that for the first result ($a^* \in A^\circ(\hat{x})$), the nonharmful externalities assumption can be weakened to requiring that for each j and a_j , $\sum_{i \neq j} U_i(\hat{x}^*, a_j, a_{-j}^*) \geq \sum_{i \neq j} U_i(\hat{x}^*, a^*)$ (i.e., that unilateral deviations have no harmful externalities on the aggregate payoff of the other agents).

Next, for any $a^\circ \in A^\circ(\hat{x}^*)$,

$$U_i(\hat{x}^*, a^\circ) \geq U_i(\hat{x}^*, a_i^*, a_{-i}^\circ) \geq U_i(\hat{x}^*, a^*) \quad \text{for each agent } i, \quad (2)$$

where the first inequality follows from Nash equilibrium and the second inequality from non-harmful externalities at $(\hat{x}^*, a^*)$. Summing over agents yields $\sum_i U_i(\hat{x}^*, a^\circ) \geq S(\hat{x}^*, a^*)$. Because the reverse inequality also holds due to $(\hat{x}^*, a^*) \in O^*$, we have $\sum_i U_i(\hat{x}^*, a^\circ) = S(\hat{x}^*, a^*)$, so $a^\circ \in A^*(\hat{x}^*)$.

Consistent with this result, recall that in our tragedy of the commons example, common ownership is efficient if, because the data center capacity is large, congestion externalities are absent. Similarly, when there is a first-best outcome involving private ownership (so that only one manager has access to the data center), private ownership—which involves no externalities—leads to a first-best outcome.¹⁸ In the agency model (Example 1) when $Y(a) = 0$ and $V_A(a) \geq V_P(a)$ for all a , there is a first-best outcome with no externalities in which the asset is owned by the agent. For example, this case applies to the classical incentive model when the agent is risk neutral, because selling the asset to her achieves optimal risk sharing and at the same time lets the agent internalize any externalities from her actions. Proposition 1 tells us that agent ownership sustains the first best in such cases.

Recall that when property rights consist of pure control rights and/or pure cash rights, we have $\hat{X}^* = \hat{X}$ (i.e., any property rights allocation can arise in the first best). (This property will also hold in dynamic settings considered in the next section in which any property rights allocation is renegotiated toward an ex post efficient allocation after actions are chosen.) For such cases, Proposition 1 establishes that any property rights allocation $\hat{x} \in \hat{X}$ such that there are no harmful externalities at $(\hat{x}, a^*)$ for some $a^* \in A^*(\hat{x})$ ensures that a first-best outcome results. For example, if property rights allocate pure cash flows and pure control rights, and their transfer to a single owner eliminates all externalities—as in the traditional view of vertical integration—it yields the first best. More generally, it suffices to eliminate only harmful externalities. For instance, in the coordination model of firm scope (Example 2), integration eliminates harmful externalities at coordinated actions, as the owner's deviation would raise the managers' private benefits. In contrast, nonintegration eliminates externalities at noncoordinated actions, as a change in just one manager's action then has no effect on the outcome. So, Proposition 1 tells us that the first best is sustained by integration when coordination is efficient and by nonintegration when noncoordination is efficient.

2.4. Externalities and Distortions

When harmful externalities are instead present at all first-best outcomes, efficiency typically cannot be achieved. As intuition suggests, equilibrium actions will be distorted in directions that generate harmful externalities. We now formalize this point, focusing for simplicity on the case in which each action space A_i is a subset of the real line $\mathbb{R}$. (A more general case, where

18. Note also that, according to Proposition 1, in both of these cases efficiency would be preserved if, in addition, the individuals could take actions (make “investments”) that enhanced their own value from using the data center or reduced their cost of effort, as such actions generate no externalities.

action spaces could be multidimensional, is treated in Segal and Whinston 2012a.) For this purpose, consider the following definition.

Definition 2 *Actions generate positive (negative) externalities at $\hat{x}$ if, for all i , all $j \neq i$, and all $a_{-i} \in A_{-i}$, $U_j(\hat{x}, a)$ is nondecreasing (nonincreasing) in a_i .*

First we show that if a single agent has a one-dimensional action choice that generates positive (negative) externalities, in equilibrium he will choose an action that is too low (high) relative to the efficient level.

Proposition 2 *Suppose that only agent i takes actions, and his action generates positive (negative) externalities at $\hat{x}$. Then $A^\circ(\hat{x})$ is below (above) $A^*(\hat{x})$ in the strong set order.¹⁹*

Proof Consider the case of positive externalities. Define the function

$$\Psi_i(\hat{x}, a, \lambda) = U_i(\hat{x}, a) + \lambda \sum_{j \neq i} U_j(\hat{x}, a) = (1 - \lambda)U_i(\hat{x}, a) + \lambda S(\hat{x}, a), \quad (3)$$

where $\lambda \in [0, 1]$. Observe that $A^*(\hat{x}) = \arg \max_{a \in A} \Psi_i(\hat{x}, a, 1)$ and $A^\circ(\hat{x}) = \arg \max_{a \in A} \Psi_i(\hat{x}, a, 0)$. Positive externalities imply that the function $\Psi_i(\cdot)$ has increasing differences in (a, λ) .²⁰ The result follows by Topkis's Monotonicity Theorem (see Milgrom and Roberts 1990). The result for negative externalities follows similarly.

As an illustration, in the agency model (Example 1), if both $Y(a)$ and $Y(a) + V_P(a)$ are nondecreasing in a (greater effort raises Y by more than any asset value deterioration for the principal), Proposition 2 tells us that the agent's choice of a will be weakly too low (in the strong set order) under any ownership structure.

The result also implies that when many agents choose actions, the equilibrium level of any action that generates positive (negative) externalities will be too low (high), holding fixed all other actions. To get a result comparing the entire equilibrium action profile with the first-best action profile, we need to make assumptions on the interactions among different actions, so that we can apply the theory of supermodular games (Milgrom and Roberts 1990).

Definition 3 *Actions are strategic complements at property rights allocation $\hat{x}$ if, for each i , A_i is a compact subset of $\mathbb{R}$, and $U_i(\hat{x}, a_i, a_{-i})$ is continuous in a and has increasing differences in (a_i, a_{-i}) .*

19. For two sets $A, B \subseteq \mathbb{R}$, A is below B in the strong set order if for all $a \in A \setminus B, b \in B \setminus A$, and $c \in A \cap B$, we have $a \leq c \leq b$.

If we know that the action has strictly positive (negative) externalities at $\hat{x}$, in the sense that $U_j(\hat{x}, a)$ is strictly increasing (decreasing) in a_i for all $j \neq i$ and all $a_{-i} \in A_{-i}$, then we can obtain the stronger conclusion that every element of $A^\circ(\hat{x})$ is below (above) every element of $A^*(\hat{x})$ by using the Monotone Selection Theorem of Milgrom and Shannon (1994).

20. A function $f(x, y, z)$ has increasing differences in (x, y) if

$$f(x', y', z) - f(x, y', z) \geq f(x', y, z) - f(x, y, z)$$

for all $(x', y') \geq (x, y)$. See Milgrom and Roberts (1990).

Proposition 3 Suppose that at a given property rights allocation $\hat{x} \in \hat{X}$, actions are strategic complements and generate positive (negative) externalities. Then $A^\circ(\hat{x})$ is below (above) $A^*(\hat{x})$ in the weak set order.²¹

Remark 2 By Milgrom and Roberts (1990), the Nash equilibrium set $A^\circ(\hat{x})$ in a game with strategic complements is nonempty and contains the largest and smallest equilibria $\bar{a}^\circ(\hat{x})$ and $\underline{a}^\circ(\hat{x})$, respectively. Thus, the proposition's conclusion is equivalent to saying that with positive (negative) externalities, $\underline{a}^\circ(\hat{x}) \leq a^*$ ($\bar{a}^\circ(\hat{x}) \geq a^*$) for all $a^* \in A^*(\hat{x})$ and $\bar{a}^\circ(\hat{x}) \leq a^*$ ($\underline{a}^\circ(\hat{x}) \geq a^*$) for some $a^* \in A^*(\hat{x})$.²² In the special case in which $A^*(\hat{x})$ contains a unique action profile a^* , Proposition 3 establishes that a^* is above the largest Nash equilibrium $\bar{a}^\circ(\hat{x})$ (below the lowest Nash equilibrium $\underline{a}^\circ(\hat{x})$).

Proof Consider the case of positive externalities (the case of negative externalities is symmetric). Take any $a^\circ \in A^\circ(\hat{x})$ and any $a^* \in A^*(\hat{x})$. (Both $A^\circ(\hat{x})$ and $A^*(\hat{x})$ are nonempty under our assumptions.) For the weak set order comparison, we must establish that (i) there exists $\bar{a} \in A^*(\hat{x})$ such that $\bar{a} \geq a^\circ$, and (ii) there exists $\underline{a} \in A^\circ(\hat{x})$ such that $\underline{a} \leq a^*$.

For part (i), we take $\bar{a}_i = \max \{a_i^*, a_i^\circ\}$ for each i and show that $U_i(\hat{x}, \bar{a}) \geq U_i(\hat{x}, a^*)$ for each agent i . We do this by moving from a^* to $\bar{a}$ in two steps and showing that agent i cannot become worse off at either step. In the first step, we hold agent i 's action fixed at a_i^* and increase the other agents' actions from a_{-i}^* to $\bar{a}_{-i}$. This increase can only benefit agent i due to positive externalities. In the second step, if $a_i^\circ > a_i^*$, we increase agent i 's action from a_i^* to $\bar{a}_i = a_i^\circ$ (otherwise, $\bar{a}_i = a_i^*$, and we do nothing). Note that this increase cannot harm agent i if all the others played a_{-i}° (because $a^\circ \in A^\circ(\hat{x})$), so by strategic complementarity it also cannot harm agent i if the others play $\bar{a}_{-i} \geq a_{-i}^\circ$. Formally, we have

$$U_i(\hat{x}, a_i^\circ, \bar{a}_{-i}) - U_i(\hat{x}, a_i^*, \bar{a}_{-i}) \geq U_i(\hat{x}, a_i^\circ, a_{-i}^\circ) - U_i(\hat{x}, a_i^*, a_{-i}^\circ) \geq 0. \quad (4)$$

Thus, the second step does not reduce agent i 's payoff either. Therefore, we have $U_i(\hat{x}, \bar{a}) \geq U_i(\hat{x}, a^*)$ for all agents i , and therefore $S(\hat{x}, \bar{a}) \geq S(\hat{x}, a^*)$. Because $a^* \in A^*(\hat{x})$, it follows that $\bar{a} \in A^*(\hat{x})$, which establishes (i), since $\bar{a} \geq a^\circ$.

To establish (ii), we observe that none of the inequalities in (4) can be strict, for otherwise we would obtain $S(\hat{x}, \bar{a}) > S(\hat{x}, a^*)$, contradicting $a^* \in A^*(\hat{x})$. Thus, when $a_i^\circ > a_i^*$, strategy a_i^* must be (along with strategy a_i°) agent i 's best response to a_{-i}° and is therefore a rationalizable strategy. Thus, the strategy $\hat{a}_i = \min \{a_i^*, a_i^\circ\}$ is rationalizable for each i , and by Milgrom and Roberts (1990: Theorem 5), the smallest Nash equilibrium $\underline{a}^\circ(\hat{x}) \in A^\circ(\hat{x})$ has $\underline{a}^\circ(\hat{x}) \leq \hat{a} \leq a^*$.

The result implies, for instance, that efforts are weakly too high (in the weak set order) under common ownership in the tragedy of the commons example when each function $V_i(\cdot)$

21. For nonempty sets $A, B \subseteq \mathbb{R}^N$, A is below B in the weak set order if for all $a \in A$ there exists $b \in B$ such that $a \leq b$, and for all $b \in B$ there exists $a \in A$ such that $a \leq b$.

22. Furthermore, with positive (negative) externalities, $\bar{a}^\circ(\hat{x})$ ($\underline{a}^\circ(\hat{x})$) is the agents' Pareto optimal Nash equilibrium, and it is a unique Pareto optimal Nash equilibrium up to payoff equivalence.

has increasing differences in its two arguments. In the coordination model of firm scope example (Example 2), it implies that coordination is weakly too low under nonintegration when $v_i(1) + w_i(1) \geq v_i(0) + w_i(0)$ for $i = 1, 2$, so that externalities are positive (of course, this result is immediate in any case).

Finally, Propositions 2 and 3 do not rule out the possibility that an equilibrium action profile could be efficient. However, if payoff functions are differentiable and the marginal externalities are strict, using the approach of Edlin and Shannon (1998), it can be shown that there is necessarily inefficiency.

2.5. Second-Best Property Rights Allocations

When there are unavoidable externalities and therefore inefficiency, what can be said about the welfare effect of the property rights allocation, and about optimal (second-best) property rights allocations? We define second-best outcomes as optimal outcomes subject to the constraint that agents choose their actions noncooperatively:²³

$$O^{**} = \arg \max_{\hat{x} \in \hat{X}, a \in A^{\circ}(\hat{x})} S(\hat{x}, a).$$

We also let $\hat{X}^{**} = \{\hat{x} \in \hat{X} : (\hat{x}, a) \in O^{**} \text{ for some } a \in A\}$ be the property rights allocations that can arise in a second-best outcome.

We first observe that because actions are too low (high) with positive (negative) externalities, any change in property rights that is both directly beneficial and encourages (discourages) those actions is welfare enhancing.

Lemma 1 *Consider two property rights allocations $\hat{x}$ and $\hat{x}'$ and a pair of Nash equilibria resulting from these property rights allocations, $a \in A^{\circ}(\hat{x})$ and $a' \in A^{\circ}(\hat{x}')$. If actions generate positive (negative) externalities at $\hat{x}'$, $S(\hat{x}', a) \geq S(\hat{x}, a)$, and $a' \geq a$ ($a' \leq a$), then $S(\hat{x}', a') \geq S(\hat{x}, a)$.*

Proof Note that

$$S(\hat{x}', a') - S(\hat{x}, a) \geq S(\hat{x}', a') - S(\hat{x}', a) \geq \sum_i \left[U_i(\hat{x}', a_i, a'_{-i}) - U_i(\hat{x}', a) \right] \geq 0,$$

where the first inequality is due to $S(\hat{x}', a) \geq S(\hat{x}, a)$, the second is due to $a' \in A^{\circ}(\hat{x}')$, and the third is due to positive (negative) externalities at $\hat{x}'$ and $a' \geq a$ ($a' \leq a$).

Lemma 1 considers property rights changes that increase the ex post surplus holding actions fixed, and also lead to surplus-enhancing behavioral changes. Such changes involve no trade-

23. This definition makes the optimistic assumption that if a property rights allocation induces multiple Nash equilibria, the agents coordinate on a surplus-maximizing Nash equilibrium. Note that if arbitrary equilibrium selections were allowed, agents may switch between equilibria arbitrarily, depending on property rights, even when property rights are not payoff relevant, which could alter the effects of property rights. However, Proposition 4 could be reformulated under the alternative assumption that the worst equilibrium is always selected—a case examined, for example, by Mookherjee (1984).

offs. In general, the optimal (second-best) property rights allocation will trade off these two effects. Our next result shows that a second-best property rights allocation is distorted away from what would be efficient ex post given the actions individuals take, and this distortion is in the direction that increases (reduces) incentives for actions with positive (negative) externalities. For simplicity, we formulate the result for the case in which the property rights allocation is one dimensional. This result will be applied later to cases with multidimensional property rights (e.g., specifying different agents' access to different assets) by varying one of these dimensions at a time.

Proposition 4 *Suppose that $\hat{X} \subseteq \mathbb{R}$, that $U_i(\hat{x}, a_i, a_{-i})$ has increasing differences in $(\hat{x}, a_i)$ for all i , and that actions are strategic complements at all property rights allocations. Take any second-best outcome $(\hat{x}^{**}, a^{**}) \in O^{**}$ and any ex post efficient allocation given actions a^{**} , $\hat{x}' \in \hat{X}^*(a^{**})$. If actions generate positive (negative) externalities at $\hat{x}'$, then either $\hat{x}^{**} > \hat{x}'$ ($\hat{x}^{**} < \hat{x}'$) or $\hat{x}' \in \hat{X}^{**}$.*

Remark 3 In the simple case in which there is a unique second-best outcome, that is, $O^{**} = \{(\hat{x}^{**}, a^{**})\}$, and actions generate positive (negative) externalities at all $\hat{x}$, Proposition 4 implies that $\hat{x}^{**}$ is weakly higher (lower) than any ex post efficient allocation $\hat{x}' \in \hat{X}^*(a^{**})$ given actions a^{**} .

Proof Suppose that actions generate positive externalities at $\hat{x}'$, and let $\hat{x}' > \hat{x}^{**}$ (with the reverse inequality, the conclusion is trivial since either $\hat{x}^{**} > \hat{x}'$ or $\hat{x}' = \hat{x}^{**} \in \hat{X}^{**}$). Under the hypotheses of the proposition, Theorems 5 and 6 in Milgrom and Roberts (1990) imply that given the property rights allocation $\hat{x}'$ there is a largest Nash equilibrium action profile $a' = \max A^\circ(\hat{x}')$, and $a' \geq a^{**}$. Because $\hat{x}' \in \hat{X}^*(a^{**})$ implies that $S(\hat{x}', a^{**}) \geq S(\hat{x}^{**}, a^{**})$, we can apply Lemma 1 to see that $S(\hat{x}', a') \geq S(\hat{x}^{**}, a^{**})$, so $\hat{x}' \in \hat{X}^{**}$. The proof for the case of negative externalities is similar.

As an illustration, consider again the agency model (Example 1) with $a \in \mathbb{R}$ and $Y(a)$, $Y(a) + V_P(a)$, and $V_A(a)$ all nondecreasing in a . Then externalities are positive for any ownership share $\hat{x}$, and the agent's payoff has increasing differences in $(\hat{x}, a)$. Proposition 4 tells us that the second-best property rights allocation in that case will be distorted toward agent ownership of the asset: in particular, she may be the optimal owner even if she values the asset less than the principal given her equilibrium action (e.g., due to being more risk averse than the principal).

An interesting special case arises when the maximal (minimal) property rights allocation is efficient for all investments. In this case, applying Proposition 4 to $\hat{x}' = \max \hat{X}$ ($\hat{x}' = \min \hat{X}$) yields the following.

Corollary 1 *Suppose that, in addition to the assumptions in the first sentence of Proposition 4, the maximal (minimal) property rights allocation is in $\hat{X}^*(a)$ for all $a \in A$, and actions generate positive (negative) externalities at this allocation. Then this allocation lies in the set $\hat{X}^{**}$ of second-best optimal property rights allocations, provided that the set is nonempty.*

For an illustration, take the agency model of Example 1 with $A \subseteq \mathbb{R}$ and $V'_A(a) > 0$ (so the increasing differences and strategic complementarity assumptions of Proposition 4 hold). Then, if agent ownership is optimal for any given action a (i.e., $V_A(a) \geq V_P(a)$ for any a), and we have positive externalities at that ownership allocation (i.e., $Y'(a) > 0$), by Corollary 1 agent ownership is a second-best optimal property rights allocation (provided that one exists). Similarly, if principal ownership is optimal for any action a (i.e., $V_A(a) \leq V_P(a)$ for all a), and we have negative externalities at that ownership allocation (i.e., $Y'(a) + V'_P(a) \leq 0$; e.g., agent effort may increase asset value but reduce the principal's current profit $Y(a)$ by more), then by Corollary 1 it is a second-best optimal property rights allocation (provided that one exists).

An important application of the Corollary is to the case in which the allocation of property rights has no direct efficiency consequences given the agents' actions, that is, $\hat{X}^*(a) = \hat{X}$ for all a . (Recall that this condition arises for pure cash flow rights. In the dynamic setting considered in the next section, this condition arises as a natural consequence of efficient renegotiation.) For this case, Corollary 1 says that the maximal (minimal) property rights allocation is optimal when the assumptions of Proposition 4 hold and actions generate positive (negative) externalities at this allocation.²⁴

3. Property Rights and Investment Hold-Up

In the previous section, property rights affected efficiency directly as well as through incentives to take noncontractible actions. However, in a longer term context, after noncontractible actions are taken, the parties may be able to renegotiate property rights that are ex post inefficient. For example, although giving an agent property rights over an asset may be optimal to increase his incentives for noncontractible investment, if he is not the efficient ex post owner, he may resell the asset to whomever is. Such renegotiation improves ex post efficiency, but it also introduces a new source of externalities, which may distort investments. These "bargaining externalities" arise because an individual's noncontractible actions may affect the surplus created by renegotiation, which is shared in bargaining with other individuals.

Example 3 Consider again the agency model of Example 1. Now, however, assume that as in Demski and Sappington (1991) and Hermalin and Katz (1991), after the agent chooses action $a \in A \subseteq \mathbb{R}$ (interpreted now as an investment), the parties can renegotiate the allocation of the asset to some other allocation $x \in \hat{X}$ (here we assume that there are no ex ante noncontractible allocations, so $X = \hat{X}$). Suppose that renegotiation is always efficient and that it gives the agent share $\lambda \in [0, 1]$ of the renegotiation surplus. Consider the case in which the principal's inalienable return $Y(a)$ is independent of the agent's actions, and normalize $Y(a) = 0$. Assume that the agent's investment raises asset values ($V'_P(a) > 0$, $V'_A(a) > 0$), and that the principal is always the efficient owner ex post ($V_P(a) > V_A(a)$ for all a).

Because the agent's investment has a positive externality on the principal at the first-best allocation (since $V'_P(\cdot) > 0$), the first best cannot be achieved if renegotiation is impossible, and

24. Corollary 1 could also be extended to cases of pure control rights. In such cases, we have $\hat{X}^*(a) = \hat{X}$ only for those $a \in A$ in which all agents choose the same action plan, but we can always find a second-best outcome $(\hat{x}^{**}, a^{**}) \in O^{**}$ with this property and apply Proposition 4 to this outcome.

we then have underinvestment under principal ownership ($\hat{x} = 0$), according to Proposition 2. In that case, agent ownership ($\hat{x} = 1$), which eliminates this externality and increases the agent's incentives to invest, may be second-best optimal (by Proposition 4), even though the asset then ends up in the hands of the agent, who values it less than does the principal.

When perfect renegotiation is possible, however, agent ownership will always be renegotiated ex post to give the asset to the principal. In that case, it may be possible to achieve the first best. Given this renegotiation, when $\hat{x} = 1$, the post-renegotiation payoffs of the principal and the agent, $U_P(\hat{x}, a)$ and $U_A(\hat{x}, a)$, respectively, are

$$\begin{aligned} U_P(1, a) &= (1 - \lambda)[V_P(a) - V_A(a)] \\ U_A(1, a) &= V_A(a) + \lambda[V_P(a) - V_A(a)] - C(a). \end{aligned}$$

Even though agent ownership eliminates the direct externality of the agent's investment on the principal, renegotiation may create a bargaining externality, because the principal gets a share $(1 - \lambda)$ of the renegotiation surplus $V_P(a) - V_A(a)$. When either the agent has all the bargaining power ($\lambda = 1$) or the investment is general in the sense that it raises the principal's and agent's values for the asset equally ($V'_P(a) = V'_A(a)$), there is no bargaining externality, and agent ownership attains the first best. But when the principal has some bargaining power ($\lambda < 1$) and the agent's investment affects the principal's and agent's values for the asset differently, the agent's investment creates a bargaining externality. For example, if $V'_P(a) > V'_A(a)$, so the investment increases the principal's value more than the agent's, the externality from investment is positive, leading to underinvestment by the agent.

The effects of property rights on noncontractible investments when renegotiation is possible after investments have been chosen has been examined in the so-called hold-up literature. This literature generalizes the idea from the above example: that agents' incentives to invest may be reduced when they expect others to "hold them up" and extract some of the gains from the investments in future bargaining. In this section, we survey the hold-up literature. Paralleling our discussion of the static model, we begin by considering when the parties can achieve the first best. We then examine settings in which harmful externalities cannot be eliminated, so that a first-best outcome cannot be achieved. We focus there on the Property Rights Theory of the Firm of Grossman and Hart (1986), Hart and Moore (1990), and Hart (1995). Then we discuss how the findings of that theory are modified when some of its assumptions are altered. Finally, we discuss the potential of designing property rights mechanisms and renegotiation procedures that reduce or eliminate investment inefficiencies.

3.1. A Model of Hold-Up

We consider a general hold-up model involving a set $\mathcal{N}$ of N agents whose interaction unfolds according to the stages described in Section 1 and depicted in Figure 1. In the ex ante stage, the parties specify property rights $\hat{x} \in \hat{X}$ and then choose actions a . Next, some uncertainty θ is realized. Both uncertainty θ and the chosen actions a are observed by all agents prior to bargaining but are not verifiable. Then, in the ex post stage, the parties can renegotiate to some other allocation $x \in X$ (recall that $X \setminus \hat{X}$ represents decisions that are contractible ex post but

Figure 1. Timing of the hold-up model.

not ex ante). If bargaining fails, the property rights allocation $\hat{x}$ is unchanged (i.e., $x = \hat{x}$). Agent i 's payoff given the final allocation x , noncontractible actions a , uncertainty θ , and transfer t_i is $v_i(x, a, \theta) + t_i$.

Let $x^*(a, \theta)$ be an efficient ex post decision given (a, θ) , that is,

$$x^*(a, \theta) \in \arg \max_{x \in X} \sum_i v_i(x, a, \theta) \quad \text{for all } (a, \theta),$$

and denote the resulting maximal ex post surplus by

$$S(a, \theta) = \max_{x \in X} \sum_i v_i(x, a, \theta).$$

The set of first-best investment profiles is $A^* = \arg \max_{a \in A} E[S(a, \theta)]$.

To formulate results that apply to a variety of settings, we sometimes avoid a specific model of bargaining and instead make only two weak assumptions on the utilities that the parties obtain by bargaining. We denote by $u_i(\hat{x}, a, \theta)$ party i 's *post-renegotiation utility*, given the initial property rights allocation $\hat{x}$, following investments a and uncertainty realization θ .²⁵ The first assumption is *feasibility*:

$$\sum_i u_i(\hat{x}, a, \theta) \leq S(a, \theta) \quad \text{for all } \hat{x}, a, \theta. \quad (5)$$

In particular, if bargaining is efficient, (5) holds with equality for all $(\hat{x}, a, \theta)$. The second is *individual rationality*:

$$u_i(\hat{x}, a, \theta) \geq v_i(\hat{x}, a, \theta) \quad \text{for all } i, \hat{x}, a, \theta. \quad (6)$$

25. Note that this reduced-form utility is assumed independent of any transfer t , because we think of t as a transfer made ex ante before bargaining. For some bargaining solutions (e.g., the Nash solution), a contractually stipulated ex post transfer is equivalent to an ex ante transfer, so it is irrelevant for bargaining. For other solutions—such as outside option bargaining considered in Section 3.6—a contractually stipulated ex post transfer may affect bargaining, unlike an ex ante transfer. In this case, the ex post transfer would need to be viewed as part of $\hat{x}$.

It says that each agent's payoff in bargaining is at least her payoff from the outcome that follows a bargaining breakdown. The two assumptions allow for a range of bargaining processes. At one extreme, we could have no renegotiation at all (bargaining always fails), in which case we are back in the static model of the last section, albeit with some uncertainty in payoffs due to θ . At the other extreme, we could have efficient bargaining, which could in principle take various forms.²⁶

One specific model of individually rational and efficient renegotiation is given by the (generalized) Nash bargaining solution

$$u_i(\hat{x}, a, \theta) = v_i(\hat{x}, a, \theta) + \lambda_i R(\hat{x}, a, \theta), \quad (7)$$

where $\lambda_i \geq 0$, $\sum_i \lambda_i = 1$, and $R(\hat{x}, a, \theta) = S(a, \theta) - \sum_j v_j(\hat{x}, a, \theta)$ is the *renegotiation surplus*.

We say that there is "no renegotiation" at $(\hat{x}, a, \theta)$ if (6) holds with equality for each i , that is, if each party's payoff equals the continuation payoff he would get under the original property rights allocation $\hat{x}$. (Note that, strictly speaking, the parties might renegotiate their original contract in such a case, but this renegotiation would yield none of them any gain; their payoffs would be the same as if they did not renegotiate.)

We will apply the static analysis of Section 2 to this dynamic setup by defining the agents' reduced-form payoffs given a property rights allocation $\hat{x}$ and investments a as their expected post-renegotiation payoffs: $U_i(\hat{x}, a) = E_\theta[u_i(\hat{x}, a, \theta)]$. The set of equilibrium investments is then given by the Nash equilibrium set $A^\circ(\hat{x})$ of the induced static investment game, given by (1).

3.2. Achieving Efficiency

We begin by considering circumstances in which a first-best outcome can be achieved. We first observe that the first best can be achieved provided that it is possible to specify a first-best property rights allocation at which there are no harmful direct externalities at the efficient investments, that is, if there would be no harmful externalities in the absence of renegotiation.

Definition 4 *There are no harmful direct externalities at $(\hat{x}, a) \in \hat{X} \times A$ if $v_i(\hat{x}, a, \theta) \leq v_i(\hat{x}, a_i, a'_{-i}, \theta)$ for all i , a'_{-i} , and θ .*

Proposition 5 *Suppose that there exists an efficient investment profile $a^* \in A^*$ and a property rights allocation $\hat{x} \in \hat{X}$ such that (i) $\hat{x}$ is ex post efficient in all states θ given investments a^* , and (ii) there are no harmful direct externalities at $(\hat{x}, a^*)$. Then, for any bargaining process that satisfies feasibility (5) and individual rationality (6), $a^* \in A^\circ(\hat{x}) \subseteq A^*$. That is, given property rights $\hat{x}^*$, investment profile a^* is sustained in a Nash equilibrium, and every Nash equilibrium investment profile a° is efficient (and thus $(\hat{x}^*, a^\circ) \in O^*$).*

26. Note that (6) might not hold if $N > 2$, and without i 's consent other parties can agree to changes in parts of x that have externalities on party i . We discuss such situations in Section 4.2.

Proof Individual rationality (6) and feasibility (5) of bargaining together with (i) imply that $u_i(\hat{x}, a^*, \theta) = v_i(\hat{x}, a^*, \theta)$ for all i and θ , so $U_i(\hat{x}, a^*) = E_\theta[u_i(\hat{x}, a^*, \theta)] = E_\theta[v_i(\hat{x}, a^*, \theta)]$ for all i . Using this fact, for all a_{-i} we have

$$U_i(\hat{x}, a_i^*, a_{-i}) \geq E_\theta[v_i(\hat{x}, a_i^*, a_{-i}, \theta)] \geq E_\theta[v_i(\hat{x}, a^*, \theta)] = U_i(\hat{x}, a^*),$$

where the first inequality is by individual rationality of bargaining and the second by nonharmful direct externalities at $(\hat{x}, a^*)$. Thus, the induced static investment game has nonharmful externalities at $(\hat{x}, a^*)$. Because $(\hat{x}, a^*)$ is a first-best outcome in the induced static game (since $\sum_i U_i(\hat{x}, a^*) = \sum_i E_\theta[v_i(\hat{x}, a^*, \theta)] = E_\theta[S(a^*, \theta)]$), applying Proposition 1 to this game yields the result.

The intuition behind Proposition 5 is that if a property rights allocation achieves efficiency without renegotiation following equilibrium investments, then any agent's investment deviation, by creating renegotiation surplus, could only have beneficial bargaining externalities on the others. If, in addition, investment deviations do not generate harmful direct externalities, then nobody will deviate from an efficient outcome.

A simple special case in which there are no harmful direct externalities occurs when direct externalities are completely absent.

Definition 5 *Agent i 's investment a_i is a self-investment if agent j 's disagreement payoff $v_j(\hat{x}, a, \theta)$ is independent of a_i for all $j \neq i$ for all $\hat{x}$, a_{-i} , and θ .*

This assumption applies, say, to agents' investment in their own human capital. It rules out both investments in physical capital that could benefit other agents and investments in other agents' human capital. If all agents' investments are self-investments, then each agent's disagreement payoff has the form $v_i(\hat{x}, a_i, \theta)$. If in addition there are no ex ante noncontractible decisions (i.e., $\hat{X} = X$) and no noncontractible uncertainty θ , then by Proposition 5, letting the property rights allocation be a first-best allocation given efficient investments (i.e., $\hat{x} = x^*(a^*)$) sustains first-best investments.²⁷

Example 4 Consider again Example 3, but assume that $V_P(a)$ and $Y(a)$ are both independent of a , so the agent's investment is a self-investment, and that the efficient ex post owner may depend on the agent's investment a . In this case, whether renegotiation is possible or not, the first best can be obtained by giving the asset to its efficient owner given first-best investments a^* . If renegotiation is not possible, this would follow from Proposition 1. If renegotiation is possible, the agent's investment deviation may induce renegotiation when it changes the ex post optimal owner. But, as Proposition 5 shows, because such renegotiation could only bestow a positive bargaining externality on the principal, the agent would not want to deviate from the efficient investment a^* .

Consider now a richer application of Proposition 5, which allows for ex ante noncontractible decisions and uncertainty.

27. This conclusion extends to cases with uncertainty θ that is verifiable, so that a contingent property rights allocation $\hat{x}(\theta) = x^*(a^*, \theta)$ can be specified ex ante. Indeed, Proposition 5 extends to such cases.

Example 5 Grossman and Hart (1986) consider a setting in which two agents make self-investments. However, unlike in our basic model, the ex post disagreement point is given by the agents' noncooperative choices of ex ante noncontractible actions $q_1 \in Q_1$ and $q_2 \in Q_2$ resulting in payoffs $v_i(a_i, \theta, q_1, q_2)$ to each agent i . Furthermore, the role of the property rights allocation $\hat{x}$ is to define control rights over these actions: similarly to the setting in Remark 1, the agent who owns asset $k = 1, 2$ has the right to choose action $q_k \in Q_k$. As a result, the ex post Nash equilibrium choice of the noncontractible actions q yields a default noncooperative outcome $q^\circ(\hat{x}, a, \theta) \in Q_1 \times Q_2$. Thus, the disagreement payoffs can be defined as $v_i(\hat{x}, a, \theta) = v_i(a_i, \theta, q^\circ(\hat{x}, a, \theta))$. The assumptions of Proposition 5 are satisfied in this setting for any property rights allocation $\hat{x}$ such that (i) $q^\circ(\hat{x}, a, \theta)$ is efficient for all (a, θ) and (ii) $v_i(\hat{x}, a, \theta) = v_i(a_i, \theta, q^\circ(\hat{x}, a, \theta))$ is independent of a_{-i} for $i = 1, 2$. Note that both conditions are satisfied when property rights $\hat{x}$ eliminate all externalities from ex ante noncontractible actions q . Grossman and Hart's (1986) Proposition 1 identifies some such cases. First, if both decisions q_1, q_2 affect the payoff of only one agent i , giving this agent control over both actions ("agent i integration" in Grossman and Hart's terminology) eliminates all the externalities from q and achieves the first best. Similarly, if the payoff of each agent $i = 1, 2$ depends only on action q_i , then giving each agent i control over action q_i ("nonintegration") achieves the first best.²⁸

The first-best result of Proposition 5 relies on the ability to eliminate renegotiation in equilibrium by specifying a property rights allocation $\hat{x}$ that is ex post efficient in all states θ following first-best investments a^* . Specifying such an allocation will be impossible when the efficient ex post outcome depends on noncontractible uncertainty and/or when ex post efficient allocations following a^* are not contractible ex ante (i.e., are outside $\hat{X}$). Fortunately, the first best may still be implementable in some such cases, provided that there is efficient renegotiation, so that initial property rights have no direct effect on efficiency. For this case, according to Proposition 1, we can sustain efficient investments a^* using any property rights $\hat{x}$ that eliminate harmful externalities at $(\hat{x}, a^*)$. However, unlike in the static setting, investments now have two sources of externalities: direct externalities and bargaining externalities through renegotiation surplus, and we now need to ensure that both kinds of externalities are nonharmful.

One example of this approach is provided by Edlin and Reichelstein (1996). In their model, all agents' investments are self-investments; hence, there are no direct externalities. As for bargaining externalities, it turns out that in some cases there is a property rights allocation that makes them nonharmful.

Proposition 6 (Edlin-Reichelstein 1996) *Suppose all agents make self-investments, bargaining is given by the Nash bargaining solution, $X \subseteq \mathbb{R}^m$, and payoffs satisfy the following separability condition:*²⁹

28. Note that some of the assumptions of Grossman and Hart are unnecessary for these results: namely, the absence of uncertainty, the separability of payoffs that ensures that noncooperative equilibrium values $q^\circ(\hat{x}, a)$ are independent of a , and the restriction to the Nash bargaining solution (instead, any bargaining process satisfying (5) and (6) would work).

29. Edlin and Reichelstein (1996) assume that property rights and investments are one dimensional ($X, A_i \subset \mathbb{R}$), assumptions that we relax here by allowing arbitrary action sets A_i and multidimensional property rights.

$$v_i(x, a_i, \theta) = \bar{v}_i(a_i) \cdot x + \hat{v}_i(x, \theta) + \tilde{v}_i(a_i, \theta) \quad \text{for all } i. \quad (8)$$

Then for property rights allocation $\hat{x} = E_\theta[x^*(a^*, \theta)] \in \hat{X}$ (the expected efficient allocation given first-best investments $a^* \in A^*$), we have $a^* \in A^\circ(\hat{x}) \subseteq A^*$. That is, given property rights $\hat{x}$, investment profile a^* is sustained in a Nash equilibrium, and every Nash equilibrium investment profile a° is efficient.

Proof Agent i 's payoff in the induced static investment game is

$$U_i(\hat{x}, a) = E_\theta[u_i(\hat{x}, a, \theta)] = E_\theta[v_i(\hat{x}, a_i, \theta)] + \lambda_i E_\theta[R(\hat{x}, a, \theta)].$$

Due to efficient renegotiation, $\hat{X}^*(a) = \hat{X}$ for all a . We now show that there are no harmful externalities at $(\hat{x}, a^*)$, when $\hat{x} = E_\theta[x^*(a^*, \theta)]$, which yields the result by Proposition 1. Given self-investments, it suffices to show that the expected renegotiation surplus $E_\theta[R(\hat{x}, a, \theta)]$ is minimized at $a = a^*$. To see this, observe that for any $a \in A$ and any $\theta \in \Theta$, $S(a, \theta) \geq \sum_i v_i(x^*(a^*, \theta), a_i, \theta)$, and the inequality holds with equality when $a = a^*$. Therefore,

$$\begin{aligned} E_\theta[R(\hat{x}, a, \theta)] &\geq E_\theta \left[\sum_i [v_i(x^*(a^*, \theta), a_i, \theta) - v_i(\hat{x}, a_i, \theta)] \right] \\ &= \sum_i E_\theta [\hat{v}_i(x^*(a^*, \theta), \theta) - \hat{v}_i(\hat{x}, \theta)], \end{aligned}$$

and the inequality holds with equality at $a = a^*$, which implies the result.

Note that the presence of noncontractible uncertainty θ typically requires equilibrium renegotiation to achieve efficient allocations. However, under the assumptions of Proposition 6, specifying the expected efficient allocation $\hat{x} = E_\theta[x^*(a^*, \theta)]$ ensures that the expected renegotiation surplus is minimized at first-best investments a^* and thus eliminates harmful bargaining externalities at $(\hat{x}, a^*)$.

Another way to ensure efficiency is by ruling out bargaining externalities at all property rights allocations $\hat{x}$ and finding a property rights allocation at which direct externalities are nonharmful. In particular, bargaining externalities are always absent when one agent invests and she has all the bargaining power; hence, other agents do not capture any of the renegotiation surplus.

Proposition 7 *Suppose that only agent i invests, that renegotiation is efficient and gives agent i all the bargaining power (i.e., it is the Nash bargaining solution with $\lambda_i = 1$), and that there is an efficient investment $a^* \in A^*$ and a property rights allocation $\hat{x} \in \hat{X}$ such that there are no harmful direct externalities at $(\hat{x}, a^*)$. Then $a^* \in A^\circ(\hat{x}) \subseteq A^*$. That is, given property rights $\hat{x}$, investment a^* is optimal for the agent, and every optimal investment profile a° is efficient.*

Proof The assumptions imply that there are no harmful externalities at $(\hat{x}, a^*)$, and $\hat{X}^*(a^*) = \hat{X}$ due to efficient renegotiation, so Proposition 1 yields the result.

For an illustration of this result, recall that in Example 3, the first best can be achieved with agent ownership if the agent has all the bargaining power ($\lambda = 1$); the agent then sells the asset ex post to the principal at price $V_P(a)$ and captures the entire social surplus $V_P(a) - C(a)$, which gives him an incentive to invest efficiently.

Proposition 7 can be extended to settings with many investing agents. Of course, in such settings it is impossible to give more than one agent the full renegotiation surplus. However, if renegotiation is governed by coalitional bargaining (formally defined in Section 3.5), there may be a set $T \subseteq N$ of agents, each of whom receives her marginal contribution to the total surplus. If only agents from T make investments, we can sustain an efficient investment profile a^* , provided that property rights $\hat{x}$ eliminate any harmful direct externalities at $(a^*, \hat{x})$ (e.g., if each agent has the right to exclude all others from profiting from her investment). Indeed, because each agent $i \in T$ appropriates her full marginal contribution, she has no aggregate bargaining externality on the others, so her total externality on their aggregate post-renegotiation payoff $\sum_{j \neq i} u_j(\hat{x}, a, \theta)$ is then nonharmful as well. A part of Proposition 1 applies to this case, implying that investment profile a^* can arise as a Nash equilibrium (see footnote 17).³⁰ However, some inefficient investment equilibria (“coordination failures”) may exist as well. (Coordination failures could be ruled out with a no complementarities condition, but it is a rather strong condition; see, e.g., Brandenburger and Stuart 2007a,b.)

Makowski and Ostroy (1995, 2001) note that when each agent has very close substitutes, it may be in fact possible to give each agent his marginal contribution. For example, this happens in classical economies when the competitive equilibrium is unique and the core shrinks to this equilibrium as the number of agents grows large. Indeed, when the core is single valued, it must give each agent his marginal contribution.³¹ In such “competitive” settings, first-best incentives are sustained when each agent is given full property rights to the fruits of his labor, so that he has no direct externality on others.

3.3. Externalities and Distortions

We now shift attention to settings in which the first best cannot be achieved with a property rights allocation. We focus here on cases studied in the Property Rights Theory of Hart and Moore (1990) and Hart (1995). This theory examines situations in which parties make self-investments (e.g., investments in their own human assets), so that there are no direct externalities. Inefficiencies in this theory are entirely due to harmful bargaining externalities, which arise because investing agents do not fully appropriate their contributions to renegotiation surplus (in contrast to the setting of Proposition 7). In contrast to the settings of Propositions 5 and 6, these bargaining externalities cannot be avoided because of the presence of decisions that are contractible ex post but not ex ante.

30. For examples of two-sided markets in which all the agents on one side receive their marginal contributions so that their efficient self-investments can be sustained, see Felli and Roberts (2001) and Kranton and Minehart (2001).

31. Examples of two-sided markets in which this occurs, so that efficient self-investments by all agents can be sustained, are given by Cole et al. (2001a,b).

Example 6 Consider the setting of Example 4, in which $V_P(a)$ and $Y(a)$ are both independent of a , so that direct externalities are absent. However, suppose that ex ante the parties can only contract on property rights $\hat{x} \in \hat{X} = \{0, \gamma\}$, where $\gamma \in (0, 1)$, while the ex post available outcomes are $X = \{0, \gamma, 1\}$. We can interpret $x = 1$ as the agent's utilization of the asset with cooperation by the principal, which is not contractible ex ante, while $x = \gamma$ (which is contractible ex ante) corresponds to the agent's ownership without the principal's cooperation. (Only share γ of the asset can be effectively used by the agent without the principal's cooperation.) The payoffs continue to be described as in Example 3.

Suppose that $V_A(a) > V_P$ for all a , which means that agent utilization with full cooperation is always ex post optimal. The parties always renegotiate to this allocation using the Nash bargaining solution, which gives them the following payoffs:

$$\begin{aligned} U_A(\hat{x}, a) &= \hat{x} V_A(a) + \lambda(1 - \hat{x}) [V_A(a) - V_P] - C(a), \\ U_P(\hat{x}, a) &= (1 - \hat{x}) V_P + (1 - \lambda)(1 - \hat{x}) [V_A(a) - V_P] + Y. \end{aligned}$$

Thus, when $\lambda < 1$ and $V'_A(a) > 0$, under both ex ante contractible property rights allocations $\hat{x} \in \{0, \gamma\}$ the agent's investment creates a positive bargaining externality, so underinvestment results. Note that if the parties were able to specify agent ownership with full cooperation ($\hat{x} = 1$), the externality would be eliminated and optimal investment would be sustained (according to Proposition 5). The inability to specify cooperation ex ante ($\gamma < 1$) and the agent's lack of full bargaining power ex post ($\lambda < 1$) allow the principal to hold up the agent ex post in return for cooperation, reducing the agent's investment incentives.

Hart and Moore (1990) examine a model of optimal property rights based on the assumption of positive bargaining externalities. Here we discuss their model, focusing for simplicity on the case with $N = 2$ agents, where renegotiation is governed by the Nash bargaining solution (7).³² As in Hart and Moore (1990), we assume one-dimensional self-investments, so that for each agent i , $A_i \subseteq \mathbb{R}$, and we can write her disagreement payoff as $v_i(\hat{x}, a_i, \theta)$.³³ Thus, any externalities from investments come through the renegotiation surplus $R(\hat{x}, a, \theta)$. We have positive externalities when the renegotiation surplus is increasing in investments, that is, when the incremental impact of investment on the total surplus $S(a, \theta)$ is greater than on the parties' disagreement payoffs, as was true in Example 6. This condition is defined as follows.

Definition 6 *Investments are relationship specific at $\hat{x}$ if the renegotiation surplus $R(\hat{x}, a, \theta) = [S(a, \theta) - \sum_i v_i(\hat{x}, a, \theta)]$ is nondecreasing in a for all θ . Investments are relationship specific if they are relationship specific at all $\hat{x}$.*

Note that self-investments are relationship specific when each agent i 's disagreement payoff $v_i(\hat{x}, a, \theta)$ increases less with his investment than does the efficient surplus $S(a, \theta)$. A simple set of sufficient conditions ensuring this is the following.

32. This analysis applies to $N > 2$ agents provided that any renegotiation requires unanimous agreement. We discuss the extension to $N > 2$ agents with coalitional bargaining in Section 3.5.

33. Hart and Moore (1990) do not explicitly model uncertainty θ , but one can view their payoff functions as expected payoffs over the realizations of some uncertainty.

Lemma 2 *Suppose that we have self-investments, that $X \subseteq \mathbb{R}^m$, and that $v_i(x, a_i, \theta)$ has increasing differences in (x, a_i) for all i . Then all investments are relationship specific at any property rights allocation $\hat{x}$ such that $\hat{x} \leq x^*(a, \theta)$ for all (a, θ) .*

Proof Given the assumptions, we obtain, for any $a'_i > a_i$,

$$\begin{aligned} S(a'_i, a_{-i}, \theta) - S(a, \theta) &\geq v_i(x^*(a, \theta), a'_i, \theta) - v_i(x^*(a, \theta), a_i, \theta) \\ &\geq v_i(\hat{x}, a'_i, \theta) - v_i(\hat{x}, a_i, \theta), \end{aligned}$$

which implies that investments are relationship specific at $\hat{x}$.

Lemma 2 shows that investments are relationship specific if they are complementary to allocations x and if the allocations contracted ex ante are always below their ex post efficient levels. For example, these assumptions are satisfied for any property rights allocation $\hat{x} \in \{0, \gamma\}$ in Example 6 (because ex post efficiency always requires $x^* = 1 \geq \gamma$), but not for the expected-efficient allocation in Proposition 6 (the model of Edlin and Reichelstein 1996), which in some states ends up below and in others above the ex post efficient level.

Because relationship-specific investments generate positive bargaining externalities, by Proposition 2 this implies underinvestment when one agent makes an investment. This conclusion extends to multiagent investments, provided that the investments are strategic complements (i.e., reduced-form payoffs $U_i(x, a) = E_\theta[u_i(x, a, \theta)]$ satisfy Definition 3), in which case Proposition 3 implies the following.

Proposition 8 *Suppose that there is Nash bargaining, and at property rights allocation $\hat{x}$ all agents' investments are relationship specific and are strategic complements.³⁴ Then $A^\circ(\hat{x})$ is below $A^*(\hat{x})$ in the weak set order.*

When there is a unique efficient investment profile a^* , Proposition 8 implies that any equilibrium investment profile is (weakly) below a^* .

One way to understand this underinvestment problem is by thinking of the parties' split of the renegotiation surplus $R(\hat{x}, a, \theta)$ in proportion to their fixed bargaining powers as an output-sharing scheme. Holmström (1982) showed that when output is an increasing function of efforts (as relationship specificity postulates), then any such output-sharing scheme yields free riding in effort provision.

3.4. Second-Best Property Rights Allocations

3.4.1. The Hart-Moore Theory

In the models of Hart and Moore (1990) and Hart (1995), the ex ante contractible decision $\hat{x} \in \hat{X}$ is a "control structure" over a set K of assets. In contrast to our treatment of the tragedy of the commons in Section 2.1, Hart and Moore's control structures rule out situations in

34. Sufficient conditions for strategic complementarity of relationship-specific investments in the induced static investment game are that for each agent i , $A_i \subseteq \mathbb{R}$, the functions $v_i(\hat{x}, a_i, \theta)$ are equicontinuous in a_i , and the function $S(a, \theta)$ is supermodular.

which more than one agent can independently access an asset. Thus, letting $\hat{x}_{ik} \in \{0, 1\}$ denote whether agent i has access to asset k , the set of feasible control structures is defined as

$$\hat{X} = \left\{ \hat{x} \in \{0, 1\}^{NK} : \sum_i \hat{x}_{ik} \leq 1 \text{ for all } k \in K \right\}. \quad (9)$$

Hart and Moore refer to the case in which no agent has control of an asset k (so that $\hat{x}_{ik} = 0$ for all i) as “joint ownership” of the asset. (This is the opposite of common ownership in the tragedy of the commons, in the sense that each agent can exclude the others without himself having the right to access the asset.) Hart and Moore also assume that there are no externalities from access in the following sense.

Definition 7 *There are no externalities from access to assets if, for all agents i , $v_i(\hat{x}, a, \theta)$ does not depend on $\hat{x}_{-i}$.*

When there are no externalities from access to assets, each agent i 's disagreement payoff depends on his access to assets, but not on other agents' access, and so can be written as $v_i(\hat{x}_i, a, \theta)$. (Note that this assumption would not be natural if common access, as in the tragedy of the commons, were allowed.) An important implication of this assumption is that, with self-investments and Nash bargaining, it makes each agent's post-renegotiation utility $u_i(\hat{x}, a, \theta)$ additively separable between a_i and $\hat{x}_{-i}$:

$$u_i(\hat{x}, a, \theta) = (1 - \lambda_i)v_i(\hat{x}_i, a_i, \theta) + \lambda_i S(a, \theta) - \lambda_i \sum_{j \neq i} v_j(\hat{x}_j, a_j, \theta). \quad (10)$$

Hence, an agent's investment incentives are affected only by his own asset ownership.

To study second-best optimal control structures, Hart and Moore also assume that access to assets increases agents' marginal incentives to invest.

Definition 8 *Investments are asset specific if, for each agent i , $v_i(\hat{x}_i, a, \theta)$ has increasing differences in $(\hat{x}_i, a_i)$.*

This property implies that the agent's post-renegotiation utility (10) has increasing differences in $(\hat{x}_i, a_i)$, so that her investment incentives are increased by shifting assets to her.

It is instructive to compare the predictions of Hart and Moore's Property Rights Theory (Hart and Moore 1990; Hart 1995) to those of the simple allocation benchmark described in Section 1. In that benchmark, there are no investments and no renegotiation, and the optimal property rights allocation simply maximizes the expected surplus $E[\sum_i v_i(\hat{x}, \theta)]$. Thus, in the absence of externalities, it is optimal simply to give assets to agents who value them the most.

In contrast, in Hart and Moore's theory, what determines efficiency is not the expected surplus at the disagreement point per se (because it is renegotiated toward full efficiency) but the sensitivity of this surplus to investments. Thus, instead of allocating assets to the highest-value agents, Hart and Moore's theory allocates assets to agents for whom they create the most beneficial investment incentives.

In particular, when only one agent invests, only her incentives matter, so she should optimally own all the assets.

Proposition 9 (Hart and Moore 1990: proposition 2) *If only agent i invests (i.e., A_{-i} is a singleton), $A_i \subseteq \mathbb{R}$, the investment is an asset-specific relationship-specific self-investment, there are no externalities from access to assets, and the set $\hat{X}^{**}$ of second-best optimal property rights is nonempty, then it is optimal for agent i to own all the assets (i.e., $(\hat{x}_i, \hat{x}_{-i}) = ((1, \dots, 1), (0, \dots, 0)) \in \hat{X}^{**}$).*

Proof Note first that because agent i 's investment is determined by $\hat{x}_i$, we can set $\hat{x}_{-i} = 0$ without affecting equilibrium investments or the resulting total surplus, which makes the constraint in (9) nonbinding. Next, under the assumptions of the proposition, $U_i(\hat{x}, a_i) = E_\theta[u_i(\hat{x}, a_i, \theta)]$ has increasing differences in $(\hat{x}_i, a_i)$. Relationship-specific investment a_i generates positive externalities. Moreover, because ex post bargaining is efficient, the aggregate surplus $\sum_i U_i(\hat{x}, a_i)$ is independent of $\hat{x}$, or in terms of the notation of Section 2, $\hat{X}^*(a_i) = \hat{X}$ for all a_i . Then applying Corollary 1 sequentially to $\hat{x}_{ik}$ for each $k \in K$ implies that it is optimal to set $\hat{x}_i = (1, \dots, 1)$.

To illustrate this result, consider again Example 6, which satisfies all the assumptions of Proposition 9. In this example, the agent underinvests for any ownership structure, since the benefit of his relationship-specific investment is partially captured by the principal through the renegotiation surplus. Because this investment is asset specific, agent ownership maximizes this investment and the resulting total surplus.

If more than one agent invests, then optimal asset allocation generally involves trade-offs, because moving an asset from agent i to agent j has the direct effect of raising i 's asset-specific investment incentives (i.e., his best-response curve) and lowering j 's. In some special cases, however, agent j 's incentives may not be affected, in which case, if agents' investments are strategic complements, we may be able to conclude that all agents' equilibrium investments increase, and welfare unambiguously goes up. Hart and Moore (1990) identified a number of such cases, and here we present a few of these results as an illustration. To do so, we first need to state two definitions.

Definition 9 *Agent i is indispensable to asset $k \in K$ if, for each agent $j \neq i$ and all a', a, θ , $v_j(\hat{x}_j, a', \theta) - v_j(\hat{x}_j, a, \theta)$ does not depend on $\hat{x}_{jk}$.*

Intuitively, indispensability of agent i to asset k means that the marginal product of other agents' investments on their disagreement payoffs is unaffected by whether they own asset k .

Definition 10 *Assets l and m are perfectly complementary if, for each agent i , $v_i(\hat{x}_i, a', \theta) - v_i(\hat{x}_i, a, \theta)$ depends on $(\hat{x}_{il}, \hat{x}_{im}) \in \{0, 1\}^2$ only through the product $\hat{x}_{il}\hat{x}_{im}$.*

Intuitively, when two assets are perfectly complementary, the marginal product of each agent's investment when he has only one of the two assets equals the marginal product when he has neither.

Proposition 10 (Hart and Moore 1990: propositions 4, 6, and 8) *If investments are asset-specific relationship-specific self-investments that are strategic complements, there are no externalities from access to assets, and the set $\hat{X}^{**}$ of second-best property rights is nonempty, then the following statements hold:*

- (i). *Joint ownership is unnecessary in an optimal control structure; that is, there exists a second-best ownership structure $\hat{x} \in \hat{X}^{**}$ such that $\sum_i \hat{x}_{ik} = 1$ for all $k \in K$.*
- (ii). *If agent i is indispensable to asset k , then agent i optimally owns asset k ; that is, there exists $\hat{x} \in \hat{X}^{**}$ such that $\hat{x}_{ik} = 1$.*
- (iii). *It is optimal for perfectly complementary assets l and m to be owned together; that is, there exists $\hat{x} \in \hat{X}^{**}$ such that $\hat{x}_{il} = \hat{x}_{im} = 1$ for some i .*

Proof Take any $\hat{x} \in \hat{X}^{**}$. For result (i), if $\sum_{ik} \hat{x}_{ik} = 0$ for some $k \in K$, then (because $U_i(\hat{x}, a) = E_\theta[u_i(\hat{x}, a, \theta)]$ has increasing differences in $(\hat{x}_i, a_i)$ and positive externalities from a_{-i} for each agent i), by Corollary 1, changing to $\hat{x}'_{ik} = 1$ for any given i holding the other dimensions of $\hat{x}$ fixed yields another allocation in $\hat{X}^{**}$. For result (ii), if $\hat{x}_{jk} = 1$ for some $j \neq i$, then (because $v_j(\hat{x}_j, a_j, \theta)$, and hence $U_j(\hat{x}, a)$, has (weakly) increasing differences in $(-\hat{x}_{jk}, a_j)$) Corollary 1 implies that changing the property rights over asset k to joint ownership $[(\hat{x}'_{ik}, \hat{x}'_{jk}) = (0, 0)]$ while holding fixed the ownership of the other assets yields another allocation in $\hat{X}^{**}$. By the argument used to show result (i), changing the property rights over asset k to agent i ownership $[(\hat{x}'_{ik}, \hat{x}'_{jk}) = (1, 0)]$ while holding fixed the ownership of the other assets must yield another allocation in $\hat{X}^{**}$. For result (iii), if $\hat{x}_{il} = \hat{x}_{jm} = 1$ for some agents $i \neq j$, then (because $v_j(\hat{x}_j, a_j, \theta)$, and hence $U_j(\hat{x}, a)$, has (weakly) increasing differences in $(-\hat{x}_{jm}, a_j)$) Corollary 1 implies that changing the ownership of asset m to joint ownership $[(\hat{x}'_{im}, \hat{x}'_{jm}) = (0, 0)]$ while holding fixed the ownership of the other assets yields another allocation in $\hat{X}^{**}$. Finally, by the argument used to show result (i), changing the ownership of asset m to agent i ownership $[(\hat{x}'_{im}, \hat{x}'_{jm}) = (1, 0)]$, making agent i the owner of both assets, must yield another allocation in $\hat{X}^{**}$.

Note that while Hart and Moore's concepts of indispensable agents and perfectly complementary assets are formulated in terms of the marginal returns to investments, $v_i(\hat{x}_i, a'_i, \theta) - v_i(\hat{x}_i, a_i, \theta)$ with $a' > a$, it seems natural for the same properties to also be satisfied by the absolute payoffs $v_i(\hat{x}_i, a_i, \theta)$. In that case, the simple allocation benchmark makes exactly the same asset ownership recommendations as Proposition 10, because the proposed asset reallocations (weakly) increase the payoff of each agent (and not just the sensitivity of this payoff to investment). The same argument applies to the proposition's recommendation of no joint ownership. Thus, Proposition 10's recommendations also hold in settings without investments in which renegotiation is either impossible or breaks down with an exogenous probability. (When the probability of bargaining breakdown is affected by property rights, the conclusion may change, as we analyze in Section 4.) Thus, although some of Hart and Moore's predictions (e.g., Proposition 9) are distinct from those of the simple allocation benchmark, others are similar, which can make it difficult to distinguish their theory empirically from alternative theories. Another diffi-

culty in testing the theory stems from the sensitivity of its predictions to alternative assumptions about the nature of investments, which we now examine.³⁵

3.4.2. Violation of Self-Investments: Cooperative Investment

We now relax the assumption of self-investments to allow so-called cooperative investments, which directly affect other agents' disagreement payoffs. Examples include an agent's training of other agents (i.e., investments in others' human capital) and investments in physical capital owned by others. For simplicity, we assume that these cooperative effects are positive.

Definition 11 *Agent i 's investment is cooperative at $\hat{x}$ if $v_j(\hat{x}, a, \theta)$ is nondecreasing in a_i for $j \neq i$ and all θ . It is cooperative if it is cooperative at every $\hat{x}$.*

Consider again Example 3, and allow $Y(a)$ to depend on the agent's investment a . Then the agent's investment is cooperative at agent ownership ($\hat{x} = 0$) when $Y'(a) \geq 0$, it is cooperative at principal ownership ($\hat{x} = 1$) when $Y'(a) + V'_p(a) \geq 0$, and it is cooperative when both inequalities hold. Optimal property rights when investments have cooperative components have been examined by Demski and Sappington (1991), MacLeod and Malcolmson (1993), Hart et al. (1997), Che and Hausch (1999), Edlin and Hermalin (2000), Segal and Whinston (2000: 24–28), Guriev (2003), and Roider (2004).

Cooperative investments introduce a direct route by which an agent's investment can generate positive externalities in addition to the bargaining externalities present in Hart and Moore's Property Rights Theory (Hart and Moore 1990; Hart 1996). As a result, the one-sided underinvestment result generalizes to the following.³⁶

Proposition 11 *If only agent i invests, $A_i \subseteq \mathbb{R}$, her investment is a cooperative relationship-specific investment, and there is Nash bargaining, then there is underinvestment for all ownership structures: $A^\circ(\hat{x})$ is below $A^*(\hat{x})$ in the strong set order for all $\hat{x} \in \hat{X}$.*

Proof The payoff of agent $j \neq i$ in the induced static game is $U_j(\hat{x}, a) = E_\theta[v_j(\hat{x}, a_i, \theta) + \lambda_j R(a_i, \theta)]$, which is nondecreasing in a_i . Applying Proposition 2 then yields the desired result.

How does asset ownership affect cooperative investment? To look at this issue in the cleanest possible way, we examine the special case of purely cooperative investments, which can be interpreted as investments in the other agents' human capital (e.g., training).

Definition 12 *Cooperative investments are purely cooperative if $v_i(\hat{x}, a, \theta) = \bar{v}_i(\hat{x}, a_{-i}, \theta) + \psi_i(a_i)$ for all i .*

35. See Whinston (2003) for a discussion of issues involved in testing Hart and Moore's theory against the transaction cost economics theory of integration (Williamson 1975, 1979, 1985; Klein et al. 1978), and of the sensitivity of Hart and Moore's theory to the nature of investments.

36. The underinvestment result also extends to bilateral cooperative investment when investments are strategic complements. However, strategic complementarity is harder to ensure when agents' disagreement payoffs depend on both their own and others' investments.

With purely cooperative investments, each agent i 's payoff in the induced static game when there are no externalities from access to assets takes the form:

$$U_i(\hat{x}, a) = E_\theta \left[(1 - \lambda_i) \bar{v}_i(\hat{x}_i, a_{-i}, \theta) - \lambda_i \bar{v}_{-i}(\hat{x}_{-i}, a_i, \theta) + \lambda_i S(a, \theta) \right] \\ + (1 - \lambda_i) \psi_i(a_i) - \lambda_i \psi_i(a_i) .$$

Thus, with purely cooperative investments, agent i 's investment incentives are affected only by the other agent's property rights $\hat{x}_{-i}$, not his own. Moreover, when agent i 's investment is asset specific, so that $v_{-i}(\hat{x}_{-i}, a_i, \theta)$ has increasing differences in $(\hat{x}_{-i}, a_i)$, his investment incentives are increased by taking assets away from agent $-i$. Therefore, with purely cooperative investments, all agents' investment incentives are maximized at once with joint ownership, and we have the following proposition.³⁷

Proposition 12 *If investments are asset-specific, relationship-specific, purely cooperative, and strategic complements; there are no externalities from access to assets; and the set $\hat{X}^{**}$ of second-best property rights is nonempty, then joint ownership is an optimal control structure, that is, $0 \in \hat{X}^{**}$.*

Intuitively, as first shown by Che and Hausch (1999), an agent's incentive to make a purely cooperative investment is enhanced rather than reduced by bargaining, because the bargaining surplus is sensitive to her investment, whereas her own disagreement payoff is not. Minimizing externalities at the disagreement payoffs now often corresponds to minimizing the disagreement payoffs and maximizing the renegotiation surplus, in contrast to the findings of Propositions 5 and 10. For instance, in Example 3 when $V'_P(a) > V'_A(a) = 0$ for all a , it is optimal to specify agent ownership and induce renegotiation, rather than specifying the ex post efficient principal ownership. (One way to think about this is that the investment's direct externality under principal ownership exceeds its bargaining externality under agent ownership.) Note also that the principal does not optimally own the asset in this example, even though she is indispensable to it.³⁸

3.4.3. Violation of Relationship-Specific Investments: Overinvestment in External Investments

Next, consider the assumption of relationship specificity. Recall that relationship-specific self-investment by agent i increases the efficient surplus $S(a, \theta)$ by more than it increases the

37. Note, however, that if only one agent invests, the same optimal outcome as under joint ownership is sustained by making him the owner of all the assets, because this takes access away from the other agents. Thus, Proposition 9 does extend to purely cooperative investments. It also extends to cooperative investments that are not purely cooperative: in that case agent i 's investment incentives increase both when assets are taken away from agent $-i$ and when assets are given to agent i .

Joint ownership also proves to be optimal in some settings in which investments are cooperative but not purely cooperative—see the example in Hart (1995: 68).

38. Even when there is no physical asset, an exclusive right can sometimes be created to enhance efficiency with cooperative investments. For instance, in Example 3, agent ownership could just be the agent's right to exclude the principal from collecting $V_P(a)$ (so the agent may have no direct benefit from the asset: $V_A(a) \equiv 0$). When given this right to exclude, the agent is able to capture some share of her investment return through bargaining, which enhances her investment incentives. Marvel (1982) offers this motive as a justification for exclusive dealing contracts between manufacturers and retailers. See also Segal and Whinston (2000).

agent's disagreement payoff $v_i(\hat{x}, a_i, \theta)$. For an investment that violates this property, take Example 4 (in which $V_P(a)$ and $Y(a)$ are independent of a , so the agent's investment is a self-investment) and suppose that principal ownership is always ex post optimal and that $V'_A(a) > 0$. Then under agent ownership the agent's investment increases his disagreement payoff but does not increase the efficient surplus, leading to a negative, rather than positive, bargaining externality and inducing overinvestment. Because the investment is asset specific, it is reduced by taking the asset away from the agent, the only investing party, in contrast to Proposition 9. In fact, in this example principal ownership induces efficient investment by the agent.

As other examples of this point, Holmström and Tirole (1991) consider negotiated transfer pricing and show that it may be optimal to ban trade outside the firm to reduce rent-seeking investment. Bolton and Whinston (1993) show that vertical integration can result in overinvestment in an integrated downstream division. This motivation can also lead to exclusive dealing contracts being adopted to induce retailers not to allocate effort or investment to other manufacturers (see e.g., Areeda and Kaplow 1988; and Segal and Whinston 2000).³⁹

3.4.4. Violation of Asset-Specific Investments: Ownership Reduces Investment Incentives

In contrast to the examples considered previously, we can also have examples in which the marginal benefit of investment is higher when an agent does not own an asset than when he does. For instance, in Example 4, we may have $V'_A(a) < 0$ if the investment reduces the agent's need for the asset. In such cases, investment is increased by taking the asset away from the agent, that is, by specifying principal ownership ($\hat{x} = 0$). (Recall also that principal ownership sustains efficient investment if it is ex post efficient given this investment.)

3.5. Property Rights with Coalitional Bargaining

Here we enrich the model to include coalitional bargaining with more than two agents, as in the model of Hart and Moore (1990). Now, what each coalition $T \subseteq \mathcal{N}$ can achieve matters, not just individual agents' disagreement payoffs and the total surplus achievable by the grand coalition $\mathcal{N}$, as we have assumed until now.⁴⁰ Our exposition generalizes Hart and Moore's framework in several dimensions.

We begin by defining the value of each coalition T , that is, how much joint surplus it can achieve through efficient negotiation by itself, without outsiders. This value is denoted by $S_T(\hat{x}, a, \theta)$, and we assume that $S_{\mathcal{N}}(\hat{x}, a, \theta) = S(a, \theta)$ and $S_{\emptyset}(\hat{x}, a, \theta) = 0$.⁴¹ Under standard cooperative game theory, these values are assumed to be independent of what agents outside of T choose to do. For example, this assumption rules out common ownership in the

39. Other examples of overinvestment in external investments and the resulting optimality of taking assets away from investing parties can be found in Rajan and Zingales (1998) and Cai (2003). Schmitz (2006) makes a related point, except that the investment is in information about the outside option, and the resulting renegotiation proceeds under asymmetric information and yields inefficiencies (as in the model studied in Section 4.1).

40. We note that in Hart and Moore (1990), x are investments and a are assets, the reverse of our notation here. To maintain comparability to the rest of the chapter, we maintain our earlier notation.

41. For example, these coalitional values could be derived as follows: letting $X_T(\hat{x}) \subseteq X$ denote the set of allocations that can be attained with cooperation of members of coalition T under property rights $\hat{x}$, the cooperative value of this coalition is $S_T(\hat{x}, a, \theta) = \sup_{x \in X_T(\hat{x})} \sum_{i \in T} v_i(x, a, \theta)$.

tragedy of the commons, where the agents' actions have externalities on each other, but it permits joint ownership in which neither agent can access the asset without the other's permission.⁴²

Hart and Moore suppose that coalitional bargaining yields Shapley value payoffs. Here we extend their results to general random-order bargaining payoffs. To do so, we define $M_T^i(\hat{x}, a, \theta) = S_{T \cup \{i\}}(\hat{x}, a, \theta) - S_T(\hat{x}, a, \theta)$ to be agent i 's marginal contribution when added to coalition T . Let Π denote the set of orderings of $\mathcal{N}$ and, for each ordering $\pi \in \Pi$ and each agent i , let π^i denote the set of agents who come before agent i in ordering π . Agent i 's bargaining payoff is assumed to be a weighted average of her marginal contributions to the preceding agents in different orderings, with the weights given by a probability distribution $\alpha \in \Delta(\Pi)$ over orderings:⁴³

$$U_i(\hat{x}, a) = E_\theta \left[\sum_{\pi \in \Pi} \alpha(\pi) M_{\pi^i}^i(\hat{x}, a, \theta) \right].$$

The Shapley value, for example, corresponds to the uniform distribution over orderings: $\alpha(\pi) = 1/N!$ for all π .

We next generalize the notion of relationship-specific investments to the coalitional setting.

Definition 13 *Investments are relationship specific if, for each i , $j \neq i$, and coalition $T \subseteq \mathcal{N}$, the marginal contribution $M_T^i(\hat{x}, a, \theta)$ is nondecreasing in a_j .*

This definition states that an agent's investments increase other agents' marginal contributions. For example, when specialized to the case of self-investments and $N = 2$, an agent's investment increases surplus more than it increases her disagreement payoff, as in our earlier definition. Definition 13 allows, however, for cooperative investments (e.g., it allows agent j 's investment to increase agent i 's marginal contributions to coalitions that do not include j). We can now state a result on underinvestment.⁴⁴

Proposition 13 *Suppose investments are relationship specific and are strategic complements.⁴⁵ Then $A^\circ(\hat{x})$ is below $A^*(\hat{x})$ in the weak set order.*

42. For examples of bargaining with externalities, see Section 4.2.

43. This bargaining solution can be characterized either axiomatically (Weber 1988) or with a noncooperative bargaining process, in which, for each realized random ordering, agent i makes a take-it-or-leave-it offer to the group of players π^i that precede her.

Brandenburger and Stuart (2007a,b) study a similar model in which each agent instead expects to receive a weighted average of her highest and lowest payoffs in the core of the cooperative bargaining game (which is nonempty in their settings). Their examples of underinvestment are similar to those of Hart and Moore (1990), but they do not study the effects of property rights.

44. Hart and Moore (1990) also prove uniqueness of equilibrium investments given any property rights allocation. This follows if the coalitional values are concave in investments and bargaining is given by the Shapley value.

45. Sufficient conditions for investments to be strategic complements in the induced static game are that for each i , A_i is a compact subset of $\mathbb{R}$, and for each $j \neq i$ and each coalition $T \subseteq \mathcal{N}$, the marginal contribution $M_T^i(\hat{x}, a, \theta)$ is equicontinuous in a and has increasing differences in (a_i, a_j) . This assumption generalizes Hart and Moore's (1990) assumption A4.

Proof The relationship-specificity assumption implies positive externalities in the induced static investment game, so the result obtains by Proposition 3.

Note that Proposition 13 generalizes Hart and Moore's (1990) underinvestment result by not restricting to self-investments (their assumption A3). In particular, the proposition incorporates the underinvestment result we discussed for cooperative investments in Section 3.4.2.

Now consider optimal asset ownership. Following Hart and Moore (1990), we define the set of feasible property rights, which Hart and Moore call "control structures":

Definition 14 *A control structure over K assets is a vector $\hat{x} \in \{0, 1\}^{2^N \times K}$ having the following properties:*

(i). $\hat{x}_{Tk}$ is nondecreasing in the size of coalition T ,

(ii). $\hat{x}_{Tk} + \hat{x}_{(N \setminus T)k} \leq 1$, and

(iii). $\hat{x}_{Nk} = 1$ for all k .

The interpretation of $\hat{x}_{Tk} = 1$ is that coalition T has access to asset k . Restriction (ii) means that an asset cannot be accessed by both a coalition and its complement, which rules out access externalities. Property (iii) means that the grand coalition can access anything. Note that, in general, $\hat{x}$ assigns coalitional rights as well as individual rights. As a special case, we can have $\hat{x}_T^k = \max_{i \in T} \hat{x}_i^k$ for all T ; that is, a coalition can only access assets that could be accessed by one of its individual members. However, we can also have $\hat{x}_T^k > \max_{i \in T} \hat{x}_i^k$ (the reverse strict inequality cannot hold by property (i)). For example, with majority voting, a coalition of more than $N/2$ members can access an asset even when no individual member could do so.

The next three definitions generalize concepts introduced earlier to the coalitional setting.

Definition 15 *There are no externalities from access to assets if, for all coalitions $T \subseteq N$, $S_T(\hat{x}, a, \theta)$ does not depend on $\hat{x}_{-T}$.*

Definition 16 *Investments are self-investments if, for all coalitions $T \subseteq N$, $S_T(\hat{x}, a, \theta)$ does not depend on a_{-T} .*

Definition 17 *Investments are asset specific if, for all coalitions $T \subseteq N$, $S_T(\hat{x}, a, \theta)$ has increasing differences in $(\hat{x}_T, a)$.*

We can now state the following proposition.

Proposition 14 *If only agent i makes an investment, $A_i \subseteq \mathbb{R}$, his investment is an asset- and relationship-specific self-investment, there are no externalities from access to assets, and $\hat{X}^{**} \neq \emptyset$, then it is optimal for agent i to own all of the assets, that is, to set $\hat{x}_T^{**} = 1$ if and only if $i \in T$.*

We omit the proof, which is similar to that of Proposition 9. We could likewise generalize Proposition 10. Note that in deriving these results, Hart and Moore's (1990) concavity assumptions, A1 and A2, are not needed.

3.6. Property Mechanisms

Property rights are simple (i.e., incomplete) contracts, which are often not sufficient to attain the first best. This raises the following natural question: is it possible to achieve an improvement with more complicated contracts? As one example, instead of a simple (noncontingent) property right, the parties might specify an option-to-own contract that gives one party the right to buy an asset ex post at a specified price. One could imagine even more complicated contracts, in which all parties have contractual choices. Formally, a contract then defines a message game in which the parties send messages and the outcome is determined by these messages. Can an improvement be achieved with such message games? In cases in which the answer is “no,” this offers a foundation for incomplete contracts.

3.6.1. Mechanism Design without Renegotiation

The hold-up model assumes that investments a and uncertainty θ are observable but not verifiable, so a contract cannot condition upon them. In particular, it is impossible to stipulate efficient investments in the contract. However, in a contractual message game, the equilibrium outcome can indirectly depend on nonverifiable information, such as investments, through messages sent in the game. This dependence in turn can improve investment incentives and perhaps even sustain first-best investments.

For the simplest possible example, consider the game in which the agents must report all information (a, θ) and are severely penalized when the reports do not agree. Truthful reporting constitutes a Nash equilibrium of this game. However, this game has two obvious problems. One is that the penalties may be renegotiated by the agents. For now we abstract from this problem, assuming that renegotiation outside the contractual framework is impossible (but see Section 3.6.2 for a discussion of renegotiation). The other problem is that the game has “bad” equilibria in which the agents coordinate on reporting a false state. This problem, however, can be avoided. To eliminate bad equilibria, the agents can be made to play a somewhat more sophisticated game, and we can use an equilibrium refinement. In particular, by asking the parties to play an extensive-form game and using the refinement of subgame-perfect equilibrium as proposed by Moore and Repullo (1988), it is possible to sustain efficient investments in the unique subgame-perfect equilibrium.

For a simple example of such subgame-perfect implementation, consider any setting in which only agent 1 invests and his investment has no harmful direct externalities at $(\hat{x}, a^*)$ for some property rights allocation $\hat{x}$ and some first-best investment $a^* \in A^*$ (e.g., it could just be self-investment). Suppose the initial contract specifies that the agents play the following two-stage **ultimatum game** ex post, and that renegotiation of this mechanism is impossible:

Stage 1. Agent 1 names an outcome (x, t) .

Stage 2. Agent 2 accepts or rejects.

If agent 2 accepts, the outcome named by agent 1 is implemented; otherwise, property right allocation $\hat{x}$ is implemented.

In the unique subgame-perfect equilibrium of this game, a surplus-maximizing outcome results, and agent 2 receives his reservation payoff. In effect, this game introduces a contract-

specified renegotiation that gives agent 1 all the bargaining power. Thus, according to Proposition 7, agent 1 will invest efficiently ex ante.⁴⁶

A common informal justification of incomplete contracts appeals to the parties' inability to foresee future allocations x or contingencies θ ex ante. However, at the same time parties are still assumed to be rational, foreseeing their future payoffs and choosing investments optimally. One way to reconcile these assumptions, proposed by Maskin and Tirole (1999), is that the parties foresee their payoffs from all possible future contingencies and actions but cannot describe them in an ex ante contract due to not yet having the "names" for them. In this light, note that the ultimatum game can be described ex ante without naming any specific ex post decisions or contingencies. Maskin and Tirole generalize this observation, showing that any mechanism can be described ex ante without naming actions or contingencies, letting the agents fill in these names in the ex post message game. Thus, the parties' inability to describe future actions or contingencies ex ante does not impose any additional restrictions on what can be implemented in a contractual message game.⁴⁷

In sum, even if unable to describe future contingencies and actions ex ante, parties who can foresee future payoffs can quite generally achieve efficiency with a sufficiently complicated contract, provided that renegotiation can be prevented.

3.6.2. Mechanism Design with Renegotiation

In reality, the parties may be able to renegotiate the contractual outcome when it is inefficient. This possibility can have dramatic effects on what can be achieved with complicated contracts. As an illustration, note that the ultimatum game prescribes an inefficient outcome $\hat{x}$ after agent 2 rejects the offer. Suppose that this outcome is always renegotiated to an efficient outcome, with agent 2 receiving share λ_2 of the renegotiation surplus. Anticipating such renegotiation, agent 2 will reject any stage-1 offer leaving him a smaller share of renegotiation surplus than λ_2 . Thus, the ultimatum game followed by renegotiation yields exactly the same outcome as does a noncontingent contract specifying property right $\hat{x}$ followed by renegotiation.

Segal and Whinston (2002) examine the power of general two-sided mechanisms (message games) under the assumption of Maskin and Moore (1999) that any inefficient outcome prescribed by the mechanism will be followed by efficient renegotiation. The role of the mechanism is thus to affect the division of surplus between the agents, which in turn affects the parties' ex ante investments. In particular, Segal and Whinston (2002) identify conditions under which a mechanism cannot improve upon simple (noncontingent) property rights followed by exogenous renegotiation.

Segal and Whinston's analysis can be explained heuristically as follows. Suppose that there is no uncertainty θ and that only one agent i chooses an investment $a \in A = [\underline{a}, \bar{a}] \subseteq \mathbb{R}$.

46. More generally, with quasi-linear utilities, using the three-stage mechanism of Moore and Repullo (1988), the agents' payoffs can be made to depend in any manner on the state (a, θ) , provided that agents' preferences vary across states. For example, with self-investments, the parties can always sustain the first best.

47. However, Segal (1999a: 68–72, 2012) identifies some settings in which an optimal mechanism requires filling in the names of a large number of possible ex post actions (unlike in the ultimatum game). In such settings, with a constraint on the length of ex post communication, the inability to name actions ex ante may indeed constrain contractual mechanisms and prevent any improvement upon an incomplete contract, such as the null contract or an authority contract in which one agent describes the outcome.

Following the investment, the two agents can send messages, and the mechanism prescribes an outcome (x, t_1, t_2) conditional on the messages, but it is always renegotiated according to the Nash bargaining solution. Let $V_i(a)$ denote agent i 's equilibrium utility in the mechanism following any investment choice a . (It is uniquely defined by the Minimax Theorem, because the mechanism defines a constant-sum game due to efficient renegotiation.) Segal and Whinston (2002) show that, provided that the agents' utilities satisfy some smoothness conditions and the space $\hat{X}$ of property rights is connected, $V_i(a)$ is differentiable almost everywhere, and its derivative takes the form

$$V'_i(a) = \frac{\partial u_i(x(a), a)}{\partial a} \quad (11)$$

for some allocation rule $x(\cdot) : A \rightarrow \hat{X}$. For mechanisms in which only one party sends a message (i.e., option mechanisms), this result follows from Mirrlees's (1971) classical Envelope-Theorem characterization of incentive compatibility (see also Milgrom and Segal 2002), and in addition, the allocation rule $x(\cdot)$ must then be nondecreasing if $u_i(\cdot)$ has increasing differences. Segal and Whinston (2002) show that the same formula must still hold for two-sided mechanisms, although the allocation rule can now be arbitrary.⁴⁸

To see how (11) implies the optimality of simple contracts, note that if a mechanism sustains investment $a^\circ \in (\underline{a}, \bar{a})$, agent i 's utility must satisfy the first-order condition $V'_i(a^\circ) = 0$. By (11), this first-order condition is preserved if we replace the mechanism with the noncontingent property rights allocation $\hat{x} = x(a^\circ)$. Thus, provided that agent i 's payoff is sufficiently concave in a , this noncontingent property rights allocation also sustains investment a° . Segal and Whinston (2002) show that the optimality of simple (noncontingent) property rights extends to a number of cases with uncertainty θ and multidimensional and/or two-sided investments, provided that the investments affect post-renegotiation payoffs through a one-dimensional state. They also identify additional settings in which noncontingent contracts can be improved upon by more complex contracts.

3.6.3. Irreversible Options and Renegotiation Design

Segal and Whinston's (2002) analysis of when mechanisms cannot strengthen incentives over noncontingent property rights hinges on the assumption that renegotiation can always occur after the mechanism is played. Noldeke and Schmidt (1995), Watson (2007), and Buzard and Watson (2012) instead consider cases in which one of the parties faces a technologically irreversible verifiable choice, and they show that this irreversibility can often be exploited to sustain first-best investments. For example, in the ultimatum game, suppose that agent 2's acceptance or rejection involves an irreversible choice of allocation x (e.g., there may be a deadline after which the asset is worthless). In that case, effective renegotiation is possible only

48. For continuous mechanisms, $x(a)$ is the allocation prescribed by the mechanism in equilibrium in state a . In general, however, $x(a)$ is a limit of off-equilibrium decisions prescribed by the mechanism when agents disagree but send reports close to a .

before agent 2's choice but not after. But note that renegotiation before agent 2's choice has no power, because her equilibrium choice is efficient.⁴⁹

Some other papers assume that while each agent has an irreversible option, she also has the choice to postpone exercising her option and continue bargaining (i.e., her option can be viewed as an "American" rather than "European" option). Such postponable irreversible options can be used to shift the division of bargaining surplus, mimicking the outcome of the ultimatum game. To understand the effect of such options, consider the following noncooperative infinite-horizon bargaining game, which is played *ex post* following the choice of investments a and the realization of uncertainty θ . Let $\bar{S} = S(a, \theta)$ denote the maximum available *ex post* surplus, and suppose that the parties have so-called outside option payoffs (o_1, o_2) and so-called disagreement payoffs (d_1, d_2) , such that $\max \{o_1 + o_2, d_1 + d_2\} \leq \bar{S}$.

Outside option bargaining game: In odd periods, agent 1 is the proposer and agent 2 the responder. In even periods, agent 2 is the proposer and agent 1 the responder. In each period, there are two stages:

Stage 1. The proposer offers a new contract, describing payoffs (s_1, s_2) to the two parties, with $s_1 + s_2 \leq \bar{S}$.

Stage 2. The responder accepts, rejects, or exercises her outside option. If the responder accepts, the game ends, and the agents receive payoffs (s_1, s_2) . If the responder exercises her outside option, the game ends, and the agents receive payoffs (o_1, o_2) . Otherwise, with probability $\delta \in (0, 1)$ the game proceeds to the next period, and with the complementary probability the game terminates, and the agents receive payoffs (d_1, d_2) .⁵⁰

Sutton (1986) shows that the unique subgame-perfect equilibrium expected payoffs of this game are

$$(u_1, u_2) = \begin{cases} (e_1, e_2) = \left(d_1 + \frac{1}{1+\delta} [\bar{S} - d_1 - d_2], d_2 + \frac{\delta}{1+\delta} [\bar{S} - d_1 - d_2] \right), & \text{if } (o_1, o_2) \leq (e_1, e_2), \\ (o_1, \bar{S} - o_1), & \text{if } o_1 > e_1, \\ (\bar{S} - o_2, o_2), & \text{if } o_2 > e_2. \end{cases}$$

49. Rubinstein and Wolinsky (1992) study a model of message games that proceed concurrently with renegotiation and find that if renegotiation occurs only after a one-period delay, then the same outcomes can be implemented as when renegotiation can only precede the game.

50. Equivalently, we can imagine that the game never terminates, but the agents are impatient and discount their future payoffs with discount factor δ , and that they receive flow payoffs $((1 - \delta) d_1, (1 - \delta) d_2)$ in every period before an agreement is reached or an outside option is exercised.

Allowing the proposer to exercise her outside option before proposing would not affect the game's equilibrium outcome (the option would not bind). Allowing the proposer to exercise her outside option after her proposal is rejected would give rise to multiplicity of subgame-perfect equilibria. In that case, by switching between equilibria to punish investment deviations, first-best investments can be sustained, as noted by Evans (2008). Note, however, that this finding relies on the parties being able to coordinate on the right continuation equilibrium, much as the Nash equilibrium considered at the start of Section 3.6.1 did.

In words, the parties split the renegotiation surplus over the disagreement point in proportion $\left(\frac{1}{1+\delta}, \frac{\delta}{1+\delta}\right)$ if neither agent's outside option binds. If one agent's outside option binds, he receives his outside option payoff, and the other agent receives the rest of the surplus (both parties' outside options cannot bind at once, because $e_1 + e_2 = \bar{S} \geq o_1 + o_2$). This conclusion is known as the *outside option principle*. As $\delta \rightarrow 1$, the first-mover advantage disappears, and the renegotiation surplus is split equally when the outside options do not bind.

Different papers make different assumptions about the nature of the agents' outside options and disagreement payoffs. First note that if both the outside options and the disagreement payoffs are given by the initial property rights, so that $(o_1, o_2) = (d_1, d_2)$, then outside options do not bind, and each agent i 's equilibrium payoff is $u_i = \bar{v}_i + \frac{1}{2}(\bar{S} - d_1 - d_2)$ as $\delta \rightarrow 1$. This is the standard noncooperative foundation for the Nash bargaining solution used in our previous model of renegotiation (Stahl 1972; Rubinstein 1982).

In contrast, Hart and Moore (1988), MacLeod and Malcomson (1993) and Aghion et al. (1994) examine situations in which the initial contract can have distinct effects on the parties' disagreement outcome and their outside options.⁵¹ One common feature of these papers is that it is possible to make one agent's—say, agent 2's—outside option very attractive relative to his disagreement payoff by entitling him to a large payment for exercising this option.⁵² As a result, agent 2's outside option binds, and letting x^o and p^o denote the resulting allocation and payment, respectively, outside option bargaining gives agent 1 the payoff $S(a, \theta) - v_2(x^o, a, \theta) - p^o$, mimicking the outcome of the ultimatum game with property rights allocation x^o . By Proposition 7, this outcome induces agent 1 to invest efficiently, provided that his investment has no direct externalities at x^o . This is true, in particular, in the case of self-investments. Furthermore, in Aghion et al. (1994), the outside option allocation x^o can be stipulated in the initial contract in a way that also provides agent 2 with the incentive to make an efficient self-investment, resulting in a first-best outcome.⁵³ In contrast, in Hart and Moore (1988) and MacLeod and Malcomson (1993), achieving the first best is generally impossible, because the contract cannot affect the outside-option allocation x^o (which represents either no trade or trade with outsiders) and can only affect the associated monetary payment.

Chiu (1998) and De Meza and Lockwood (1998) apply the same approach to examine the role of asset ownership under outside-option bargaining. They assume that asset ownership gives the owner an irreversible outside option to use her assets. Furthermore, they assume that asset use is not verifiable, so the exercise of outside options cannot be influenced by monetary rewards, such as financial hostages or breach penalties. In this case, one agent's outside option can still be made to bind by giving her the ownership of a sufficiently valuable asset, which

51. MacLeod and Malcomson (1993) postulate the outside option principle, whereas Hart and Moore (1988) postulate a noncooperative renegotiation game that differs from the one described above but yields the same outcome.

52. In Aghion and et al. (1994), the payment is interpreted as a financial hostage that agent 2 is entitled to receive back from agent 1; in Hart and Moore (1988) and MacLeod and Malcomson (1993), the payment is a breach penalty imposed on agent 1 by a court that cannot observe which party exercised its outside option.

53. The same result is obtained by Chung (1991), who allows the contract to shift bargaining power to one party rather than deriving this shift from the outside option principle.

induces the other agent to make an efficient self-investment, in contrast to the underinvestment that obtains when her outside option does not bind. This conclusion reverses the key finding of Hart and Moore (1990) that an agent's investment incentives are raised by asset ownership (see our Proposition 9). Also, in contrast to Hart and Moore (1990), the conclusion does not depend on whether the investment is asset specific. For example, the asset could be fully general (e.g., equivalent to a financial hostage). What is important is that its ownership gives an attractive unilateral option that forestalls any subsequent renegotiation.

The applicability of these theories depends on the availability of irreversible unilateral decisions. For example, if the use of an asset requires some irreversible modifications that rule out any alternative uses, we can think of this use as an outside option. If, instead, an agent can use the asset without modifying it while continuing to bargain with others regarding its alternative uses, then asset ownership defines the disagreement point, as in Hart and Moore's (1990) theory. In that case, option contracts are of limited benefit and often cannot improve upon simple property rights.

4. Property Rights and Bargaining Inefficiencies

The allocation of property rights can matter, even in the absence of noncontractible actions or investments, when these rights affect the efficiency of agreements reached by the parties. As noted in Section 1, in the simple allocation benchmark in which renegotiation is impossible, optimal property rights simply allocate assets to agents who value them the most in expectation. The same conclusion obtains if bargaining completely breaks down with an exogenous probability and is perfectly efficient with the complementary probability. However, a richer model of property rights emerges when property rights affect the probability and the extent of bargaining inefficiencies.

In this section we discuss the impact of property rights with two sources of bargaining imperfections—*asymmetric information* and *contracting externalities*. We can think of the parties bargaining either over a final allocation (as in stage 4 of the model described in Section 1) or over initial property rights (as in stage 1). In the latter interpretation, the parties' payoffs should be viewed as reduced-form payoffs that account for the effects of property rights on future noncontractible investments and/or bargaining. The analysis then shows how bargaining outcomes may differ from the optimal property rights identified in Sections 2 and 3. In such cases, legal rules defining *ex ante* property rights (prior to stage 1) and/or restricting the parties' abilities to strike bargains may affect efficiency, in contrast to the assertion of the Coase Theorem.

4.1. Asymmetric Information

One important reason negotiations may break down is *asymmetric information* (for another discussion of this issue, see Farrell 1987).

Example 7 Two agents may each use an asset for production. *Ex post* efficiency requires that the asset be owned by the agent who can use it most productively. Each agent i 's value from use θ_i is uncertain initially, is independently drawn from a uniform distribution on $[0, 1]$, and is known only by agent i .

The celebrated Myerson-Satterthwaite Theorem (Myerson and Satterthwaite 1983) states that efficient bargaining is impossible if the asset is initially owned by one agent.⁵⁴ Formally, their result follows from the finding that no efficient, incentive-compatible, interim individually rational, and budget-balanced mechanism exists in this setting, because any efficient (voluntary) bargaining procedure must have these four properties. Intuitively, efficient revelation of information requires that each agent appropriate the whole gains from trade, which is impossible. When each agent must instead share the gains from trade with the other agent, he has an incentive to understate these gains. Thus, the initial owner—the potential seller of the asset—has an incentive to overstate his valuation in negotiations, while the potential buyer of the asset has an incentive to understate his valuation. These incentives for misrepresentation inevitably lead to breakdowns in bargaining, where the asset remains in the hands of the agent with the lower value.

In contrast, efficient bargaining may be possible in this example for other property rights allocations. Cramton et al. (1987) consider the case in which property rights are divisible: for example, either the asset is perfectly divisible (with agent i 's property right providing him with payoff $\theta_i x_i$ when he owns fraction $x_i \in [0, 1]$) or randomized ownership is possible (where x_i is the probability of agent i owning the asset (with $x_1 + x_2 = 1$)).⁵⁵ They show that efficient bargaining is possible (i.e., there is an efficient, incentive-compatible, individually rational, and budget-balanced mechanism) provided that the agents start from an allocation of property rights (x_1, x_2) that is close enough to the equal allocation $(1/2, 1/2)$. Intuitively, intermediate ownership levels reduce the incentives for misrepresentation, because each agent does not know whether he will ultimately end up as a seller or a buyer of the asset.

4.1.1. A Characterization of When Efficient Bargaining Is Possible

We now formulate a model to investigate more generally which property rights permit efficient bargaining (generalizing the insight of Cramton et al. 1987) and which do not (generalizing the insight of Myerson and Satterthwaite 1983). The model covers as special cases a large number of settings considered in the literature.

Consider a set $\mathcal{N}$ of N of expected-utility maximizing agents whose utilities are quasi-linear in money. The agents' privately observed types are independently distributed random variables $\tilde{\theta}_1, \dots, \tilde{\theta}_N$ with values in the sets $\Theta_1, \dots, \Theta_N$.⁵⁶ The state space is thus $\Theta = \Pi_i \Theta_i$. The utility of each agent i is given by $u_i(x, \theta_i) + t_i$, where $t_i \in \mathbb{R}$ is the payment to the agent, $x \in X$ is the final allocation, and $\theta_i \in \Theta_i$ is the agent's type.⁵⁷ The total surplus given allocation x and state θ is $s(x, \theta) = \sum_i u_i(x, \theta_i)$, and the maximal available surplus in state θ is

54. The result holds more generally: efficient bargaining is impossible when each agent i 's value is drawn from a strictly increasing distribution function F_i on some set $[\underline{\theta}_i, \bar{\theta}_i]$ and $(\underline{\theta}_1, \bar{\theta}_1) \cap (\underline{\theta}_2, \bar{\theta}_2) \neq \emptyset$.

55. The agents must be able to bargain with each other before learning the outcome of the randomization.

56. Riordan (1990) and Schmidt (1996) assume that property rights directly affect the information structure, but here we assume that this structure is independent of property rights. In a hybrid model, Schmitz (2006) endogenizes the effect of property rights on noncontractible efforts to acquire private information.

57. Formally, we assume that the spaces $X, \Theta_1, \dots, \Theta_N$ are measurable, that X is a subset of a convex topological space, and that the functions $u_i : X \times \Theta_i \rightarrow \mathbb{R}$ are measurable and uniformly bounded (i.e., $\sup_{i, x \in X, \theta_i \in \Theta_i} |u_i(x, \theta_i)| < \infty$). The last two assumptions ensure that expectations exist and that the infima below are finite.

$S(\theta) = \max_{x \in X} s(x, \theta)$. An allocation rule $x^* : \Theta \rightarrow X$ is *efficient* if $s(x^*(\theta), \theta) = S(\theta)$ for all $\theta \in \Theta$. Throughout we shall assume that an efficient allocation rule $x^*(\cdot)$ exists.

Following Myerson and Satterthwaite (1983), the literature has adopted the following definition.

Definition 18 *The property rights allocation $\hat{x} \in X$ permits efficient bargaining if there exists a Bayesian incentive-compatible and interim individually rational mechanism implementing an efficient allocation rule in which the total payment to the agents is zero in all states.*

By the revelation principle, to see whether efficient bargaining is possible given an initial property rights allocation $\hat{x}$, we can focus on direct revelation mechanisms $\langle x^*, \tau \rangle$ with an efficient allocation rule $x^*(\cdot)$ and a payment rule $\tau : \Theta \rightarrow \mathbb{R}^N$. The Bayesian incentive compatibility and interim individual rationality constraints can be written as

$$E_{\tilde{\theta}_{-i}} \left[u_i(x^*(\theta_i, \tilde{\theta}_{-i}), \theta_i) + \tau_i(\theta_i, \tilde{\theta}_{-i}) \right] \geq E_{\tilde{\theta}_{-i}} \left[u_i(x^*(\theta'_i, \tilde{\theta}_{-i}), \theta_i) + \tau_i(\theta'_i, \tilde{\theta}_{-i}) \right] \quad (\text{IC})$$

for all $\theta_i, \theta'_i \in \Theta_i$

$$E_{\tilde{\theta}_{-i}} \left[u_i(x^*(\theta_i, \tilde{\theta}_{-i}), \theta_i) + \tau_i(\theta_i, \tilde{\theta}_{-i}) \right] \geq u_i(\hat{x}, \theta_i) \quad \text{for all } \theta_i \in \Theta_i. \quad (\text{IR})$$

Note that the property rights allocation $\hat{x}$ enters the IR constraints, determining agents' payoffs if bargaining breaks down (by an agent opting out of the mechanism).

It will prove convenient to focus on mechanisms with payments of the following form:

$$\tau_i(\theta | \hat{x}, \hat{\theta}_i) = \sum_{j \neq i} u_j(x^*(\theta), \theta_j) - K_i(\hat{x}, \hat{\theta}_i), \quad (12)$$

where $\hat{\theta}_i$ is some fixed type of agent i , and

$$K_i(\hat{x}, \hat{\theta}_i) = E_{\tilde{\theta}_{-i}} [S(\hat{\theta}_i, \tilde{\theta}_{-i})] - u_i(\hat{x}, \hat{\theta}_i). \quad (13)$$

Note that these payments describe a Vickrey-Clarke-Groves mechanism (see Mas-Colell et al. 1995; 876–882). The variable portion of the payment, $\sum_{j \neq i} u_j(x^*(\theta), \theta_j)$, causes each agent i to fully internalize her effect on aggregate surplus, thereby inducing her to announce her true type and implementing the efficient allocation rule $x^*(\cdot)$. The fixed participation fee K_i equals type $\hat{\theta}_i$'s expected gain from participating in the mechanism absent the fixed charge, so it causes that type's IR constraint to hold with equality. If we imagine that there is an intermediary in

For analyses in which types are interdependent, see Fieseler et al. (2003), Jehiel and Paudner (2006), and Segal and Whinston (2011). See Rahman (2010) for a model with correlated types.

charge of this trading process, her expected profit with this mechanism is given by

$$\begin{aligned}\pi(\hat{x}, \hat{\theta}) &= -E \left[\sum_i \tau_i(\tilde{\theta}|\hat{x}, \hat{\theta}_i) \right] \\ &= \sum_i \{E_{\tilde{\theta}_{-i}}[S(\hat{\theta}_i, \tilde{\theta}_{-i})] - u_i(\hat{x}, \hat{\theta}_i)\} - (N-1) E[S(\tilde{\theta})] \quad (14)\end{aligned}$$

$$= \sum_i E_{\tilde{\theta}_{-i}}[S(\hat{\theta}_i, \tilde{\theta}_{-i})] - s(\hat{x}, \hat{\theta}) - (N-1) E[S(\tilde{\theta})]. \quad (15)$$

To ensure that all types participate, the participation fee for each agent i can be at most $\inf_{\hat{\theta}_i \in \Theta} K_i(\hat{x}, \hat{\theta}_i)$, resulting in an expected profit for the intermediary of

$$\bar{\pi}(\hat{x}) = \inf_{\hat{\theta} \in \Theta} \pi(\hat{x}, \hat{\theta}). \quad (16)$$

The sign of this expected profit determines whether property rights allocation $\hat{x}$ permits efficient bargaining.⁵⁸

Lemma 3 (i) Any property rights allocation $\hat{x} \in X$ at which $\bar{\pi}(\hat{x}) \geq 0$ permits efficient bargaining. (ii) If, moreover, for each agent i , Θ_i is a smoothly connected subset of a Euclidean space, and $u_i(x, \theta_i)$ is differentiable in θ_i with a bounded gradient in θ_i on $X \times \Theta$, then property rights allocation $\hat{x} \in X$ permits efficient bargaining only if $\bar{\pi}(\hat{x}) \geq 0$.

4.1.2. Impossibility Results

Part (ii) of Lemma 3 can be used to show that efficient bargaining is impossible in some cases. For instance, consider Example 7 when one agent i initially owns the asset. Taking $\hat{\theta} = (\hat{\theta}_i, \hat{\theta}_{-i}) = (1, 0)$ —the types who never find it efficient to trade—we have $S(\hat{\theta}_i, \theta_{-i}) = s(\hat{x}, \hat{\theta}) = 1$ for all θ_{-i} and $S(\theta_i, \hat{\theta}_{-i}) = \theta_i$ for all θ_i . Thus, $\bar{\pi}(\hat{x}) \leq \pi(\hat{x}, \hat{\theta}) = E[\hat{\theta}_i - S(\tilde{\theta})] < 0$ when trade is efficient with a positive probability.

This impossibility argument can be extended to a number of settings where each agent has an “opt-out type,” for which it is efficient to keep the agent at his initial property rights allocation regardless of other agents’ types (if $N > 2$, it may still be efficient for the others to trade among themselves). Our exposition here draws on and extends unpublished work by Makowski and Ostroy (1989).

Let $X \subseteq \prod_i X_i$, where $x_i \in X_i$ represents the property rights allocation of agent i , and assume that there are no externalities at property rights $\hat{x}$ (i.e., that $u_i(\hat{x}_i, x_{-i}, \theta_i)$ does not depend on x_{-i}). As in Section 3.5, define the cooperative value of each coalition $T \subseteq \mathcal{N}$ given $\hat{x}$ when

58. Versions of this result appear, for example, in Makowski and Mezzetti (1994), Krishna and Perry (1998), Neeman (1999), Williams (1999), Che (2006), Schweizer (2006), Figueroa and Skreta (2008), and Segal and Whinston (2011, 2012b). Part (i) of Lemma 3 can be proven by building a budget-balanced mechanism as suggested by Arrow (1979) and d’Aspremont and Gérard-Varet (1979), and satisfying all agents’ participation constraints with appropriate lump-sum transfers. Part (ii) follows from the classical Revenue Equivalence Theorem.

its members' types are θ_T as the maximum joint surplus it can attain while holding outsiders at their status quos:

$$S_T(\hat{x}, \theta_T) = \sup_{x \in X: x_{-T} = \hat{x}_{-T}} \sum_{i \in T} u_i(x, \theta_i).$$

Definition 19 Given property rights $\hat{x} \in X$, type $\theta_i^\circ \in \Theta_i$ of agent i is an opt-out type if there is an efficient allocation rule $x^*(\cdot)$ such that $x_i^*(\theta_i^\circ, \theta_{-i}) = \hat{x}_i$ for all $\theta_{-i} \in \Theta_{-i}$.

In words, given property rights $\hat{x} = (\hat{x}_i, \hat{x}_{-i})$, agent i 's type θ_i° is an opt-out type if regardless of θ_{-i} it is efficient for agent i to get his initial ownership allocation $\hat{x}_i$. Note that when an opt-out type θ_i° exists, this is always the type with the smallest participation surplus $E_{\hat{\theta}_{-i}}[S(\hat{\theta}_i, \hat{\theta}_{-i})] - u_i(\hat{x}, \hat{\theta}_i)$ in the above mechanism, often called the agent's "critical type."

Lemma 4 For a given property rights allocation $\hat{x} \in X$, if type $\theta_i^\circ \in \Theta_i$ is an opt-out type for agent i , then it is also agent i 's critical type in any Vickrey-Clarke-Groves mechanism.

Proof Because θ_i° is an opt-out type, we can write $S(\theta_i^\circ, \theta_{-i}) = S_{N \setminus \{i\}}(\hat{x}, \theta_{-i}) + u_i(\hat{x}, \theta_i^\circ)$. Thus,

$$S(\theta_i^\circ, \theta_{-i}) - u_i(\hat{x}, \theta_i^\circ) = S_{N \setminus \{i\}}(\hat{x}, \theta_{-i}) \leq S(\theta_i, \theta_{-i}) - u_i(\hat{x}, \theta_i) \quad \text{for all } \theta_i,$$

where the inequality follows from the definitions of $S(\theta_i, \theta_{-i})$ and $S_{N \setminus \{i\}}(\hat{x}, \theta_{-i})$.⁵⁹

When every agent has an opt-out type $\hat{\theta}_i^\circ$, the profile of these critical types achieves the infimum in (16) (as an examination of (14) shows). In this case, the participation fee for each agent i is $K_i(\hat{x}, \hat{\theta}_i^\circ) = E_{\hat{\theta}_{-i}}[S(\hat{\theta}_i^\circ, \hat{\theta}_{-i})] - u_i(\hat{x}, \hat{\theta}_i^\circ) = S_{N \setminus \{i\}}(\hat{x}, \hat{\theta}_{-i})$. Substituting into (14), we see that when all agents have opt-out types, the expected profits (16) can be written as

$$\bar{\pi}(\hat{x}) = E \left[S(\tilde{\theta}) - \sum_i (S(\tilde{\theta}) - S_{N \setminus \{i\}}(\hat{x}, \tilde{\theta}_{-i})) \right]. \quad (17)$$

Thus, each agent i receives a payoff equal to his marginal contribution to the total surplus, $S(\theta) - S_{N \setminus \{i\}}(\hat{x}, \theta_{-i})$, and the intermediary collects the total surplus net of these marginal contributions. This profit can be shown to be negative, and efficient bargaining impossible, in a number of economic settings in which the core is nonempty.⁶⁰

59. Another way to understand why the opt-out type θ_i° is agent i 's critical type is by observing that any other type of agent i could get the opt-out type's expected participation surplus $E_{\hat{\theta}_{-i}}[\tau_i(\theta_i^\circ, \hat{\theta}_{-i})]$ by reporting θ_i° and receiving allocation $\hat{x}_i$.

60. Recall that, given an initial property rights allocation $\hat{x}$, $w \in \mathbb{R}^N$ is a core payoff vector in state θ if the payoff of every coalition of players is at least as large as what they can receive on their own; that is, $\sum_{i \in T} w_i \geq S_T(\hat{x}, \theta_T)$ for all $T \subseteq N$, with equality when $T = N$.

Proposition 15 *If at property rights allocation $\hat{x} \in X$ there are no externalities, each agent has an opt-out type, and the core is nonempty in all states and contains multiple payoffs with a positive probability, then property rights allocation $\hat{x}$ does not permit efficient bargaining.*

Proof If w is a core payoff vector in state θ , then using the core conditions for $T = \mathcal{N}$ and $T = \mathcal{N} \setminus \{i\}$ for all i , we have

$$\sum_i (S(\theta) - S_{\mathcal{N} \setminus \{i\}}(\hat{x}, \theta_{-i})) \geq \sum_i \left(\sum_j w_j - \sum_{j \neq i} w_j \right) = \sum_i w_i = S(\theta).$$

Furthermore, if there exist two distinct core payoff vectors in state θ , then in at least one of them the core inequality holds strictly for $T = \mathcal{N} \setminus \{i\}$ for some i , so the inequality in the above display is strict. Hence, under the assumptions of the proposition, the expected profit in (17) is negative.

The assumptions of Proposition 15 cover many classical economic settings. For one example, consider the double-auction setting of Williams (1999), in which there are N_s sellers with values drawn from a distribution on $[\underline{\theta}_s, \bar{\theta}_s]$ and N_b buyers with values drawn from a distribution on $[\underline{\theta}_b, \bar{\theta}_b]$ with $(\underline{\theta}_b, \bar{\theta}_b) \cap (\underline{\theta}_s, \bar{\theta}_s) \neq \emptyset$. Note that (i) a buyer of type $\underline{\theta}_b$ is an opt-out type if either $\underline{\theta}_b \leq \underline{\theta}_s$ or $N_b > N_s$, and (ii) a seller of type $\bar{\theta}_s$ is an opt-out type if either $\bar{\theta}_s \geq \bar{\theta}_b$ or $N_s > N_b$. Moreover, a competitive equilibrium exists in every state and is not unique with a positive probability. Because a competitive equilibrium is always in the core, Proposition 15 applies when both (i) and (ii) hold.⁶¹

Proposition 15 also applies to the public good setting of Mailath and Postlewaite (1990), in which each of N consumers' values is drawn from a distribution on $[0, \bar{\theta}]$, the cost of provision is $c > 0$, and the status quo property right is no provision ($\hat{x}_i = 0$ for all i). Letting $x_i \in \{0, 1\}$ denote whether agent i is given access to the public good and assuming a default of equal cost-sharing among the agents who have access to it, we have $u_i(x, \theta_i) = \theta_i - c / \sum_j x_j$ if $x_i = 1$, and $= 0$ otherwise. Thus, when $\hat{x} = 0$ we have no externalities, and each agent's type 0 is an opt-out type. Note that a Lindahl equilibrium exists in every state and is not unique with a positive probability. Because a Lindahl equilibrium is in the core, Proposition 15 applies.⁶²

61. The argument can also be extended to show impossibility when $N_b = N_s$. In this case, note that in an efficient allocation, any agent of type below $\underline{\theta} \equiv \max\{\underline{\theta}_s, \underline{\theta}_b\}$ receives an object with probability zero, so she is therefore indistinguishable from type $\underline{\theta}$, and any agent of type above $\bar{\theta} \equiv \min\{\bar{\theta}_s, \bar{\theta}_b\}$ receives an object with probability one, so she is therefore indistinguishable from type $\bar{\theta}$. Therefore, the profit in the mechanism must be the same as if all agents' types were instead distributed on the same interval $[\underline{\theta}, \bar{\theta}]$ (with possible atoms at its endpoints), in which case efficient bargaining is impossible by the argument given in the text.

62. Proposition 15 does not address the extent of bargaining inefficiencies or the form they take. These questions have been studied in a number of papers. Myerson and Satterthwaite (1983) and McKelvey and Page (2002) find that in certain settings, the inefficiencies exhibit a status quo bias: the final allocation lies between the initial and efficient allocations. Other papers examine the dependence of inefficiency on the number of agents. In the double-auction setting, Gresik and Satterthwaite (1989) find that the inefficiency in an ex ante optimal mechanism shrinks to zero as $N_b, N_s \rightarrow \infty$. Intuitively, this finding relates to the fact that the core converges (in

4.1.3. Efficiency-Permitting Property Rights Allocations

We now use Lemma 3 to investigate when efficiency is possible and which property rights allocations permit efficient bargaining. Segal and Whinston (2011) establish the following result.

Proposition 16 *Suppose that the total surplus $s(x, \theta)$ is convex in x for all $\theta \in \Theta$ and that $x^* : \Theta \rightarrow X$ is an efficient allocation rule. Then the initial property rights allocation $\hat{x} = E[x^*(\hat{\theta})] \in \hat{X}$, equal to the expected efficient allocation, permits efficient bargaining.*

For example, in the Cramton et al. (1987) model, in which all agents' valuations are drawn from the same distribution and their utilities are linear in the allocation x , the expected efficient allocation involves giving each agent an equal ownership share. But the result applies to cases with asymmetric valuations and to much more general allocation problems. Indeed, the result generalizes several previous results in the literature that establish the existence of an efficiency-permitting property rights allocation (Cramton et al. 1987; Schmitz 2002; Che 2006; Schweizer 2006; Gershkov and Schweitzer 2010; Yenmez 2012) and also points to a natural property rights allocation that achieves this goal: the expected efficient allocation.⁶³

To understand the result, recall that—ignoring IR—an efficient ex post allocation can be achieved with a Vickrey-Clarke-Groves mechanism. Furthermore, as noted by Arrow (1979) and d'Aspremont and Gérard-Varet (1979), the transfers in this mechanism can be modified to yield a balanced-budget mechanism (the expected externality mechanism) while preserving agents' incentives for truth telling (IC). Observe, however, that one way agent i could lie is by announcing randomly each of his possible types with their true probabilities. Doing so results in a random allocation with the same distribution as the efficient allocation. Because the agent never has an incentive to lie, this random outcome must be worse for every type of agent i than what he gets in the mechanism. Now, if agent i 's payoff is convex in the allocation, the expected efficient allocation must be even worse for him than this random outcome, ensuring that IR is satisfied when the initial property rights allocation is the expected efficient allocation. Using part (i) of Lemma 3, this conclusion can be extended to cases in which only the sum of the agents' payoffs, the surplus $s(x, \theta)$, is convex in the allocation x .

Of course, as originally seen in the Cramton et al. (1987) model, when efficient bargaining is possible, there are typically many property rights allocations that allow it.⁶⁴ For example, the expected efficient allocation typically differs from the property rights allocation that maximizes

probability) to the unique competitive equilibrium of the continuous limit economy; hence, in the limit the agents can fully appropriate their marginal contributions (as in Makowski and Ostroy 1989, 1995, 2001). In contrast, in the public good setting of Mailath and Postlewaite (1990), the core grows in relative size as $N \rightarrow \infty$, and inefficiency is exacerbated (in fact, the probability of providing the public good in any mechanism goes to zero).

63. In some cases, efficient noncontractible actions can also be sustained with this property rights allocation; see the discussion in Segal and Whinston (2011), which extends an insight of Rogerson (1992).

64. Indeed, this multiplicity typically obtains when $\bar{\pi}(E[x^*(\hat{\theta})]) > 0$, because $\bar{\pi}(\hat{x})$ is continuous in $\hat{x}$ as long as each $u_i(\cdot)$ is equicontinuous in x . Moreover, when the convexity assumptions of Proposition 16 hold, the intermediary's expected profit function $\bar{\pi}(\hat{x})$ is concave in $\hat{x}$, implying that the set $\hat{X}^*$ of property rights allocations permitting efficient bargaining is a nonempty convex set.

the intermediary's profit, $\hat{x}^* = \arg \max_{\hat{x} \in X} \bar{\pi}(\hat{x})$. The latter allocation is studied by Schmitz (2002: proof of proposition 3), Che (2006), Schweizer (2006), and Figueroa and Skreta (2008).

Note, however, that when the space of feasible property rights X is not convex, it may not contain an expected efficient allocation $E[x^*(\tilde{\theta})]$, in which case Proposition 16 does not apply and there may be no feasible property rights allocation permitting efficient bargaining. For example, in the setting of Example 7, when only extreme property rights allocations are feasible (agent 1 ownership or agent 2 ownership), neither permits efficient bargaining.⁶⁵ Even with a convex allocation space X , the assumption of convexity of the total surplus $s(x, \theta)$ in the allocation x is also crucial. Neeman (1999: 685) offers an example of bargaining over pollution, in which the convexity assumption fails and there is no efficiency-permitting property rights allocation.⁶⁶ In contrast, Segal and Whinston (2011) offer examples with concave payoffs in which efficient bargaining is still permitted by some property rights allocations (which may or may not include the expected efficient allocation).

Applying the Envelope Theorem to (16) using (15), we can see that $\nabla \bar{\pi}(\hat{x}) = -\nabla_x s(\hat{x}, \hat{\theta})$, so changes in property rights that reduce surplus at the critical types make efficient negotiation (which requires $\bar{\pi}(\hat{x}) \geq 0$) more likely. This result highlights an important difference between the role of property rights when we are concerned with bargaining efficiency under asymmetric information and their role when we are concerned with noncontractible investments. In the Hart and Moore (1990) model with noncontractible investments, increased ownership is good in that it encourages investments, which are in general below efficient levels. With asymmetric information bargaining, however, ownership is an impediment (as it was with cooperative investments in Section 3.4.2): efficiency is easiest to achieve when the parties have no claims at all to useful assets. Thus, for example, splitting up the ownership of complementary assets, so that no one can use them in the event of a disagreement, can enable efficient bargaining.⁶⁷

One can also ask which property rights are optimal when efficiency cannot be achieved, perhaps because the set of feasible property rights allocations is constrained in some way (e.g., in Example 7, the asset might have to be owned by a single agent, and we might ask which one should own it). The answer to this question may depend on the setting. When an outside agency will subsidize bargaining to achieve efficiency, the appropriate criterion would be maximization of the profit $\bar{\pi}(\hat{x})$. When no such agency exists, we may instead want property rights that maximize the expected surplus that can be achieved in a second-best (balanced-budget) mechanism. And if bargaining is impossible, it is instead best simply to maximize the expected disagreement surplus, as in the simple allocation benchmark. Matouschek (2004), in the first paper to consider second-best optimal property rights under asymmetric information bargaining, studies a model in which one agent is initially the owner of an asset x and there are later trade decisions q .

65. For other examples with a nonconvex decision space X in which there is no property rights allocation permitting efficient bargaining, see Ornelas and Turner (2007) and Turner (2008).

66. When simple property rights allocations cannot lead to efficiency, more complicated property rights mechanisms might be optimal. The legal literature, for example, has discussed the benefits of liability rules—which can be interpreted as options to own—relative to simple property rights (Ayes and Talley 1995; Kaplow and Shavell 1995–1996; Ayres 2005). For a formal analysis of liability rules, see Che (2006) and Segal and Whinston (2012b).

67. The benefit of having a default outcome for which the total surplus is low also arises in self-enforcing contracts, where the default is used as an off-equilibrium punishment, as discussed in Malcomson (this volume).

(There are no noncontractible actions a .) Trade decisions q cannot be specified ex ante, while ownership of the asset x cannot be renegotiated ex post. He analyzes how ownership of the asset should be allocated ex ante to maximize the expected surplus achieved in the best budget-balanced mechanism at the ex post bargaining stage. He finds that, depending on the parameters, the optimal property rights x will either maximize the total surplus at the disagreement point (as if no renegotiation were possible) or minimize it (as if renegotiation were possible over both x and q). In more recent work, Segal and Whinston (2012b) study second-best optimal property rights when the set of ex ante and ex post contractible decisions are the same (so $\hat{X} = X$), comparing the optimal property rights for settings with no ex post bargaining (the simple allocation benchmark of Section 1), bargaining subsidized by an outside agency, and second-best (budget-balanced) bargaining.

Finally, we note that the mechanism-design approaches taken in the above work may well adopt too optimistic a view of bargaining procedures. One response to this concern would be to study optimal property rights for specific suboptimal bargaining processes. Another would be to incorporate additional constraints in the mechanism-design approach.⁶⁸

4.2. Bilateral Contracting with Externalities

Even if bargaining over the ex post allocation of property rights occurs under symmetric information, inefficiency may nonetheless arise if there are more than two parties bargaining and they cannot write a single “grand” contract. When agents can write only bilateral contracts (i.e., make bilateral trades), they may fail to internalize externalities from their trades on others, yielding inefficient outcomes. In this section, we examine how the initial allocation of property rights affects their final allocation in such settings. The following example shows one situation in which such externalities can arise.

Example 8 (common agency model) Consider an extension of the agency model (Example 1) to the case of $N \geq 2$ principals. Suppose that the asset is divisible, and let $x_i \in [0, 1]$ denote the share of the asset held by each principal $i = 1, \dots, N$, with the remaining share $1 - \sum_{i=1}^N x_i$ held by the agent. Suppose that the asset’s values to the principals and the agent, $V_P(1 - \sum_{i=1}^N x_i)$ and $V_A(1 - \sum_{i=1}^N x_i)$, respectively, depend on the agent’s share. This dependence captures in reduced form the effects of the agent’s ownership on her noncontractible actions affecting the asset’s value. For instance, as in Example 1, holding a larger share of the asset may better incentivize the agent to enhance its value. Alternatively, the agent’s control rights stemming from her higher share may enable her to engage in value-reducing activities (e.g., looting, empire-building, or resisting value-enhancing takeovers). The agent’s resulting inalienable costs (or negative benefits) from these activities are represented by $C(1 - \sum_{i=1}^N x_i)$. As for the

68. One sense in which the approach described here may be too optimistic is in the IR and IC constraints it assumes. Because an agent may be able to walk away from a deal at the last moment, an ex post IR constraint may make more sense. Galavotti et al. (2011) identifies some cases in which efficiency can be achieved when ex post IR is required. For example, in the setting of Example 7, he shows that equal ownership permits efficient bargaining in this stronger (ex post IR) sense. Compte and Jehiel (2007) suggest that an even stronger constraint might be appropriate if agents can lie and then quit.

principals' inalienable benefits (Y), we assume them to be zero. Therefore, the parties' payoffs exclusive of transfers take the form

$$U_A(x_1, \dots, x_N) = \left(1 - \sum_{i=1}^N x_i\right) V_A \left(1 - \sum_{i=1}^N x_i\right) - C \left(1 - \sum_{i=1}^N x_i\right)$$

$$U_i(x_1, \dots, x_N) = x_i V_P \left(1 - \sum_{i=1}^N x_i\right) \quad \text{for } i = 1, \dots, N.$$

These payoffs exhibit externalities from asset ownership when the asset's public value V_P depends on the agent's ownership share. By selling or buying shares from a principal, the agent imposes externalities on every other principal i for whom $x_i > 0$.

Externalities from bilateral contracts may arise from many underlying forces other than those identified in the example. For example, they may arise when the parties subsequently bargain and the initial bilateral contracts affect the division of subsequent bargaining surplus (see, e.g., Segal 2003a; Gans 2005; Elliott 2009). Many other examples of externalities are discussed in Segal (1999b). Here, we incorporate the externalities in reduced-form payoffs, subsuming any noncontractible actions or bargaining that generate these externalities.

Many possible bargaining procedures could arise in these settings. Here we focus on the very simple contracting game considered in Segal (1999b), in which one agent makes simultaneous take-it-or-leave-it bilateral contracting offers to $N \geq 2$ other agents. This game illustrates the role of property rights in these environments, although it lacks some of the richness of outcomes that arise in more dynamic processes of bargaining with externalities that have been studied (e.g., Jehiel and Moldovanu 1999; Bloch and Gomes 2006; Gomes and Jehiel 2005).⁶⁹

A key feature of this contracting game turns out to be whether commitment to a set of publicly observed contract offers is possible—that is, whether the offers are publicly or privately made.

4.2.1. Public Offers

Suppose that one party, agent 0 (the proposer), can contract with N other agents labeled $i = 1, \dots, N$ (the responders). Each responder i 's final property rights allocation is denoted by $x_i \in X_i$, and the overall allocation $x = (x_1, \dots, x_N) \in X = \prod_{i=1}^N X_i$ determines each agent's nonmonetary utility $U_i(x)$ for $i = 0, 1, \dots, N$ (the proposer's property rights are the residual available given those of the responders). The initial allocation of property rights, the status quo, is $\hat{x} \in X$. Let X^* denote the set of allocations maximizing the total surplus of the $N + 1$ parties, $\sum_{i=0}^N U_i(x)$.

In this section we analyze the following two-stage game: In the first stage, agent 0 publicly proposes a pair (x_i, t_i) to each other agent i , naming the responder's final property rights allocation x_i and a transfer t_i . In the second stage, those agents simultaneously respond, either

69. A distinct literature on bargaining inefficiencies under full information takes a coalitional approach—see Ray (2007) for a survey. This approach allows each agent to enter into one contract (coalition) at a time, whereas in Example 8 and the model of this section, one of the agents could simultaneously write separate contracts with different agents.

accepting or rejecting their respective offers. We study the proposer's preferred subgame-perfect Nash equilibrium (SPNE) of the game.⁷⁰

Because the proposer can always make the status quo offer $(x_i, t_i) = (\hat{x}_i, 0)$ to agent i , without loss of generality we can restrict attention to equilibria in which all offers are accepted, which occurs if and only if

$$U_i(x) + t_i \geq U_i(\hat{x}_i, x_{-i}) \quad \text{for all } i \in 1, \dots, N. \quad (18)$$

The right-hand side of (18) is the reservation utility of responder i , that is, the utility he gets by rejecting his offer, provided that everyone else accepts. In the proposer's preferred SPNE, all responders' participation constraints must bind (otherwise she could reduce some payments while preserving the constraints). Expressing transfers from the binding constraints and substituting them in the proposer's objective function, her profit-maximizing property rights offers given the initial property rights allocation $\hat{x}$ can be defined as

$$X_{pub}^\circ(\hat{x}) = \arg \max_{x \in X} \sum_{i=0}^N U_i(x) - \sum_{i=1}^N U_i(\hat{x}_i, x_{-i}). \quad (19)$$

Note that the proposer's objective function differs from the total surplus by its last term, the sum of the responders' reservation utilities, which depends on the initial property rights allocation. As a result, the proposer's incentive to deviate from efficiency arises precisely when she can harm the other agents at their status quos. This observation leads to the following definition and result.⁷¹

Definition 20 *There are no harmful externalities on agent $i = 1, \dots, N$ at allocation $x \in X$ if $U_i(x) \leq U_i(x_i, x'_{-i})$ for all $x'_{-i} \in X_{-i}$; these externalities are absent if $U_i(x_i, x'_{-i})$ does not depend on $x'_{-i} \in X_{-i}$.*

Proposition 17 *If $x^* \in X^*$ and there are no harmful externalities on each agent $i \geq 1$ at allocation $(\hat{x}_i, x_{-i}^*)$, then $x^* \in X_{pub}^\circ(\hat{x}) \subseteq X^*$.⁷² If externalities on all agents are absent at the status quo $\hat{x}$, then $X_{pub}^\circ(\hat{x}) = X^*$.*

Proof For each $x^\circ \in X_{pub}^\circ(\hat{x})$, condition (19) implies that

$$\sum_{i=0}^N U_i(x^\circ) - \sum_{i=1}^N U_i(\hat{x}_i, x_{-i}^\circ) \geq \sum_{i=0}^N U_i(x^*) - \sum_{i=1}^N U_i(\hat{x}_i, x_{-i}^*). \quad (20)$$

70. Under some conditions, the game may have more than one SPNE, and the equilibrium preferred by the responders may differ from that preferred by the proposer. See Segal (2003b) for conditions in which multiple equilibria arise and an analysis of equilibria preferred by the responders.

71. Propositions 17 and 19 generalize results from Segal (1999b) to the case of nonharmful externalities.

72. It is enough for this result to assume that $\sum_{i=1}^N U_i(\hat{x}_i, x_{-i})$ is minimized at $x = x^*$.

By nonharmful externalities, we have $U_i(\hat{x}_i, x_{-i}^\circ) \geq U_i(\hat{x}_i, x_{-i}^*)$ for all $i \geq 1$; hence, (20) implies that $x^\circ \in X^*$. Moreover, for any such $x^* \in X^*$, nonharmful externalities imply that

$$\sum_{i=0}^N U_i(x^*) - \sum_{i=1}^N U_i(\hat{x}_i, x_{-i}^*) \geq \sum_{i=0}^N U_i(x') - \sum_{i=1}^N U_i(\hat{x}_i, x'_{-i}) \quad \text{for all } x' \in X,$$

so $x^* \in X_{pub}^\circ(\hat{x})$. Finally, if externalities are absent at $\hat{x}$, then they are nonharmful at $(\hat{x}_i, x_{-i}^*)$ for any $x^* \in X^*$, which implies that $X^* \subseteq X_{pub}^\circ(\hat{x}) \subseteq X^*$.

The result states that when, given initial property rights $\hat{x}$, the proposer can maximize the total surplus while at the same time minimizing the agents' reservation utilities, this is optimal for her, and any equilibrium outcome must do so. For instance, in the common agency model (Example 8), externalities are absent when the agent is the proposer and initially owns the entire asset ($\hat{x} = 0$). In contrast, when externalities are present at any status quo, efficiency cannot be attained, because the proposer has an incentive to distort the allocation to reduce the sum of agents' reservation utilities. Segal (1999b) shows that the effect of this rent-seeking motivation on the contracting outcome x depends on the sign of these externalities: when efficiency depends only on the aggregate allocation $\sum_i x_i$ as in Example 8 (and a domain restriction holds), positive (negative) externalities on reservation utilities imply that the allocation is too low (high).⁷³ Note in particular that if the status quo is efficient but has externalities, the final allocation may be inefficient, so bargaining may actually reduce aggregate welfare.

4.2.2. Private Offers

Now consider what happens when the proposer cannot publicly commit. Various contracting games in which the proposer does not have commitment power have been considered in the literature. Here we simply modify the observability in the two-stage game to make the offers private. Each responder $i = 1, \dots, N$ observes the offer (x_i, t_i) made to him but not the offers made to the other responders. (Note that because an equilibrium outcome must still satisfy participation constraints (18), this private observability can only hurt the proposer, agent 0.)

Each responder's acceptance decision in this game depends on his beliefs about offers extended to other agents. In a perfect Bayesian equilibrium, arbitrary beliefs can be assigned following the proposer's out-of-equilibrium offers, which gives rise to enormous multiplicity of equilibria. To make a more precise prediction, Segal (1999b) follows Cr  mer and Riordan (1987), Hart and Tirole (1990), and McAfee and Schwartz (1994) in assuming so-called passive beliefs: even after observing an unexpected offer from the proposer, a responder continues to believe that other responders have received their equilibrium offers.

73. For example, note that increasing the status quo in Example 8 from $\hat{x} = 0$ to $\hat{x} > 0$ will increase or decrease the final allocation, depending on the sign of externalities at $\hat{x}$.

This inefficiency is eliminated if the principal can make an offer conditional on the acceptance of all agents, while implementing maximal punishment following anyone's rejection (as with conditional tender offers in takeovers). However, Segal (1999b) shows that when the number of agents is large and their acceptances are subject to noise, the power of such conditional offers to make individual agents pivotal vanishes, and the same inefficiencies obtain as with bilateral contracting.

Consider the proposer's incentive to deviate from an equilibrium allocation x° . Because she can always make agent i the offer $(x_i, t_i) = (\hat{x}_i, 0)$, without loss of generality, we can restrict attention to deviations in which all responders accept their offers. When responder i holds passive beliefs, he accepts an offer (x_i, t_i) if and only if $U_i(x_i, x_{-i}^\circ) + t_i \geq U_i(\hat{x}_i, x_{-i}^\circ)$. The proposer's optimal deviation maximizes her payoff subject to these participation constraints, which always bind at her optimal offers. Expressing transfers from the binding constraints and substituting them into the objective function, we find that x° is an equilibrium allocation if and only if⁷⁴

$$x^\circ \in \arg \max_{x \in X} U_0(x) + \sum_{i=1}^N U_i(x_i, x_{-i}^\circ). \quad (21)$$

Letting X_{pr}° denote the set of property rights x° satisfying (21), our first observation is the following.

Proposition 18 *The set X_{pr}° of equilibrium property rights allocations with private offers does not depend on the initial property rights allocation $\hat{x}$.*

Although this irrelevance of initial property rights is reminiscent of the Coase Theorem, the contracting outcome with externalities may be inefficient. This inefficiency can be traced to externalities at efficient allocations. When externalities at an efficient allocation are nonharmful, private contracting yields efficient outcomes, regardless of any externalities at other allocations.

Proposition 19 *If there exists $x^* \in X^*$ at which externalities are nonharmful, then $X_{pr}^\circ \subseteq X^*$.*

Proof For any $x^\circ \in X_{pr}^\circ$, condition (21) and nonharmful externalities at x^* imply that

$$\sum_{i=0}^N U_i(x^\circ) \geq U_0(x^*) + \sum_{i=1}^N U_i(x_i^*, x_{-i}^\circ) \geq \sum_{i=0}^N U_i(x^*).$$

Therefore, $x^\circ \in X^*$.

For an application, consider the common agency model (Example 8) under the assumption that it is efficient to have $x = 0$ (full agent ownership). Then any contracting outcome with private offers must be efficient, regardless of the property rights allocation. Contrast this to the public offers setting, where the bargaining outcome may be inefficient due to externalities at the initial property rights allocation when $\hat{x} \neq 0$.

74. The condition implies (but is stronger than) the condition

$$x_i^\circ \in \arg \max_{x_i \in X_i} [U_0(x_i, x_{-i}^\circ) + U_i(x_i, x_{-i}^\circ)] \quad \text{for all } i \geq 1,$$

which is called "contract equilibrium" by Crémer and Riordan (1987) and "pairwise proofness" by McAfee and Schwartz (1994). The nonemptiness of X_{pr}° is only ensured under additional assumptions (see Segal 1999b: 384–386), and all subsequent results will be vacuous (but formally correct) when X_{pr}° is empty.

When externalities are present at all efficient allocations, they must distort the contracting outcome. Segal (1999b) shows that when efficiency depends only on the aggregate allocation $\sum_i x_i$ (and a domain restriction holds), this aggregate allocation is too low (high) when there are positive (negative) externalities at any efficient allocation. To compare this outcome to that under public offers, note that, with private offers and passive beliefs, the proposer can no longer influence the responders' reservation utilities, but she also ceases to internalize the externalities on responders' equilibrium payoffs from changes in the proposed allocation. So the noninternalized externalities are now those at equilibrium allocations rather than the status quo allocation. Depending on the comparison of these externalities, one contracting regime may be more or less efficient than the other.

Although we have focused on a simple two-stage contracting game, similar results on bargaining inefficiencies have been obtained for infinite-horizon games with frequent recontracting. Thus, in Jehiel and Moldovanu (1999) and Gomes and Jehiel (2005), any allocation can be renegotiated very soon, and because of this lack of commitment, the game's equilibrium outcomes are similar to those of the two-stage game with private offers (in particular, they obtain results similar to Propositions 18 and 19).⁷⁵ In contrast, Bloch and Gomes (2006) consider a game in which agents can exercise irreversible outside options during bargaining (as in Section 3.6.3), and the inefficiencies are due to externalities on these outside options, as in the two-stage public-offers game.

5. Conclusion

The importance of property rights for reducing externalities, improving incentives, and achieving more efficient outcomes has been noted for centuries. However, the subject of property rights received renewed attention following the suggestion of Grossman and Hart (1986) and Hart and Moore (1990) that property rights over assets can be used to define boundaries of firms. Since then, much progress has been made in applying game-theoretic tools to study property rights. Still, much remains to be learned.

One area where more work would be useful is the examination of optimal property rights when the first best cannot be achieved, both in hold-up models and in models of inefficient bargaining (as well as in hybrid models that include both features). In addition, work that examines the determinants of optimal property rights in models with more structure on the actual decisions being made (e.g., in Alonso et al. 2008; Rantakari 2008) would be welcome.

A better understanding of the reasons property rights are used instead of more complete contracts is of great importance. In most existing models of property rights, they can be improved on by more complicated contracts. The literature on "foundations of incomplete contracts" (discussed in Section 3.6) identified some assumptions under which more complicated mechanisms cannot improve on simple property rights. However, this literature also finds that the optimal arrangement is sensitive to very fine technological details, such as the degree to which choices

75. Segal and Whinston (2003) examine the set of equilibrium outcomes in a class of bargaining games without commitment, allowing for arbitrary beliefs. In their model, the proposer may be able to benefit from offering more complicated mechanisms (specifically, menus from which the proposer will later choose) because of their ability to influence responders' beliefs. They show that in many cases in which externalities are present at the efficient property rights allocation, inefficiencies must arise in all equilibria when such menus can be used.

are irrevocable or which mechanisms would be enforced by courts. In reality, these details may not be known with great precision by market participants.⁷⁶ One advantage of simple contracts, such as property rights, over more complicated contracts may be that their performance could be more robust to features of the environment. This robustness is particularly important for complex environments. On the one hand, in complex environments the agents may have many ways to game a complicated contract, so simple contracts can emerge as being optimal (e.g., Segal 1999a). On the other hand, complicated contracts in complex environments may be prohibitively costly to write or execute because of contracting or communication costs (e.g., Segal 2012) or cognitive limitations.

Another issue is that property rights over assets are only one of many ways incentives are provided in large firms or other organizations. Other incentive instruments include decision rights that are not tied to assets, for example, authority over people (see Bolton and Dewatripont, this volume), compensation schemes (Mookherjee, this volume), relational incentives (Gibbons and Henderson, this volume; Malcomson, this volume), and promotions (Waldman, this volume). One view is that in large firms, property rights do not play a central role. For example, shareholders hold property rights, but effective rights of control seem to reside with top management. One reason for this may be that managers' superior information gives them "real authority" over the decisions (Aghion and Tirole 1997). Yet, changes in the boundaries of large firms—that is, changes in property rights—often seem to lead to changes in many of these other instruments. For example, when one firm acquires another, which firm is the acquirer does appear to matter (e.g., the CEO of the acquired firm, while often given a top job at the time of acquisition, often seems to leave unhappily not long after, and the business of the acquired firm often withers). So property rights may indeed matter, but they are filtered through the decision rights that are conveyed to management. (Alternatively, the identity of the acquirer may matter simply because its managers are in control.)

Finally, it is important to understand how the predictions of the theories outlined here match facts with regard to both the effects of property rights on incentives and the determination of property rights. Different theories do give rise to distinct predictions, but the distinctions often hinge on such features as the relative importance of various kinds of investments, which can be difficult to assess empirically (see, e.g., the discussion in Whinston 2003). In particular, even though there exists a substantial literature testing the predictions of transactions cost economics (see Tadelis and Williamson, this volume), only recently have papers been published that try to test some theories surveyed in this chapter (e.g., Baker and Hubbard 2003, 2004; Elfenbein and Lerner 2003). Much more work on this front is needed.

Transaction Cost Economics

Steven Tadelis and Oliver E. Williamson

1. Introduction

The study of the governance of economic organization has become a lively and diverse field of research over the past four decades. This chapter describes the fundamental ideas of transaction cost economics (TCE) as these evolved in the 1970s and since to offer a methodology through which to analyze how the governance of economic organization has economizing consequences. Our view, as well as the general outlook of TCE, is that organization matters for economists if and as organization is made susceptible to analysis by the application of economic reasoning.

As such, TCE is part of a broader effort to study the economics of organization, which includes agency and/or mechanism-design theory, team theory, property rights theory, and resource-based and/or competency theories. Many of these are explored in this handbook and, as appropriate, we make references to the similarities and difference between them and TCE. Lest we be misunderstood, we do not regard TCE as an all-purpose theory of firm and market organization. Instead, we subscribe to pluralism—on the conditions that all candidate theories (1) name the phenomena to which they apply and (2) derive refutable implications that lend themselves to empirical testing. Subject to these provisos, we are certain that a richer, deeper, better understanding of complex economic organization is well served by the spirit of pluralism.

We begin in Section 2 by sketching early contributions on which TCE builds, and we describe how TCE differs from the orthodoxy of the 1960s in three crucial respects: moving from the *lens of choice* to the *lens of contract*; taking *adaptation* to be the main problem of economic organization; and taking *transaction cost economizing* to be the main case for deriving refutable implications.

In Section 3 we lay out the working parts by which TCE was transformed into an operational methodology by taking the make-or-buy decision to be the focal transaction. We thereafter introduce the proposition that transactions, which differ in their attributes, will be implemented

We thank Bob Gibbons, Jon Levin, and John Roberts for helpful comments on previous drafts, as well as Tarek Ghani for providing excellent research assistance. Financial support from National Science Foundation grant SES-0239844 is gratefully acknowledged.

by different modes of governance, which differ in their adaptive strengths and weaknesses. Section 4 presents a simple formal model of TCE that parallels the less formal arguments of Section 3, with emphasis on how the choice of governance elicits different contractual incentives. Extensions and applications—including hybrid contracting, reality testing, variations on a theme, empirical TCE, and ramifications for public policy—are sketched in Section 5. Section 6 relates TCE to other economic theories of organization. Section 7 concludes.

2. Background and Essential Ideas

TCE traces its origins to a series of developments between 1930 and 1970 in economics (Commons 1932; Coase 1937, 1960; Hayek 1945; Simon 1951; Arrow 1969), organization theory (Barnard 1938; Simon 1947; Selznick 1949), contract law (Llewellyn 1931; Summers 1969), and business history (Chandler 1962). Because this chapter is mainly directed to an economics audience and organization theory, contract law, and business history are addressed elsewhere,¹ we focus in this section, as well as in this chapter, mainly on the economic arguments.

2.1. Transactions and Transaction Costs

Albeit largely ignored in textbook microeconomic theory, John R. Commons early perceived the need to move beyond simple market exchange (e.g., exchanging nuts for berries on the edge of the forest or buying a can of coke at a vending machine) to include transactions for which the continuity of an exchange relationship was often important. He furthermore described the fundamental problem of economic organization as follows: “the ultimate unit of activity . . . must contain in itself the three principles of conflict, mutuality, and order. This unit is a transaction” (Commons 1932: 4). As developed in Section 3, TCE concurs that the transaction is the basic unit of analysis and treats governance as the means by which to infuse order, thereby to mitigate conflict and realize mutual gain.²

Ronald Coase, in his classic 1937 paper “The Nature of the Firm,” both introduced the concept of transaction costs to the study of firm and market organization³ and uncovered a serious lapse in the accepted textbook theory of firm and market organization. Upon viewing firm and market as “alternative methods of coordinating production” (Coase 1937: 388), Coase observed that the decision to use one mode rather than the other should not be taken as given (as was the prevailing practice) but should be derived. Accordingly, economists were advised

to bridge what appears to be a gap in [standard] economic theory between the assumption (made for some purposes) that resources are allocated by means of the price mechanism

1. On organization theory, contract law, and business history, see Williamson (1993, 2005a, and 1985: 273–297, respectively).

2. Whereas Commons viewed organization and the continuity of contractual relations as important, the economic paradigm of resource allocation, which dominated the field all through the 1970s, made negligible provision for either. Instead, it focused on prices and output, supply and demand. The institutional economics of the 1930s was mainly relegated to the history of thought because it failed to advance a positive research agenda that was replete with predictions and empirical testing.

3. Though Coase did not use the term “transaction costs” in his 1937 article, he did suggest that employment relations were especially susceptible to transaction costs.

and the assumption (made for other purposes) that that allocation is dependent on the entrepreneur-coordinator. We have to explain the basis on which, in practice, this choice between alternatives is effected. [Coase 1937: 389]

Although this challenge was ignored over the next 20 years, two important articles in the 1960s would upset this dismissive state of affairs. Upon pushing the logic of zero transaction costs to completion, the unforeseen and disconcerting implications of the standard assumption of zero transaction cost were displayed for all to see.

Coase's 1960 article "The Problem of Social Cost" reformulated the externality problem in contractual terms and pushed the logic of zero transaction cost reasoning to completion, with an astonishing result: "Pigou's conclusion (and that of most economists of that era) that some kind of government action (usually the imposition of taxes) was required to restrain those whose actions had harmful effects on others (often termed negative externalities)" was incorrect (Coase 1992: 717). That is because with zero transaction costs, parties will costlessly bargain to an efficient result whichever way property rights are assigned at the outset. In that event, externalities and frictions of other kinds would vanish. But the real message was this: hereafter, "study the world of positive transaction costs" (Coase 1992: 717). Kenneth Arrow's 1969 examination "The Organization of Economic Activity: Issues Pertinent to the Choice of Market versus Nonmarket Allocation" likewise revealed a need to make a place for positive transaction costs, both with respect to market failures and in conjunction with intermediate product market contracting: "the existence of vertical integration may suggest that the costs of operating competitive markets are not zero, as is usually assumed in our theoretical analysis" (Arrow 1969: 48).

Introducing positive transaction costs, however, posed three problems. First, upon opening the "black box" of firm and market organization and looking inside, the black box turned out to be Pandora's Box: positive transaction costs were perceived to be everywhere. Because some form of transaction cost could be invoked to explain any condition whatsoever after the fact, the appeal to transaction costs acquired a "well deserved bad name" (Fischer 1977: 322). Second, transaction costs take on comparative institutional significance only as they can be shown to differ among modes of governance (say, as between markets and hierarchies). Third, transaction costs that pass the test of comparative contractual significance need to be embedded in a conceptual framework from which predictions can be derived and empirically tested. The unmet need was to focus attention on key features and provide operational content for the intriguing concept of positive transaction costs.

2.2. Governance and the Lens of Contract

James Buchanan (1975: 225) distinguished between the lens of choice and lens of contract approaches to economic organization and argued that economics as a discipline went "wrong" in its preoccupation with the science of choice and the optimization apparatus associated therewith. If "mutuality of advantage from voluntary exchange is . . . the most fundamental of all understandings in economics" (Buchanan 2001: 29), then the lens of contract approach is an underused perspective. Thus, to analyze the inner working of such institutions as markets and hierarchies, the orthodox lens of choice (the resource allocation paradigm, with emphasis on prices and output, supply and demand) would need to give way to the evolving lens of

contract. This position was implicit in Commons (1932) and Coase (1937) and was explicit in Coase (1960) and Arrow (1969). Upon examining governance and organization through the lens of contract, the firm was no longer a black box for transforming inputs into outputs according to the laws of technology but was interpreted instead as an alternative mode of contracting.

Indeed, this shift to the lens of contract was adopted not only by TCE but also more generally—in mechanism design, agency theory, information economics, and formal property rights theory. But there were also differences (described in more detail in Section 6). Whereas the aforementioned theories located the analytical action in the *ex ante* incentive alignment stage of contract, TCE concentrated the main action in the *ex post* governance of contractual relations. This emphasis on *ex post* governance is congruent with TCE's taking adaptation to be the main problem of economic organization.

2.3. Adaptation as the Central Problem

Hayek (1945) suggested that “economic problems arise always and only in consequence of change” (1945: 523), whereupon “rapid adaptation to changes in the particular circumstances of time and place” was taken to be the main problem of economic organization (1945: 524). Interestingly, Chester Barnard (1938), who was an organization theorist rather than an economist, likewise regarded adaptation as the central problem of organization. But while Barnard and Hayek were in agreement on the importance of adaptation, each had reference to different types of adaptation.

Hayek focused on the adaptations of autonomous economic actors who adjusted spontaneously to changes in the market, mainly as signaled by changes in relative prices. An illustrative recent example is the increase in the demand for fossil fuels that caused gasoline prices to rise sharply in 2008. As a result, automobile firms adapted their strategies to invest in alternative-energy vehicles and create new products, which in turn will affect the demand for fuel. Prices will shift to equilibrate the new choices, and consumers and producers will adapt their consumption and production behavior as part of the equilibrium. The marvel of the market thus resides in “how little the individual participants need to know to be able to take the right action” (Hayek 1945: 526–527).

In contrast, Barnard featured coordinated adaptation among economic actors working through administration. In his view, the marvel of hierarchy is that coordinated adaptation is accomplished not spontaneously but in a “conscious, deliberate, purposeful” way through administration (Barnard 1938: 4). As an illustration, Boeing experienced major malcoordination problems in 2007, because its outside suppliers were preoccupied and sometimes overwhelmed with their own problems to the neglect of Boeing's systems concerns. Serious delays in the production of their most important future aircraft, the 787 Dreamliner, resulted. Boeing, in effect, bet on the efficacy of outsourcing on a scale that they had never previously attempted, to the neglect of the benefits of ongoing coordinated adaptation to which Barnard ascribed to hierarchy. The problem was relieved when Boeing acquired the fuselage supplier in the summer of 2009.

TCE takes adaptation to be the central problem of economic organization and makes provision for both autonomous and coordinated adaptations. The “marvel of the market” (Hayek) and the “marvel of hierarchy” (Barnard) are now therefore joined. The upshot is that the old

ideological divide of markets or hierarchies now gives way to the combined use of markets and hierarchies.

2.4. Efficiency

TCE holds that adaptations of both kinds are undertaken principally in the service of efficiency. Specifically, the choice among alternative modes of governance mainly has the purpose of economizing on transaction costs.

However, although TCE claims that nonstandard and unfamiliar contracting practices mainly operate in the service of efficiency, other purposes, of which market dominance (monopoly) is one, are sometimes responsible for nonstandard practices. Making allowance for monopoly is very different, however, than presuming that monopoly is mainly responsible for nonstandard and unfamiliar contracting practices and modes of organization. As discussed in Section 5.5, this preoccupation with monopoly was wrongheaded and gave rise to convoluted antitrust enforcement, which in the 1960s sometimes spun out of control.

3. Making TCE Operational: Vertical Integration

As developed elsewhere (Williamson 1971, 1975, 1985, 1991), and as described in this section, TCE was made operational by taking three basic steps. First, it took the transaction to be the basic unit of analysis and named the key attributes across which transactions differ. Second, it described the properties of alternative modes of governance. Third, these two were joined by applying the discriminating alignment hypothesis: different kinds of transactions are more efficiently governed by different modes of governance (see Section 3.3).

Conceivably, these ideas could be implemented in the abstract. But rather than develop a general theory from the outset, TCE was built from the ground up by examining the particulars. Taking vertical integration (more generally, the intermediate product market transaction—the make-or-buy decision) to be the focal transaction led quickly and easily to an interpretation of many other phenomena as variations on a theme.

The other obvious candidate to serve as a focal transaction was the employment relation (as in Coase 1937; Simon 1951). Although both of these papers were influential, the employment relation never led to a theory of firm and market organization where other transactions were interpreted as variations on a theme. One possible reason is that the employment contract possessed “peculiarities . . . that distinguish it from other types of contracts” (Simon, 1951: 293). Indeed Coase, in the first of his lectures at the conference organized in 1987 to celebrate the fiftieth anniversary of his 1937 paper, identified a “weakness in my [1937] exposition . . . that hampered further developments” (1988: 37). Specifically, “the main weakness of my article stems from use of the employer-employee relationship . . . [in that it both] gives an incomplete picture of the nature of the firm . . . [and] more important . . . it misdirects attention” (Coase 1988: 37).⁴

4. Coase appealed to labor law to support the primacy of labor: because “the fact of direction is the essence of the legal concept of ‘employer and employee’ just as it was in the economic concept which was developed above . . . [we can] conclude that the definition we have given is one which approximates closely to the firm as it is considered in the real world” (1937: 404).

Once a focal transaction has been decided, the three key operational moves are to (1) name the attributes of the unit of analysis, (2) do the same for modes of governance, and (3) advance the efficient alignment hypothesis.

3.1. Unit of Analysis: Classifying Transaction Attributes

The obvious place to start is with the ideal transaction of simple market exchange where identity does not matter and the terms of trade are completely specified. Competition and market-mediated exchange can be presumed to prevail in such circumstances. A simple example would be the market for standard thread screws, but any well-defined, standardized commodity that is readily and competitively supplied through anonymous spot market transactions will do.

Whereas simple market exchange works well for transactions where identity does not matter, transactions where identity does matter pose complications for which added governance might be warranted. Longer term contracts for which the parties value continuity come under scrutiny in this way.

3.1.1. *Asset Specificity and the Fundamental Transformation*

TCE gave early prominence to the relatively neglected condition of *asset specificity*, which became a crucial defining attribute of transactions. Asset specificity describes the condition where the identity of the parties matters for the continuity of a relationship. It can take a variety of forms—physical, human, site specific, dedicated, brand name capital, and episodic (sometimes described as temporal specificity)—the optimal response to which varies somewhat but involves greater reliance on “administration.” Whatever the form, these assets cannot be redeployed to alternative uses or users without loss of productive value (Williamson 1971, 1975, 1976, 1985; Klein et al. 1978). Although asset specificity is often purposeful, it can also arise spontaneously, without conscious and costly investments, as with knowledge and skills that are incidentally acquired by the parties while working together.

By transaction-specific assets we mean ones for which a *bilateral dependency relationship develops between the parties*. Even though a large number of qualified suppliers could compete for the initial contract, investments in transaction-specific assets made by the initial winning bidder, either at the outset or during contract implementation, effectively transforms this large numbers bidding competition into a small numbers supply relationship thereafter. A *fundamental transformation* in the contractual relation thus sets in as bilateral dependency builds up.⁵ Identity thereafter matters.

3.1.2. *Uncertainty, Complexity, and Incomplete Contracts*

Asset specificity, in any of its forms, does not by itself pose contractual hazards that require nonmarket governance. In principle, a long-term contract could stipulate how future contingent decisions will be made and proper compensation accomplished. In fact, contractual hazards arise if and as long-term contracts *are incomplete* (by reason of the prohibitive cost [Dye 1985; Bajari and Tadelis 2001] or the impossibility of contractual completeness) and are subject

5. Note that because asset specificity is a design variable, the good or service to be delivered could be redesigned by reducing asset-specific features, albeit at a sacrifice in performance of the good or service in question (Riordan and Williamson 1995).

to (1) disturbances (or contingencies) during the contract implementation phase for which (2) defection from the spirit of cooperation to insist on the letter of the contract can be projected for outliers (where the stakes are great), and (3) inability of the courts to fill gaps and settle disputes in a timely, knowledgeable, and efficient fashion.

Accordingly, in addition to a condition of bilateral dependency (a consequence of asset specificity), factors that contribute to contractual hazards for which added governance measures can sometimes provide relief include (1) uncertainty and contractual incompleteness,⁶ (2) strategic defection (when the stakes are large), and (3) the serious limits of court ordering. On the assumption that contractual incompleteness, strategic propensities, and the limits of court ordering are all consequential, *asset specificity and disturbances for which unprogrammed adaptations are needed* are the key attributes of transactions for understanding the governance of contractual relations.⁷

3.2. Governance Structures

Problems with outsourcing become more severe as assets become more specific and contracts more incomplete. An obvious solution is to introduce governance safeguards that mitigate these contractual hazards. This poses the challenge of naming and describing alternative modes of governance and explaining the strengths and weaknesses that are associated with each. Following our discussion in Section 2, we focus principally on the two conventional polar modes of governance—markets (“buy”) and hierarchies (“make”).

TCE maintains that each polar mode of governance—market and hierarchy—is described as an internally consistent pattern of attributes that describe its core adaptive competence. Although Williamson (1985, 1991, 2010) makes provision for three main attributes by which to describe each mode of governance—(1) *incentive intensity* (which is measured by the extent to which a technologically separable stage of economic activity appropriates its net profits), (2) *administrative authority and control* (which has a bearing on the autonomy of a stage in both operating and investment respects as well as on procedural controls [routines, accounting procedures]), and (3) *contract law regime*—our focus in this chapter, especially in the formal model of Section 4, is on the first two attributes: incentive intensity and administrative control.⁸

6. Incompleteness becomes more severe as the number of features of transactions (precision, linkages, compatibility) across which adaptations are needed increases and as the number of consequential disturbances that impinge on these features increases. These features can be thought of as a measure of complexity (see Section 4.1.2).

7. A related factor, which we pass over here because of its ambiguous implications, is the frequency with which transactions recur. On the one hand, if a transaction seldom recurs, it may not be cost effective to develop a specialized internal structure. If instead it recurs frequently, then recovering the costs of creating a specialized management infrastructure is possible. On the other hand, recurrent contracting implies that future business is at stake, for which a good reputation figures in. Market contracting, if supported by good-reputation effects, thus becomes part of the comparative contractual calculus.

8. The important consideration of supporting legal regimes is set aside due to the challenge of modeling this aspect of governance. By and large the formal literature—be it mechanism design or the property rights approach—assumes that whatever is contractually verifiable will be enforced by some unmodeled third party. In this regard one can view this chapter as a bit schizophrenic: we recognize here that contract law regime can and will vary along with the choice of governance, yet in Section 4 we follow the standard modeling approach and focus only on incentive intensity and administrative control.

Assuming that incentive intensity and administrative control can take on either of two values, strong or weak, we describe the market mode (independent ownership) as having strong incentive intensity within each stage and weak administrative controls at the contractual interface, whereas hierarchy (unified ownership) has weak incentives within each stage and strong administrative control at the interface. Recall, moreover, that TCE takes the main problem of economic organization to be that of adaptation, of which autonomous and coordinated adaptation are distinguished. The decision of which transactions are organized by which mode of governance thus turns on how the attributes of different transactions pose different adaptation needs, on the one hand, and how alternative modes of governance are, by reason of their attribute differences, well or poorly qualified to respond to different adaptation needs, on the other.

Getting this balance “right” is what efficient alignment is all about. Specifically, the market mode is superior for dealing with transactions of the generic kind for which autonomous adaptations suffice (the so-called marvel of the market; Hayek 1945), whereas transactions where the parties are bilaterally dependent benefit from coordinated adaptation (the “marvel of hierarchy”; Barnard 1938).

With respect to this last point, note that low-powered incentives in firms are not to be thought of as a cost of hierarchy (bureaucracy burdens aside, see Section 5.2) but as a purposeful attribute of hierarchy without which coordinated adaptation would be compromised. To repeat, low-powered incentives in combination with administrative control at the interface (as implemented by the interface coordinator, as shown in Figure 1) are what hierarchy is all about. There is a place for each generic mode, and each should be kept in its place.

Note that two other configurations can be described. Strong incentives at each stage and strong administrative control at the interface is an inconsistent combination that leads to conflict. Strong incentives are accomplished if each stage has claims on its own net receipts. Strong administrative control accomplishes cooperative adaptation at the interface, provided that compliance by each stage can be presumed—which entails the sacrifice by each stage of claims on its own net receipts.

Weak incentives at each stage and weak administrative control at the interface lead to what is more akin to noncommercial organization. It is approximated among commercial firms by cost-plus outside procurement where, within some bounds, the supplier does what the buyer asks because it is assured of reimbursement, although some auditing by the buyer will usually attend such relations.⁹ Table 1 summarizes the four implied governance modes.¹⁰

As stated above, market-mediated exchange takes place between independently owned and operated stages, whereas hierarchy-mediated exchange is accomplished by unified ownership and coordinated interface mediation. These operating differences are truly consequential and warrant elaboration.

9. For a formal treatment of relative benefit of cost-plus contracts over fixed price contracts with respect to adaptation, see Bajari and Tadelis (2001).

10. To briefly relate legal rules to the choices of incentives and administrative control, a contract law regime must be supportive of the attribute that is strong (incentive intensity or administrative control). For strong incentives to be effective, parties should have control over their processes and the letter of the contract should be expected to be enforced (strong legal rules). In contrast, the forbearance law contract regime (private ordering with weak legal rules) is supportive of strong administrative control, because interference by courts would undermine the efficacy of control by fiat. For more, see Williamson (1991).

**Table 1.** Alternative modes of governance

Administrative Control	Incentive intensity	
	Strong	Weak
Weak	Market (buy)	Cost-plus contracts (less common)
Strong	Recipe for conflict (empty)	Hierarchy (make)

The upper and lower panels of Figure 1 illustrate how market and hierarchy differ in mediating the exchange between successive stages of production with respect to trading, adaptation, and dispute settlement. The upper panel corresponds to market-mediated exchange where the supplier receives a fixed payment for delivery of the prescribed goods and services, changes require renegotiation, and disputes are dealt with by courts, which apply the appropriate legal rule to award monetary damages. The parties to simple market exchange play hard ball.

In contrast, coordinated adaptation under hierarchy, as shown in the lower panel of Figure 1, is promoted by unified ownership of the two stages coupled with the creation of a new actor, *the interface coordinator*, to whom each stage reports and receives administrative direction and control. Consequential disturbances that would give rise to poor coordination are dealt with by the interface coordinator, who has ultimate responsibility for coordinated responses; internal disputes between stages are likewise settled by the interface coordinator with reference to mutual gain (private ordering).¹¹

3.3. Efficient Alignment

The *discriminating alignment hypothesis* to which TCE owes much of its predictive content is this: transactions, which differ in their attributes, are aligned with governance structures, which differ in their adaptive capacities, so as to realize an efficient result. Note that (1) markets enjoy the advantage of autonomous adaptation for transactions that are supported by generic assets, (2) the importance of coordinated adaptation increases as the supporting assets become more specific, and (3) the loss of incentive intensity and the bureaucratic costs of hierarchy are a deterrent to integration except when coordinated adaptation benefits are more than offsetting.

Figure 2 further illustrates the trade-offs using σ as an index of asset specificity. Efficient alignment is accomplished by assigning transactions for which asset specificity is low to markets and transactions for which asset specificity is high to hierarchy.¹²

The previously discussed adaptation differences that distinguish market and hierarchy (where the market has the advantage for autonomous adaptations and hierarchy has the advantage for coordinated adaptations) are implicit in Figure 2.

Thus, the market enjoys the advantage when asset specificity is negligible (σ close to 0), because the disturbances for which adaptations are needed are signaled by changes in relative prices to which buyers and sellers respond autonomously (the “marvel of the market”). The use of hierarchy in these circumstances would entail a loss of incentive intensity, and the added costs of mediating the interface with a coordinator (as shown in Figure 1) would be quite without purpose.

The affirmative case for unified ownership of successive stages builds up as bilateral dependency progressively increases due to asset specificity (increases in σ). Because the need for coordinated adaptations now presents itself, unified ownership becomes the governance structure of choice for values of σ that exceed σ^* .

Note, moreover, that the associated lowering of incentives is not an unwanted consequence of unified ownership but is purposeful—it predisposes each stage to respond cooperatively to a succession of adaptive needs as perceived by the interface coordinator. This lowering of internal incentives nevertheless incurs added bureaucratic costs and reduces productive efficiency. For one thing, because the pecuniary rewards that attend autonomous adaptation are absent, the

11. To tie this discussion briefly to legal rules and regimes, the efficacy of internal dispute resolution and of coordinated adaptations, as decided by the interface coordinator, would be severely compromised if disgruntled managers could go over the coordinators’ heads and appeal to the courts. In effect, the firm is its own court of ultimate appeal.

12. In this binary setup, transactions for which asset specificity is in the neighborhood of σ^* can go either way, because it does not matter very much; but see the discussion of hybrids in Section 5.1.

Figure 2. Efficient governance.

individual stages have less incentive to be diligent. And there are system consequences as well. As additional stages are integrated, the oversight and control of the operating units by the top management is compromised. Sometimes this can be mitigated by organizational innovations, of which the move from a unitary to a multidivisional structure—as discussed by Chandler (1962) and interpreted by TCE in efficiency terms (Williamson 1981)—is an example.

Note, however, that whereas TCE can help to interpret the efficiency benefits that accrue to major changes in the structure of bureaucracy in large corporations, organization form differences are not matters that TCE can address as variations on the basic contractual theme of which vertical integration is the paradigmatic case. As this *Handbook* demonstrates, economic organization is a big house—to which TCE relates but is not an all-purpose construction.

3.4. The Impossibility of Combining Replication with Selective Intervention

Sections 3.1–3.3 outline the main logic of TCE as applied to the make-or-buy problem. We discuss here a related but different puzzle posed by Frank Knight (1921) and Ronald Coase (1937): Why can't a large firm do everything that a collection of smaller firms can do and more? Tracy Lewis (1983: 1092) argues that an established firm can always realize greater value because it can “utilize the input exactly as the entrant would have used it . . . [and can furthermore] improve on this by coordinating production from his new and existing inputs.” TCE takes exception with this argument by examining the efficacy of the two mechanisms on which Lewis's formulation implicitly relies: *replication* and *selective intervention*.

Imagine, without loss, that the buyer stage acquires the supplier stage with the understanding that (1) the supplier will operate in the same autonomous way post-acquisition as in the pre-acquisition status (by replication) except when (2) the buyer intervenes selectively, because expected net gains can be achieved through coordinated adaptations. The combined firm can then never do worse (by replication) and will sometimes do better (by selective intervention). Therefore, more integration is always better than less, and repeating this logic implies that everything will be organized in one large firm.

This logic breaks down upon examining four implicit assumptions on which the implementation of replication and selective intervention rely: (1) the buyer (owner) promises the acquired

supplier its net receipts in all state realizations, thereby preserving strong incentives; (2) the supplier promises to use the supply-stage assets that the buyer now owns with due care; (3) the buyer promises to exercise authority (*fiat*) only when expected net gains can be ascribed to selective intervention; and (4) the buyer promises to reveal and divide the net gains from selective intervention as stipulated in the original agreement. The problem is that none of these promises is self-enforcing. To the contrary, in the absence of perfect information (to include a costless arbiter), each condition will be compromised. An elaboration on why each of the four conditions above fails is reported elsewhere (Williamson 1985: 135–139).¹³

Note the recurrent theme: the action resides in the application of a focused lens to identify and examine the mechanisms of alternative modes of economic organization in a comparative institutional way—which reveals that markets and hierarchies differ in discrete structural respects, each with its strengths and weaknesses.

4. A Simple Model of Governance

Building on Tadelis (2002), we construct a model of contractual choice that parallels the arguments in Section 3. Despite its extreme reduced form, the model relies on microfoundations developed by Grossman and Hart (1986), Holmström and Milgrom (1991), and Bajari and Tadelis (2001).¹⁴ The model contributes by exposing complementarities between cost incentives and governance that help clarify the underpinnings of the TCE framework outlined in Section 3.

The model parallels Section 3 in that (1) exchange takes place between successive (technologically separable) stages of production; (2) spot markets aside, all contracts are incomplete to varying degrees; (3) the critical attributes of transactions are asset specificity and contractual incompleteness (disturbances), where the former is responsible for bilateral dependency and the latter creates the adaptive need; (4) if the parties are independent and if a disturbance occurs for which the contract is not adequate, adaptation is accomplished by renegotiation and/or court ordering; and (5) efficiency is served by aligning transactions with governance structures in a way that economizes on transaction costs.

To simplify, however, there are two differences between the formal model and Section 3 that are worth noting, and more discussion will follow. First, adaptation costs are incurred only by the buyer. (The efficient alignment result does not depend on this asymmetry.) Second, asset specificity is treated as a probability of finding an alternative seller without incurring adaptation costs, rather than as an actual loss in surplus if the seller is replaced. This is done for simplicity purposes.

13. Contributing factors include (1) the owner (buyer) controls the accounting system and, within limits, can declare depreciation, transfer prices, and benefits so as to shift net receipts to its advantage; (2) failures of due care become known only with delay and are difficult to prove; (3) the buyer can also falsely declare state realizations to favor its own stream of net receipts; and (4) in consideration of the foregoing, the division of benefits under selective intervention can be compromised. Also, (5) the political game is now played in a larger firm that is more susceptible to bureaucratic ploys and political positioning than in smaller firms. Suffice it to observe that the breakdowns to which we refer are not beyond the grasp of intelligent businessmen and their lawyers, who recognize the trade-offs and factor them into the integration calculus.

14. An early step in formalizing TCE can be found in Riordan and Williamson (1985).

4.1. Transactions and Governance

Consider a transaction where a buyer achieves value $v > 0$ if it procures a good (or service) from a supplier and successfully incorporates it into its own output. The transaction is characterized by the degrees of asset specificity and contractual incompleteness.

4.1.1. Asset Specificity

Recall from Section 3.1.1 that asset specificity can manifest itself in several ways: physical, human, site, dedicated assets, and brand name capital. Asset specificity can arise from both purposeful investments and spontaneously, where the latter takes the form of knowledge and skills that are incidentally acquired by the parties while working together. Whatever the form, these assets cannot be redeployed to alternative uses and users without some loss of productive value.

Asset specificity is modeled by $\sigma \in [0, 1]$, where higher values of σ represent higher degrees of asset specificity. It will be technically convenient to interpret σ as the probability that the supplier cannot be replaced by a competitor when disturbances occur, and adaptation costs will be incurred. With probability $(1 - \sigma)$, however, there exists an alternative supplier who will compete to perform any adaptations that are needed, and adaptation costs will be avoided.

Though we believe that more asset specificity does imply that more value is lost when an alternative supplier is used, from an ex ante perspective the probabilistic nature of our measure of asset specificity is equivalent: when σ is higher, the expected loss from having to switch suppliers will be larger, making the fundamental transformation more severe.

4.1.2. Complexity and Incomplete Contracts

Let $\rho \in [0, 1]$ be the probability that the contract will need to be renegotiated due to a significant disturbance, at which point the contract's ex ante design will fail to achieve the value v . In this event, ex post adaptation at some extra cost will be needed to achieve v .¹⁵ Bajari and Tadelis (2001) consider a model where it is possible to invest more or fewer resources in design ex ante, making design (i.e., contractual incompleteness) an endogenous variable that responds to project complexity. They show that transactions characterized by higher degrees of exogenous complexity result in endogenously chosen contracts that are more incomplete. We thus treat ρ as exogenous and interpret it as the *contractual incompleteness* of the transaction, a characteristic discussed in Section 3.1.2, where higher values of ρ correspond to transactions with higher degrees of contractual incompleteness.¹⁶

4.1.3. Markets and Hierarchies

Two modes of governance are considered: market and hierarchy. Recall from Section 3.2 that TCE identifies markets with two features: high-powered cost incentives and retention of administrative control by each party. In contrast, hierarchy is identified with low-powered cost incentives and the parties relinquishing administrative control to an interface coordinator. We

15. For simplicity we keep v constant, so that any loss from adaptation is captured by adaptation costs, to be defined precisely later.

16. In addition to design costs there are also costs of measuring whether performance was met as planned, which are another form of transaction costs (see Barzel 1982).

proceed to formally define market versus hierarchy using only one of these attributes: the assignment of administrative control over production and adaptation processes. The strength of incentives will be endogenously derived.¹⁷

Define market governance M to be the choice in which each party retains autonomy over its own production process decisions, and the supplier is expected to deliver a product that meets the contractual specifications. Any adaptation to adjust the *ex ante* design due to disturbances needs to be renegotiated by the autonomous parties. For simplicity, we assume that adaptation will be required only for the supplier's production process. Our asymmetric treatment of disturbances simplifies the analysis and offers a first step in formalizing the ideas described in Section 3. Naturally, the buyer may have to adapt its process to accommodate some disturbances as well. Symmetric disturbances on both sides of the transaction will result in a more cumbersome analysis, obscuring the main insights.

Define hierarchy H to be the choice in which the parties relinquish administrative control to a third party, the interface coordinator. Thus, routine tasks are followed as planned, but when disturbances arise, the decisions are made by the interface coordinator, who possesses unified ownership and control over production and adaptation for both stages of buyer and supplier.

It is important to note that our notion of hierarchy as unified control and coordinated adaptation differs from a directional integration argument of whether the buyer integrates the supplier into its business and becomes the interface coordinator, or the reverse, which is a novel and central feature of the Property Rights Theory (PRT) that is presented in Segal and Whinston (this volume). In contrast, our notion of integration assigns responsibility for implementing routines to the managers at each stage, whereas disturbances for which coordinated adaptations are required are done at the direction of the interface coordinator (see Figure 1). TCE identifies this interface coordinator as often being a third party whose incentives are aligned with total profit maximization. That is, instead of a preexisting buyer and supplier, the transaction is a *de novo* investment whose governance needs to be determined. Efficiency considerations will determine whether the transaction is integrated (controlled by an interface coordinator) or not integrated (controlled by the contract and mutually agreed-upon adaptations). PRT, in contrast, identifies integration with the situation in which one of the two parties becomes the owner of all productive assets and controls the decisions related to their use. The predictions of PRT are as much about which of the two parties maintains control as about when unified ownership is called for.

Aside from the allocation of administrative control, a compensation scheme that the buyer (or interface coordinator) uses to compensate the supplier must also be chosen as part of the interfirm contract (or intrafirm compensation scheme). This scheme will influence the supplier's incentives to reduce costs. Denote the supplier's production costs by c , which includes material and other expenses (lost opportunities, possibly the wages of laborers under its direction, etc.). We restrict attention to linear compensation schemes that have a fixed component F and a share of production costs $(1 - z) \in [0, 1]$. A supplier that incurs cost c is paid $F + (1 - z)c$, where $z \in [0, 1]$ is the share of production costs that are borne by the supplier, often referred to as the

17. The model ignores conflict resolution law and follows the common approach in contract theory that the courts will enforce whatever the contract stipulates. This approach is also taken by Grossman and Hart (1986). It is important to note, however, that current business law, which is very much commensurate with the brief description in Section 3.3, would further strengthen the conclusions of our theoretical modeling exercise.

“strength” of cost incentives that the supplier faces. For example, if $z = 1$ and $F > 0$, then the supplier receives a fixed-price payment of F and bears all the production costs, which seems to be the norm for almost all market transactions. The supplier will have strong incentives to reduce production costs. In contrast, if $z = 0$ and $F > 0$, then a cost-plus contract is in place where the supplier receives some fixed compensation F and bears none of the production costs c , which seems to be the case for most hierarchical structures (of course, in this case the chosen level of F will be different from the case in which $z = 1$). The supplier has no gain from engaging in activities that reduce production costs. Both F and z will be endogenously chosen in our analysis.

4.2. Production Costs

The supplier's production costs are given by the function $c(e, G) = \bar{c} - Ge$, where $e \geq 0$ is the effort intensity that the supplier puts into the project, and $G \in \{M, H\}$ denotes the mode of governance, where $M > H > 0$. Effort is the extra time and attention that the supplier puts into directing production of other employees, into choosing production alternatives that reduce costs, and so forth. The (opportunity) cost to the supplier of effort e is equal to $y(e)$, where $y'(e) > 0$, $y''(e) > 0$, and $y'''(e) \leq 0$.¹⁸ To guarantee an interior solution to the seller's optimization problem we assume that $y'(0) = 0$. We also impose the standard agency assumption that contracting on effort is impossible.

As is apparent, we assume that more effort reduces production costs, and effort is more effective in reducing production costs when market governance is chosen. This assumption seems intuitive because decisions about how to produce or adapt the production process are an input into this process. If the supplier has complete control of its production process, then the ability to control all the inputs, including effort and decisions, should make the supplier more effective at cutting costs. If, however, decisions are in the hands of the interface coordinator, then the supplier's lack of autonomy will make its effort less effective.¹⁹

In addition to its intuitive appeal, the assumption that effort is more effective when the supplier maintains control has some established microfoundations.²⁰ Note also that this assumption

18. As shown in the proof of our main proposition, this last condition is sufficient but not necessary for monotone comparative statics.

19. Expanding the model to have buyer effort and a role for buyer incentives is easy, with each stage's effort being more effective for that stage when the stage has control over all aspects of production. Our asymmetric simplification relates this to the supplier stage alone.

20. First, Grossman and Hart (1986) model ex post decisions that need to be made after a state of nature is realized, yet contingent contracts cannot be written ex ante. The state of nature is very much like our ex post disturbances that are not contracted for. If the decisions themselves affect the way in which effort reduces production costs, then when the supplier controls both decisions and effort, it is better able to reduce its costs. Ownership of productive assets—as defined by PRT—gives the supplier control over the allocation of productive assets ex post, and this makes its cost-reducing effort more effective. Indeed, this assumption is our parallel of assumption 6 in Hart and Moore (1990). Second, our assumption is also consistent with the models of Holmström and Milgrom (1991, 1994). They show that the supplier's effort may be misdirected when it does not own the productive assets, where ownership is associated with having control over the use and sale of assets. If the productive assets are not owned by the supplier, then it will not necessarily take the asset's long run value into account, imposing additional long-run costs on production. (This idea is discussed explicitly in Williamson 1985: 137–138.)

is about a marginal reaction, namely, the effect of the allocation of administrative control on the slope of the cost function with respect to effort, which is a common assumption in the PRT literature.²¹

4.3. Adaptation Costs

If a disturbance occurs, then additional costly adaptations must be made to obtain the value v . Adaptation costs can have at least two sources. The first involves activities that were wasted and redone, or modifying initially planned production processes that fit the original design. These adaptation costs stem from contractual incompleteness and could have been spared if a complete contract and accurate design were in place. The second source of adaptation costs results from haggling, rent seeking, and other renegotiation costs that parties expend to get a better deal, which are a pure dead-weight loss.²² We are agnostic as to which of these two sources of adaptation costs dominates, and we aggregate them together as total adaptation costs, denoted by $k(z, G) > 0$.

Adaptation costs are incurred if and only if two events happen. First, a disturbance must happen, which occurs with probability ρ , the incompleteness of the contract. Second, a new supplier from the competitive market cannot do the work, which occurs with probability σ , our measure of specificity. Indeed, if the required adaptation is not specific, then other suppliers can compete to perform the adaptation, and no loss from haggling will occur.

We simplify and assume that adaptation costs are borne only by the buyer. We can easily have the supplier also bear some adaptation costs, which would add symmetry to the problem of adaptation without changing the qualitative results.²³ We also assume that $v - k(z, G) > 0$, implying that adaptation costs are worth incurring ex post to achieve v . Hence, the expected gross benefit from the transaction is given by $v - \rho\sigma k(z, G) > 0$, and expected adaptation costs are increasing in both contractual incompleteness ρ and asset specificity σ .²⁴

21. Thus, we make use of the method developed by Grossman and Hart (1986) to model the effect of administrative control. They modeled changes in the ownership of assets as changing the marginal effect of effort. Even though the driving forces and economic insights that we derive are different than those in PRT, the PRT modeling method will prove useful in formalizing the original ideas developed by TCE.

22. These haggling costs can be generated from a rent seeking game in the spirit of Tullock (1980) or Skaperdas (1992). As a simple example, imagine that the surplus to be split is 10 and that without hiring lawyers, a court (or arbitrator) would direct the parties to split the surplus equally. Assume that if a party hires a lawyer to argue in court, then it would get $3/4$ of the surplus if the other party has no lawyer, but symmetrically, would get $1/2$ of the surplus if the other party has a lawyer. If the lawyer costs are $k < 2.5$, then this game is a prisoner's dilemma in which hiring a lawyer is a dominant strategy, the parties split the 10 equally, but each pays k and is left with $5 - k$. Hence, as far as the relationship is considered, rents were dissipated. This idea is explored in Ashenfelter and Bloom (1993), who show that parties to disputes indeed have an incentive to engage in legal representation, which suggests that some excessive legal expenses are incurred.

23. For instance, if ex ante competition pushes expected rents ex ante to zero, then any adaptation costs (or renegotiation income) that the supplier expects to spend (or gain) will be incorporated into his bid and will fall back on the buyer (see, e.g., Bajari et al. 2012).

24. One can model the effects of adaptation as lowering the payoff v to some $v' < v$, above and beyond any additional adaptation costs of k , as in Tadelis (2002). This is redundant, because the expected gross benefit (ignoring production costs) to the buyer would be $(1 - \rho)v + \rho[(1 - \sigma)v + \sigma(v' - k)] = v - \rho\sigma(v - v' + k)$,

We assume further that the choice of governance affects adaptation costs.²⁵ Bilateral dependence causes a conflict of interest between the buyer (or the interface coordinator) and the supplier when adaptation is required. With autonomy (market), the supplier is in a stronger position to hold up the buyer and direct activities in its interest. Furthermore, if the supplier controls the adaptation process, then it has more power to choose actions that direct rents toward it, which would impose added costs on the buyer even at the expense of total surplus. In a hierarchy, however, the interface coordinator has control over the adaptation process. This reduces the adaptation costs that the supplier can impose.²⁶ The following assumption summarizes this discussion.

Assumption 1 *Adaptation costs are lower in hierarchy: $k(z, M) > k(z, H)$ for all z .*

The intuitive justification of Assumption 2 is further supported by the microfoundations of the hold-up problem. The more specific assets of any kind are concentrated under an independent supply stage, the worse is the fundamental transformation. When the supplier owns the dedicated assets, then the *temporal lock-in* is stronger, because the aggregate degree of bilateral dependency has increased.²⁷

The choice of incentives will also affect adaptation costs. Williamson proposed that “low powered incentives have well known adaptability advantages. That, after all, is what commends cost plus contracting.” (1985: 140). Indeed, if the supplier bears less of the production costs, then it has less to gain from haggling with the buyer (or interface coordinator) over the adaptation.

Assumption 2 *Adaptation costs are lower when cost incentives are weaker: $\frac{\partial k(z, G)}{\partial z} > 0$.*

The microfoundations for Assumption 3 are explored in Bajari and Tadelis (2001). In a buyer-supplier contracting model with bilateral dependency they show that if the supplier's incentives are stronger, then the rents dissipated during adaptation are larger. Intuitively, when the supplier incurs more of the costs, then the conflict of interest between buyer and supplier is intensified: the buyer wants a change that maximizes its net benefit, while the supplier will be motivated to reduce its costs.²⁸ This insight should carry over to an integrated setting where

and because $v - v' > 0$, this is just part of the adaptation costs as we define them above. Also, it is without loss of generality that we assume that adaptation is always efficient. It is easy to incorporate a more involved setting where adaptation costs are random and may sometimes be inefficient, in that projects are sometimes terminated (see, e.g., Bajari and Tadelis 2001).

25. This general idea appears already in Williamson (1985: 131–147) and is also related to the work of Milgrom and Roberts (1988).

26. In a symmetric model where the buyer can impose adaptation costs on the supplier (or interface coordinator), then with autonomy, the buyer can impose adaptation costs to redirect rents toward itself. Adaptation costs imposed by both sides would be reduced under hierarchy.

27. Furthermore, consistent with the assumptions of PRT, giving the supplier ownership over assets (or simply control over adaptation decisions) will strengthen its bargaining position (outside option) and increase its renegotiations rents.

28. Bajari and Tadelis (2001) show that ex ante competition between potential suppliers will cause any adaptation costs borne by the supplier to be passed on to the buyer. This idea is used by Bajari et al. (2012) to measure adaptation costs in highway procurement.

an interface coordinator directs adaptation: if the interface coordinator mediates both stages of production and seeks to maximize combined surplus, then both supplier and buyer will impose more resistance if they face stronger cost incentives.

Bajari and Tadelis (2001) do not include governance in their analysis of contracts, so we need to consider ways in which changes in governance will change the marginal effect of incentives on adaptation costs. To fix ideas, begin with a fixed-price contract, $z = 1$, where adaptation costs are highest, and consider a reduction in incentives (a decrease in z) that will in turn reduce adaptation costs. From Assumption 2, adaptation costs in a hierarchy are lower than in market governance. From Assumption 3, a decrease in supplier incentives will reduce adaptation costs. We add a third assumption that the marginal reductions in adaptation costs are higher when hierarchy is chosen.

Assumption 3 *Reducing adaptation costs by weakening incentives is more effective under hierarchy:* $\frac{\partial k(z, H)}{\partial z} > \frac{\partial k(z, M)}{\partial z} > 0$.

This assumption lacks microfoundations, but it seems reasonable in light of the argument that hierarchy promotes coordinated adaptations. To keep things simple, we assume that when adaptation happens, we are not affecting the utility of the supplier (it is exactly compensated for any extra costs that adaptation imposes on it). As such, adaptation causes extra costs and inefficiencies that are imposed on the buyer or the interface coordinator, but no extra rents are gained or lost by the supplier. This assumption is not important, but it conveniently simplifies the analysis.²⁹

4.4. Selective Intervention

Assumptions 1–3 imply that supplier autonomy defined by market governance reduces production costs but increases adaptation costs, while hierarchy does the opposite. There is, perhaps, an obvious solution: let the supplier retain control of production decisions related to the original design, and let the interface coordinator (or possibly the buyer) retain control over adaptation decisions. This, however, is ruled out by the assumption that *selective intervention* is severely limited.

Assumption 4 *Administrative control is allocated over both production and adaptation, and the two processes cannot be separated to allow for selective intervention.*

This assumption is in line with the discussion in Section 3.4 where it was argued that it is impossible to combine replication and selective intervention (Williamson 1985: 135–140). The model takes an extreme position on the inability to have selective intervention, but clearly what matters is that at the margin some selective intervention is impossible. Realistically, a contract may specify some domains of control that each party may have. As long as contracts are incomplete, however, the impossibility of perfect selective intervention will persist.

29. In Bajari and Tadelis (2001), when adaptation occurs, there are some expected rents to the supplier due to lock-in, and they are competed away ex ante. This could be included here with a more sophisticated focus on ex post adaptation with asymmetric information, but it would not shed light on the forces we wish to illuminate.

4.5. Markets versus Hierarchies

We proceed with the analysis of endogenously choosing governance and incentives. First consider the objective of the supplier,

$$\max_{e \geq 0} u_S(e; z, G) = F - z(\bar{c} - Ge) - y(e).$$

Lemma 1 *Given the pair (z, G) , the supplier's optimal choice $e^G(z)$ is increasing in z , $e^G(0) = 0$ for $G \in \{M, H\}$, and $e^M(z) > e^H(z) > 0$ for any $z \in (0, 1]$. Furthermore, $\frac{de^M(z)}{dz} > \frac{de^H(z)}{dz}$ for any $z \in [0, 1]$.*

This result is derived in the Appendix and follows from the rather standard assumptions made in Section 4.2. It says that stronger incentives increase effort, which is expected, and that given a fixed strength of incentives, effort is higher under market governance. This is a consequence of the assumption that the supplier's effort is more effective when it maintains control over decisions. Finally, the marginal response of the supplier to incentives is stronger under market governance.

Given the optimal response of the supplier, surplus maximization is given by the following program:³⁰

$$\max_{\substack{G \in H, M \\ z \in [0, 1]}} S(z, G; \rho, \sigma) = v - \overbrace{(\bar{c} - Ge^G(z)) - \underbrace{y(e^G(z))}_{\text{Compensation}} - \underbrace{\sigma \rho k(z, G)}_{\text{Expected adaptation costs}}}_{\text{Production costs}}.$$

The components of this program are easy to see. The benefit is the value to the buyer, and the costs have three components. The first is the production cost, the second is the compensation needed to cover the seller's opportunity costs of effort, and the third is the expected adaptation cost. Solving this program leads to the central result of this section.

Proposition 1 *When asset specificity increases (higher σ), or when contracts are more incomplete (higher ρ), the relative benefits of hierarchy over markets increase. Furthermore, optimal incentives become weaker.*

In the Appendix we show that the program exhibits increasing differences in all of its arguments, resulting in monotone comparative statics (see, e.g., Milgrom and Shannon 1994). The intuition for this result is quite straightforward. Strong cost-reducing incentives reduce production costs at the expense of raising adaptation costs (Assumption 2). Market governance makes cost-reducing incentives more effective at the expense of raising adaptation costs (Assumption 1). Hence, more asset specificity and more contractual incompleteness, which increase

30. We substitute $e^G(z)$ in place of e in the objective function to take account of the supplier's incentive compatibility constraint. We assume that the participation constraint does not impose a problem, which in itself is innocuous. The buyer's expected utility is $u_B(z, G; \rho) = v - F - (1 - z)c(e^G(z), G) - \sigma \rho k(z, G)$, and total surplus is just $S(\cdot) = u_B(\cdot) + u_S(\cdot)$.

the expected costs of adaptations, favor the use of hierarchies with weak cost-reducing incentives. Because at the margin, controlling adaptation costs through incentives is more effective under hierarchy (Assumption 3), incentives and governance choices are *complements* in the organizational design. This result is not transparent in the less formal arguments of TCE. Finally, the entire argument rests on the impossibility of selective intervention (Assumption 4). Without it, one can assign control of different processes selectively to the agent who is most impacted, reducing adaptation costs dramatically without the sacrifice of lower productivity. Illuminating the complementarity between governance and incentives is a useful contribution of the formal model with respect to the semi-formal arguments in Section 3.³¹

It is useful to illustrate the result through a simple numerical example. Let $k(z, G) = G + 4z$ and $y(e) = e^2/2$, where $G = 1$ represents hierarchy, and $G = 2$ represents market. Given an incentive scheme $F + (1 - z)c$, the supplier chooses $e^G(z)$ to maximize $F - z(2 - Ge) - e^2/2$, resulting in the optimal choice $e^G(z) = zG$. Substituting this into the objective function of surplus maximization yields

$$\max_{\substack{z \in [0, 1] \\ G \in \{1, 2\}}} S = v - (\bar{c} - G^2 z) - \sigma \rho (G + 4z) - \frac{z^2 G^2}{2}.$$

Because $G \in \{1, 2\}$ corresponds to $\{H, M\}$, we can separately solve for $z_H^*(\sigma, \rho) = \max\{0, 1 - 4\sigma\rho\}$ and $z_M^*(\sigma, \rho) = 1 - \sigma\rho$. The resulting optimal surplus for market is $S_M^*(\sigma, \rho) = v - \bar{c} - 6\sigma\rho + 2(\sigma\rho)^2 + 2$ and for hierarchy is

$$S_H^*(\sigma, \tau) = \begin{cases} v - \bar{c} - 5\sigma\rho + 8(\sigma\rho^2 + \frac{1}{2}) & \text{if } 0 \leq \sigma\rho \leq \frac{1}{4} \\ v - \bar{c} - \sigma\rho & \text{if } \frac{1}{4} \leq \sigma\rho \leq 1. \end{cases}$$

Comparing the expressions for total surplus, we obtain $S_H^*(\sigma, \rho) > S_M^*(\sigma, \rho)$ if and only if $\sigma\rho > 0.5$. For example, if the contract is not too incomplete ($\rho < 0.5$) or if the transaction is not too specific ($\sigma < 0.5$), then markets are always optimal. If, however, the contract is totally incomplete ($\rho = 1$), then for $\sigma > 0.5$ hierarchy will dominate the market, because it has lower total transaction costs. This case corresponds exactly to Figure 2 with $\sigma^* = 0.5$.

In reference to Figure 2, as contractual incompleteness increases, total transaction costs increase for both markets and hierarchies, causing both functions to rise. However, market transactions costs increase faster, making hierarchies better for a larger range of specificity σ . This is a point that the model illuminates. Because σ and ρ are multiplied, contractual incompleteness and asset specificity are complementary. Thus, the negative effects that incompleteness has on

31. The appropriate legal rules would strengthen our result. Namely, if the contract stipulates that the supplier retains control of supply processes, then the courts will enforce the letter of the contract that defines performance (design) and payments. This gives the supplier more bargaining power when adaptation is requested—it can use the original contract as a threat, which imposes extra costs due to haggling during the renegotiation process. If, however, the contract stipulates that both stages implement adaptations at the direction of the interface coordinator, then the courts will not enforce the performance measures under the doctrine that if the interface coordinator maintains control and can direct the parties as it wishes, then the supplier (or buyer) cannot be made accountable for detailed design-based performance. In this situation the courts will defer to the power of fiat, as is common in employment relationships. As such, adaptation is further facilitated when hierarchy is selected.

adaptation costs are exacerbated when asset specificity is higher. One can consider other specifications where this would not be the case, yet interestingly, this specification is consistent with the empirical results of Masten (1984).

5. Extensions and Applications

5.1. Hybrids

The advantages of the two polar modes, simple market exchange and hierarchy, are pronounced for transactions that deviate significantly from the crossover value σ^* , as shown in Figure 2. Hybrid contracting arrangements, however, that are located between hierarchy and simple spot market transactions, appear to be common and thus warrant brief consideration. We interpret the hybrid as an intermediate mode of organization that uses credible commitments to support exchange for transactions that pose an intermediate range of hazards (close to the value σ^*).

In some instances credible commitments are contractually agreed on by the parties to help provide additional assurances, of which the 32-year coal supply agreement between the Nevada Power Company and the Northwest Trading Company is illustrative (Williamson 1991: 272–273).³² These assurances may include additional supports, such as formal auditing and information disclosure procedures, as well as reliance on private ordering dispute resolution mechanisms that are outside the formal courts (Llewellyn 1931; Macaulay 1963; Summers 1969; Macneil 1974; Galanter 1981). The use of hostages to support exchange (Williamson 1983) is both an ancient and contemporary example that can be interpreted in credible contracting terms, in that defection from cooperation is deterred by reciprocal exposure of specific assets that experience positively correlated disturbances.

5.2. Reality Testing

TCE addresses itself to issues of scaling up, remediableness, and bureaucracy, and recommends that other theories of firm and market organization consider doing likewise.

5.2.1. *Scaling up*

The object of a simple model is to capture the essence, thereby to explain puzzling practices and make predictions that are subjected to empirical testing. But that is not the only relevant test. Simple models can also be tested with respect to scaling up. Does repeated application of the simple model's basic mechanism yield a result that recognizably describes the phenomenon in question?

The test of scaling up is often ignored, possibly out of awareness that scaling up of the model in question is very demanding. Sometimes it is recognized but deferred,³³ possibly in the belief that scaling up can be accomplished easily. We advise that claims of real world relevance,

32. In other instances credible commitments come into place spontaneously, which is the case when a supplier's good (poor) history becomes a reputational asset (liability). See, for example, Bar-Isaac and Tadelis (2008).

33. Michael Jensen and William Meckling expressly recognized the importance of scaling up from a single owner-manager to a multitude of owners in a modern corporation and stated that this was an issue that they planned to deal with it in a later paper (1976: 356). That paper never materialized, presumably because of the difficulties. (Their 1976 paper has nonetheless been influential.)

including public policy relevance, of any candidate theory of the firm that cannot be shown to scale up from toy model status to approximate the phenomenon of interest (usually, the modern corporation) should be regarded with caution.

With reference to the theory of the firm as governance structure, the question is this: Does successive application of the make-or-buy decision, as it is applied to individual transactions in the TCE setup, scale up to describe something that approximates a multistage firm? Note that, as described previously, TCE assumes that the transactions of principal interest are those that take place *at the interface between* (rather than within) technologically separable stages, which is the “boundary of the firm” issue as described elsewhere (Williamson 1985: 96–98). Upon taking the technological core as given, attention is focused on a series of separable make-or-buy decisions—backward, forward, and lateral—to ascertain which should be outsourced and which should be incorporated within the ownership boundary of the firm. So described, the firm is the inclusive set of transactions for which the decision is to make rather than buy—which does implement scaling up, or at least is an approximation thereto (Williamson 1985: 96–98).³⁴

Indeed, whereas examining whether to make or buy a series of technologically separable components is a relatively straightforward process where stages, if acquired, are all under unified ownership, it is not at all obvious how scaling up applies to the employment relationship (where successive employees have different propensities, e.g., for risk aversion) or to directional integration (as opposed to unified ownership) in the modern property rights setup.

5.2.2. Remediability

Public policy analysts have often assumed that transaction costs in the public sector are zero. That is unrealistic, yet standard public policy proceeded in an asymmetric way: private sector contracting experienced market failures, by reason of positive transaction costs, but there was no corresponding concept for public sector failures.³⁵ Little surprise, then, that convoluted public policy prescriptions were often (unwittingly) anchored in the asymmetric application of zero transaction cost reasoning, of which public policy on regulation was an example: only private sector supply was burdened with positive transaction costs; regulation was a zero transaction cost alternative (Coase 1964).

The remediability criterion is an effort to deal symmetrically with real world institutions, both public and private. The criterion is this: an existing mode of organization for which no superior feasible form of organization can be described and implemented with expected net gains is presumed to be efficient (Williamson 1996: 195–213). In other words, a “revealed preference” approach is applied to the choice of governance.

Because all feasible modes of organization are flawed, the feasibility stipulation precludes all appeals to the fiction of zero transaction costs (in any sector whatsoever—public, private, nonprofit, etc.) from the very outset. The implementation stipulation requires that the costs

34. In the context of a multidivisional firm (Chandler 1962), the scaling up to which we refer corresponds more nearly to that of an operating division (which could be a freestanding firm that has been acquired by a diversified enterprise) than to the entire multidivisional enterprise—where the general office provides an additional level of strategic participation.

35. Albeit a caricature, “normative public policy analysis began by supposing that . . . policy was made by an omnipotent, omniscient, and benevolent dictator” (Dixit 1996: 8)—which, in transaction cost terms, assumes the absence of implementation obstacles, bounds on rationality, and opportunism, respectively.

of implementing a proposed feasible alternative (one that is judged to be superior to an extant mode in a *de novo* side-by-side comparison) be included in the net gain calculus.³⁶

The upshot is that the remedialness criterion is an effort to disallow asymmetric efficiency reasoning of a zero transaction cost kind, thereby to force the relevant efficiency issues for the making of public policy (Dixit 1996) to the surface.

5.2.3. *Burdens of Bureaucracy*

The impossibility of implementing either replication or selective intervention is partly attributable to the incentive distortions that arise when successive stages of production that had previously been independent are placed under unified ownership (to include the control over accounting practices that accrues thereto). But there is more to it than that.

Reaching beyond the scope of the analysis in Sections 3 and 4, some of the more insidious burdens of bureaucracy arise because “integration affects the internal politics of the corporation with systematic performance consequences” (Williamson 1985: 145). These effects include tilting the managerial promotion game away from merit in favor of politics (subgoal pursuit), the increased propensity to intervene (overmanage and overcontrol), limits on internal incentives due to internal equity considerations, and the distortion of operating and investment decisions (Williamson 1985: 147–152). The appearance of what Paul Milgrom and John Roberts (1988) refer to as “influence costs” are also in the spirit of bureaucratic burdens.

Understanding of the strengths and weaknesses of bureaucracy is very underdeveloped compared with understanding of the strengths and weaknesses of markets—mainly because bureaucracy is both a comparatively neglected and a formidably difficult subject. Robert Michels nevertheless taught us how to proceed. Rather than end his study with the finding that “who says organization, says oligarchy” (1962 [1911]: 365), Michels advises instead that, upon recognition of this prospect, we take the next step and push the logic to completion: “nothing but a serene and frank examination of the oligarchical dangers of [organization] will enable us to [mitigate] these dangers” (1962 [1911]: 370). The corresponding lesson for our purposes here is this: a more informed assessment of markets and hierarchies will result as we uncover the basic regularities and work out the ramifications for economic organization in a candid, disciplined, and microanalytic way.

5.3. Variations on a Theme

Many regularities that are associated with the intermediate product market transaction recur, in variable degree, as variations on a theme. TCE not only has many applications in the field of industrial organization but also in most applied fields of economics as well, including labor, public finance, comparative economic systems, and economic development and reform. Applications to business—to the fields of strategy, organizational behavior, marketing, finance, operations management, and accounting—are likewise numerous. Many applications to the contiguous social sciences (especially sociology, political science, social psychology, and aspects of the law;

36. The presumption that a chosen mode is efficient if the expected net gain is negative is nevertheless rebuttable: it can be challenged by showing that the obstacles to implementing an otherwise superior feasible alternative are unfair. See Williamson (1996: 195–213) for a discussion.

Williamson 2005b) have also been made. More generally, TCE has broad reach because any problem that arises as or can be reformulated as a contracting problem can be examined to advantage in TCE terms. (See Macher and Richman (2008) for a discussion of the applications with references to the relevant literature.)

5.4. Empirical Evidence

Shortly after the main ideas of TCE were laid out, several seminal empirical papers confirmed the main prediction of the theory, including Monteverde and Teece (1982), Masten (1984), Joskow (1985); also see Shelanski and Klein (1995), and Lafontaine and Slade (2007). Macher and Richman (2008) report that there were more than 900 published empirical papers on TCE during 1980–2004, with more in progress. Indeed, “despite what almost 30 years ago may have appeared to be insurmountable obstacles to acquiring the relevant data [which are often primary data of a microanalytic kind], today transaction cost economics stands on a remarkably broad empirical foundation” (Geyskens et al. 2006: 531). As Michael Whinston puts it: TCE has been “one of the great [empirical] success stories in industrial organization over the past [30] years” (Whinston 2001: 185). There is no gainsaying that TCE has been much more influential because of its broad and varied applications and the empirical work that it has engendered. Most recently, new empirical studies have focused attention on the importance of adaptation to empirically validate the central themes of TCE (e.g., Forbes and Lederman 2009, 2010; Costinot et al. 2011).

5.5. Antitrust and Regulation

TCE was stimulated in part by the disarray in antitrust enforcement and regulation during the 1960s. As Coase observed,

If an economist finds something—a business practice of one sort or another that he does not understand, he looks for a monopoly explanation. And as in this field we are very ignorant, the number of ununderstandable practices tends to be very large, and the reliance on a monopoly explanation, frequent. [Coase 1972: 67]

The possibility that complex contract and organization had beneficial governance purposes was ignored. The implausibility of such monopoly reasoning coupled with a small but growing interest in transaction cost economizing would eventually help to bring relief from such excesses.³⁷

37. Interestingly, Timothy Muris, during his term as chair of the Federal Trade Commission, held that much of the new institutional economics “literature has significant potential to improve antitrust analysis and policy. In particular, . . . [the transaction cost branch has] focused on demystifying the ‘black box’ firm and on clarifying important determinants of vertical relationships” (2003: 15). Opening the black box and acquiring an understanding of the mechanisms inside has had an impact, moreover, on practice:

The most impressive recent competition policy work I have seen reflects the NIE’s teachings about the appropriate approach to antitrust analysis. Much of the FTC’s best work follows the tenets of the NIE and reflects careful, fact-based analyses that properly account for institutions and *all* the relevant theories, not just market structure and [monopoly] power theories. [Muris 2003: 11; emphasis in original]

As applied to regulation and deregulation, more attention to the details and to strategic behavior on the part of participants in regulated or deregulated sectors needs to be factored in.³⁸ As Paul Joskow observes of efforts to deregulate electricity in California, too much deference was given to the (assumed) efficacy of smoothly functioning markets and insufficient attention to potential investment and contractual hazards and appropriate governance responses thereto:

Many policy makers and fellow travelers have been surprised by how difficult it has been to create wholesale electricity markets . . . Had policy makers viewed the restructuring challenge using a TCE framework, these potential problems are more likely to have been identified and mechanisms adopted *ex ante* to fix them. [Joskow 2000: 51]

6. Some Challenges

As Williamson (2010) observes, TCE, like many other theories, has undergone a natural progression from informal (1930–1970), to pre-formal (1970s), to semi-formal (1980s and beyond), of which full formalization is the last step.

The pathbreaking paper by Sanford Grossman and Oliver Hart (1986) and the follow-on paper by Hart and John Moore (1990), which founded the PRT literature, have been very influential. They have established the modeling apparatus used in Section 4, in which governance choices affect the incentives of parties to a transaction. That said, there are three fundamental differences between the PRT and TCE approaches.

First, TCE emphasizes *ex post* adaptation as the main problem of organization, whereas the PRT has focused more on the problem of *ex ante* alignment of incentives to invest in specific assets, mainly of the intangible (human asset) kind. This same focus on *ex ante* incentives is also at the core of most agency-based theories.

Second, PRT and agency-based theories are silent about how transactions differ with respect to complexity, uncertainty, and contractual incompleteness. Instead, agency theory and PRT explore the consequences of incomplete information in that some aspects of the transaction have zero costs of contracting, while others have infinite costs. Namely, in standard agency models, output measures of the transaction (e.g., the component's functionality, quality, or a signal of these) can be specified at no cost, while the effort and actions of people who work toward achieving the desired goals cannot be specified at any cost. The PRT paradigm assumes that contingent decisions related to how to do the job or how to respond to changes in the environment cannot be specified at any cost, whereas it is costless to decide who has the rights to make decisions and execute them, and it is costless to enforce these rights. TCE, in contrast, focuses on measurable dimensions over which transactions differ, with emphasis on identifying how different kinds

38. Interestingly, the first "empirical" application of TCE was to regulation. The issue was the purported efficacy of franchise bidding for natural monopoly, as advanced by Demsetz (1968) and applied to the cable television industry by Posner (1972). Missing from both of these sanguine assessments of the efficacy of franchise bidding were (1) an examination of the details by which franchise bidding would be implemented and (2) an awareness that the nonredeployability of asset-specific investments would pose serious (but unexamined) problems (Williamson 1976).

of transactions are discriminately allocated to different governance structures. This emphasis accounts for much of its predictive content and empirical success described in Section 5.4.³⁹

Third, PRT identifies ownership of assets as the critical variable and takes the view that ownership determines who has the residual right to decide how to use the productive assets. As such, changes in ownership of assets from one party to another will change the incentives of the parties to invest in the specific relationship, implying a unified framework for the costs and benefits of integration. The implications are that separable, well-defined assets ought to be owned by the individuals whose incentives are most affected by ownership. But there is more: *directional* ownership is predicted. PRT asserts that either buyer or seller should own the assets, and it matters who the owner is. In fact, however, bundles of assets are owned by firms, not by individuals. Holmström (1999), who raises this important critique, argues that owning bundles of assets allows the firm to internalize many of the externalities that are associated with incentive designs in a world characterized by informational imperfections, which are responsible for contractual incompleteness. By associating the decisionmaker with more assets under his control, his administrative control is expanded, and he possesses more levers through which to implement coordinated adaptation. This observation is very much in line with our notion of the interface coordinator as the executive who has the authority to coordinate adaptation as needed, even though she as an individual need not own the assets.

Still, the Grossman-Hart methodology is an instrumental contribution. Building on their methods and the insights in Bajari and Tadelis (2001), Tadelis (2002) makes a step toward formalizing some of the central ideas of TCE. Additional efforts have been made by Gibbons (2005). The model we offer in Section 4 is an attempt to push the full formalization of TCE yet another modest step forward. More work, however, still needs to be done, and a full incorporation of the role of law in formal models is indeed very challenging.

7. Conclusion

Compared with the top-down neoclassical theory of the firm as production function, the theory of the firm as governance structure is a bottom-up construction in the following respects: (1) rather than work through the price-theoretic lens of choice, TCE examines economic activity through the lens of contract; (2) rather than focus on composite goods and services (supply and demand, prices and output), TCE focuses on transactions and the organization thereof; (3) rather than take the boundary of the firm as given by technology, TCE derives the boundary in comparative contractual terms; (4) the resulting contractual strategy for examining

39. Despite TCE being an empirical success story, there is an interesting challenge in making more progress on the empirical front. As discussed in Section 5.2, a complete understanding of the pros and cons of bureaucracy is still underdeveloped. Indeed, “distortion-free internal exchange is a fiction and is not to be regarded as the relevant organizational alternative in circumstances where market exchange predictably experiences nontrivial frictions” (Williamson 1975: 124–125). Most empirical studies of TCE show that relative to internal organization, market transactions do worse when there is either more asset specificity or more transaction complexity (which leads to contractual incompleteness). What these studies cannot usually measure is by how much do the costs of each mode of governance change with changes in a transaction’s attributes. A first step in this direction was made by Masten et al. (1991), who use a censored regression approach to study the procurement of components and services by a large naval shipbuilder.

economic organization in terms of the microanalytics of transactions and governance structures has broad reach, in that a large number of contractual phenomena turn out to be variations on a few key contractual themes to which the discriminating alignment hypothesis applies; (5) transaction-level analysis opens up a whole new range of activities to which empirical analysis can be applied; and (6) public policy analysis is more nuanced and more objectively comparative in the process. Also, although fully formal TCE analysis is a work in progress, headway has been made, and more is in prospect.

Indeed, headway in the future will be realized as it has in the past—not by the creation of a general theory but by proceeding in a modest, slow, molecular, definitive way, placing block upon block until the value added cannot be denied. It is both noteworthy and encouraging that so many young scholars have found productive ways to relate. More generally, the economics of organization has benefited from rival and complementary perspectives, especially those that subscribe to the four precepts of pragmatic methodology. Such pluralism brings energy to the elusive ambition of realizing the “science of organization” to which Chester Barnard (1938) made reference 75 years ago and to which this *Handbook of Organizational Economics* speaks.

Appendix

Here we prove the Lemma and Proposition stated in Section 4.5.

Proof of Lemma: It follows from $y(e)$ being convex with $y'(0) = 0$ that there is a unique solution $e^G(z)$ to the first-order condition, $zG - y'(e^G(z)) = 0$, with $e^G(0) = 0$. Because $M > H > 0$, it immediately follows that $e^M(z) > e^H(z) > 0$ for all $z \in (0, 1]$. Now consider the derivative of the first-order condition with respect to z :

$$G - y''(e^G(z)) \frac{de^G(z)}{dz} = 0,$$

or

$$\frac{de^G(z)}{dz} = \frac{G}{y''(e^G(z))}.$$

Because $M > G > 0$ and $e^M(z) \geq e^H(z)$, the assumption that $y'''(e) \leq 0$ is a sufficient condition for $\frac{de^M(z)}{dz} > \frac{de^H(z)}{dz}$.

Proof of Proposition: The proposition states that as σ or ρ increase, both solutions $z^*(\sigma, \rho)$ and $G^*(\sigma, \rho)$ will (weakly) decrease. It therefore suffices to prove that the objective function of maximizing total surplus exhibits increasing differences (Milgrom and Shannon 1994). In particular, we need to show that $\frac{\partial^2 S}{\partial z \partial \rho} < 0$ and $\frac{\partial^2 S}{\partial z \partial \sigma} < 0$, that $\frac{\partial S}{\partial \rho}$ and $\frac{\partial S}{\partial \sigma}$ are decreasing in G , and that $\frac{\partial S}{\partial z}$ is increasing in G . Observe that

$$\frac{\partial S}{\partial z} = G \frac{de^G(z)}{dz} - y'(e^G(z)) \frac{de^G(z)}{dz} - \sigma \rho \frac{\partial k(z, G)}{\partial z}, \quad (1)$$

and in turn,

$$\frac{\partial^2 S}{\partial z \partial \rho} = -\sigma \frac{\partial k(z, G)}{\partial z} < 0,$$

and

$$\frac{\partial^2 S}{\partial z \partial \sigma} = -\rho \frac{\partial k(z, G)}{\partial z} < 0,$$

which both follow from $\frac{\partial k(z, G)}{\partial z} > 0$ (Assumption 2). To show that $\frac{\partial S}{\partial \rho}$ is decreasing in G , we need to show that

$$\left. \frac{\partial S}{\partial \rho} \right|_{G=M} - \left. \frac{\partial S}{\partial \rho} \right|_{G=H} < 0.$$

Observe that $\frac{\partial S}{\partial \rho} = -\sigma k(z, G)$, so that

$$\left. \frac{\partial S}{\partial \rho} \right|_{G=M} - \left. \frac{\partial S}{\partial \rho} \right|_{G=H} = -\sigma k(z, M) + \sigma k(z, H) < 0,$$

which follows from Assumption 1. Showing that $\frac{\partial S}{\partial \sigma}$ is decreasing in G follows the same steps (where σ is replaced with ρ). We are left to show that $\frac{\partial S}{\partial z}$ is increasing in G . That is, we need to show that $\left. \frac{\partial S}{\partial z} \right|_{G=M} - \left. \frac{\partial S}{\partial z} \right|_{G=H} > 0$ or, using (1),

$$\begin{aligned} [M - y'(e^M(z))] \frac{\partial e^M(z)}{\partial z} - [H - y'(e^H(z))] \frac{\partial e^H(z)}{\partial z} \\ + \sigma \rho \left(\frac{\partial k(z, M)}{\partial z} - \frac{\partial k(z, H)}{\partial z} \right) > 0. \end{aligned}$$

Assumption 2 implies that $\sigma \rho \left(\frac{\partial k(z, M)}{\partial z} - \frac{\partial k(z, H)}{\partial z} \right) > 0$, so it suffices to show that

$$[M - y'(e^M(z))] \frac{\partial e^M(z)}{\partial z} - [H - y'(e^H(z))] \frac{\partial e^H(z)}{\partial z} > 0. \quad (2)$$

From the supplier's first-order condition, we can substitute $y'(e^G(z)) = zG$ into the left-hand side of (2) to obtain

$$(1 - z)M \frac{\partial e^M(z)}{\partial z} - (1 - z)H \frac{\partial e^H(z)}{\partial z} > 0,$$

which is satisfied because $M > H$ and from Lemma 1, $\frac{\partial e^M(z)}{\partial z} > \frac{\partial e^H(z)}{\partial z}$.

Clinical Papers in Organizational Economics

George P. Baker and Ricard Gil

1. Introduction

1.1. The Legacy of Fisher Body

The story of General Motors' acquisition of the Fisher Body company in 1926 constitutes one of the more influential anecdotes in economics. Along with Adam Smith's pin factory, Ronald Coase's lighthouse, and George Akerlof's used-car market, the story of how General Motors first contracted with, then got held up by, and finally bought out Fisher Body has influenced the way economists have thought of agency problems, transactions costs, and make-or-buy decisions for more than 30 years. The paper that first told this story—Klein et al. (1978) in the *Journal of Law and Economics*—stands as the fourth most highly cited paper in that journal, with the number of citations in the thousands. It has inspired many other articles, motivated much theory, and generated a considerable amount of controversy. To refresh the memory of the reader, we provide the famous paragraph in its entirety here:

[I]t is interesting to study in some detail the vertical merger that occurred in 1926 of General Motors with Fisher Body. The original production process for automobiles consisted of individually constructed open, largely wooden, bodies. By 1919 the production process began to shift towards largely metal closed body construction for which specific stamping machines became important. Therefore in 1919 General Motors entered a ten-year contractual agreement with Fisher Body for the supply of closed auto bodies. In order to encourage Fisher Body to make the required specific investment, this contract had an exclusive dealing clause whereby General Motors agreed to buy substantially all its closed bodies from Fisher. This exclusive dealing arrangement significantly reduced the possibility of General Motors acting opportunistically by demanding a lower price for the bodies after Fisher made the specific investment in production capacity. Since exclusive dealing contractual conditions are relatively cheap to effectively specify and enforce, General Motor's post-contractual threat to purchase bodies elsewhere was effectively eliminated. But large opportunities were created by this exclusive dealing clause for Fisher to take advantage of General Motors, namely to

demand a monopoly price for the bodies. Therefore, the contract attempted to fix the price which Fisher could charge for the bodies supplied to General Motors. However, contractually setting in advance a “reasonable” price in the face of possible future changes in demand and production conditions is somewhat more difficult to effectively accomplish than merely “fixing” required suppliers. The price was set on a cost plus 17.6 per cent basis (where cost was defined exclusive of interest on invested capital). In addition, the contract included provisions that the price charged General Motors could not be greater than that charged other automobile manufacturers by Fisher for similar bodies nor greater than the average market price of similar bodies produced by companies other than Fisher and also included provisions for compulsory arbitration in the event of any disputes regarding price. Unfortunately, however, these complex contractual pricing provisions did not work out in practice. The demand conditions facing General Motors and Fisher Body changed dramatically over the next few years. There was a large increase in the demand for automobiles and a significant shift away from open bodies to the closed body styles supplied by Fisher. Meanwhile General Motors was very unhappy with the price it was being charged by its now very important supplier, Fisher. General Motors believed the price was too high because of a substantial increase in body output per unit of capital employed. This was an understandable development given the absence of a capital cost pass-through in the original contract. In addition, Fisher refused to locate their body plants adjacent to General Motors assembly plants, a move General Motors claimed was necessary for production efficiency (but which required a large very specific and hence possibly appropriable investment on the part of Fisher). By 1924, General Motors had found the Fisher contractual relationship intolerable and began negotiations for purchase of the remaining stock in Fisher Body, culminating in a final merger agreement in 1926. [Klein et al. 1978: 308–310]

Note how this story touches on many relevant aspects of hold-up, appropriable quasi-rents, and vertical integration decisions. The complex and interrelated roles of specific investments, unforeseen contingencies, and contractual incompleteness are all highlighted. Fisher Body serves as an example of the role that stories play in economic research and organizational economics in particular.

1.2. Why Are Stories So Powerful?

Stories hold a privileged position in the human mind. They are more interesting, more memorable, and more powerful (to most people) than facts or theories.

The story—from Rumpelstiltskin to *War and Peace*—is one of the basic tools invented by the human mind, for the purpose of gaining understanding. There have been great societies that did not use the wheel, but there have been no societies that did not tell stories. [Ursula K. Le Guin, *The Language of the Night*, 1979]

Throughout human history, stories have been used to create and diffuse knowledge. McCloskey (1990) argues that there are only two ways of understanding things: metaphor (read “model”) and story. The story as a cognitive tool has been widely used in the social sciences, the

humanities, and even in the “hard” sciences (Einstein’s man in a rocket and Schrödinger’s cat are well-known examples). McCloskey postulates that even when we are trying to fit complex reality through highly stylized models, we are storytellers who focus on the very important details of each specific case under study and fill the sketch with unmodelable features that are better explained by narrative.

The Fisher Body story related by Klein et al. (1978) has many of the ingredients to which Le Guin and McCloskey refer. The paragraph cited in Section 1 presents a situation rich in detail, yet provides a very simple and elegant explanation that allows us to gain understanding of the forces involved in setting firm boundaries. We believe that the story of Fisher Body has been so influential largely because of this combination of the particular and the general: the specifics of the story are relevant and important, yet the generality of the situation is obvious. The theory that explains the set of facts and actions presented in this story can be used, and has been used, to provide a very general explanation that can be applied to many other settings.

1.3. What Are Clinical Studies?

This chapter discusses clinical studies in organizational economics. Most clinical studies are stories, and we argue in this chapter that clinical studies (stories) can and should play an essential role in the development of theories in organizational economics, as well as in the design and implementation of empirical research. Like the Fisher Body story, they combine the specific and the general to guide theorists and empiricists in what to model, how to model it, and how to tell whether their results are valid and sensible.

A clinical study is essentially a detailed account, often involving a combination of qualitative data, anecdotal evidence, and sometimes quantitative data of a specific situation or phenomenon. Several things may distinguish a clinical study from a more standard empirical investigation. Clinical studies often contain qualitative information that is not amenable to statistical analysis. They also make no strong claim to representativeness; indeed, it is often the case that the best clinical studies are about situations that are clearly outliers or extreme cases. Although this trait would be considered a significant drawback for a standard empirical investigation, it is often a very important characteristic of a clinical study: if the purpose is to better uncover the causal mechanisms behind some phenomenon, then finding an extreme situation may be the best place to look.

Clinical studies also frequently contain data—qualitative or quantitative—that may or may not be relevant to understanding the situation. This is what distinguishes a clinical study from an *example*. An example is generally used to illustrate some theoretical insight or result. Clinical studies are most useful when they describe situations for which the existing theory is inadequate or nonexistent. This is the reason that clinical studies often contain (what will turn out to be) irrelevant data: without good theory, one does not know which data are relevant and which are not.

What purpose do clinical studies serve? As mentioned above, clinical studies are most useful when they examine phenomena for which we do not have adequate theory. In this chapter we argue that clinical studies serve four important functions in the development of the field:

(1) telling theorists what to model, (2) providing guidance on how to model these things, (3) assessing “possibility theorems,” and (4) providing evidence of a certain type for testing theory.

1.4. Types of Clinical Studies

Before discussing the role of clinical studies in the development of organizational economics, we begin with a simple classification of types of studies and short discussions of numerous papers that fit into these classifications. We come back to discuss some of these papers in more detail in later sections. All share the characteristics of in-depth description of one or a small number of situations, questionable (or at least difficult to prove) representativeness, and the likely inclusion of irrelevant detail.

The most common type of clinical study is the *teaching case*. The Harvard Business School case library alone contains more than 10,000 case titles. Teaching cases range from the prosaic (e.g., *Butler Lumber*, a small lumber yard, which, though profitable, needs to borrow money to grow) to the bizarre (e.g., *Optical Distortion* [Clarke and Wise 1975], a case about a company trying to market contact lenses for chickens to keep them from pecking each other to death in captivity). Some teaching cases are very well known: Lincoln Electric (Berg and Fast 1975), the best-selling case in the business school’s history, describes an aggressive incentive system in an American arc-welding company. The case details not only the ingredients of the tremendously successful incentive system but also all the other organizational features that surround the incentive program. Reading through the text, it is hard to miss that there may be other, softer, factors at work than simply a high-powered incentive scheme. Indeed, there is so much about culture and leadership in the case that by the end the reader wonders whether the main purpose of the text was to highlight the importance of incentives or underline the relevance of leadership and culture in organizations.

Aside from the entertainment and education about the world provided to students by teaching cases, we might ask whether they also provide value to scholars outside the classroom, in their writing and research. One may worry that the style encountered in teaching cases, mostly narrative and descriptive, resembles too much the journalistic style of the business press. At the same time, teaching cases present scholars with facts about organizations, industries, and markets, and they often highlight interesting and important issues faced by economic agents. Teaching cases, like newspaper articles, highlight the key trade-offs necessary to understand how a firm or industry works. In the same way that economists turn to newspapers and magazines to collect institutional knowledge necessary for their research, they can also use information from teaching cases. In that sense, teaching cases help economists highlight the important features in their models despite their journalistic style.

A second type of study, and the central focus of this chapter, is the *in-depth clinical paper*. As we describe below, this work ranges from relatively qualitative narratives to relatively quantitative investigations. For the most part, however, all these papers stop short of explicitly testing hypotheses.

Some of the earliest papers that we describe here were published as a result of an initiative by the *Journal of Financial Economics*. Beginning in 1989, this journal began to publish papers about individual firms or a small number of them. Among the first of these to appear was by Baker and Wruck (1989) on the leveraged buyout (LBO) of the O. M. Scott & Sons grass seed

company. In this study Baker and Wruck document in detail the divisional LBO of the O. M. Scott & Sons company by Clayton & Dubilier from giant conglomerate ITT, while identifying the organizational changes that took place within O. M. Scott & Sons that led the firm to increase performance after the buyout. We discuss this paper in greater detail in Section 2.2.

Another of this genre is the excellent series of articles by Kaplan (1989, 1990, 1994) on the acquisition of Federated department stores by the Canadian financier Robert Campeau in 1988 and its ultimate bankruptcy in 1990. This series of clinical studies does a remarkable job of clarifying the value creation potential of LBOs, even when the ultimate fate of the company is bankruptcy. Campeau bought Federated for \$7.6 billion, which represented a \$3.4 billion premium over the pre-buyout value of the company. Ninety-seven percent of the buyout price was financed with debt. The main contribution of the papers is Kaplan's painstaking and detailed reconstruction of the value of Federated post-bankruptcy and his demonstration of the value that was actually created by the buyout. This analysis shows that Federated's bankruptcy was not a consequence of value destruction in the post-LBO company but rather of overoptimism at the time of the buyout and the contractual "locking in" of this optimism through very high leverage. In fact, Campeau increased the value of Federated by \$1.8 billion (43%) through the LBO, but because this was not enough to cover the money borrowed for the deal, he still went bankrupt. Through this clinical study and the rich detail provided in it, Kaplan differentiates the economic concept of value creation (through a more efficient allocation of resources) from the contractual concept of bankruptcy.

Another *Journal of Financial Economics* clinical paper, by Dial and Murphy (1995), explores the issue of value creation in a dying industry. They describe the trajectory of General Dynamics (GD) between 1991 and 1994 under the leadership of CEO William Anders. GD was the third largest defense contractor in the world but was suffering from serious declines in profitability and market value after the fall of the Berlin Wall. This paper, which is discussed in more detail in Section 2.1, tells the story of how Anders and others at GD adopted a strategy of downsizing, consolidation, and exit at the end of the Cold-War era as long-term demand and profitability in the weapons manufacturing industry suffered what appeared to be a permanent negative shock. Through the rich detail offered in this story, Dial and Murphy clarify two important concepts. First, value-creating actions in a booming industry are likely to have the opposite effect in a shrinking one. Second, they show that even in a shrinking business it is possible to create value effectively (if somewhat more painfully) through the efficient allocation of resources.

Baker's (1992) paper on the growth by acquisition and death by divestiture of the conglomerate Beatrice takes a broad historical look at a single firm. It attempts to answer the questions: How does a strategy of acquisition—Beatrice was the most acquisitive firm in America during the 1950s and 1960s—create value? And then how can a strategy of divestiture—Beatrice did more divestitures in the 1980s than any other firm—also create value? Baker uses data from company documents, press accounts, personal remembrances of managers, and accounting and market data to reconstruct the strategic direction of the firm throughout its 80-year history, noting the shifts in corporate strategy associated with different CEOs and attempting to account for value creation and value loss stemming from these changes in firm policies and strategy.

In addition to these early clinical studies in the *Journal of Financial Economics*, there are similar contributions ranging from the mostly qualitative to more quantitative. One example of in-depth clinical studies at the qualitative end of the spectrum is the study of the Danish

hearing-aid company Oticon by Foss (2003). In this paper, Foss provides an intimate account of how Oticon's CEO Lars Kolind reorganized the Danish hearing-aid firm to delegate as much authority and decision power as possible to employees. To do so, Kolind engineered a "market for ideas" within the firm in which employees were allowed to start on their own projects, recruit teams within the firm, and even set their own wages. All this occurred under very little oversight or control from top management. As a result, the average time to project completion was cut by half, and the rate of innovation improved drastically in the 3 years after the reorganization. As time went on, however, the management began to "selectively intervene" in several projects that appeared unprofitable, discouraging workers from pursuing their own initiatives. Foss, through the story of Oticon, sheds light on the debate among theorists about how to model delegation. This story shows that managers are unable to formally delegate decision rights to their subordinates; in fact, decision rights are only loaned to subordinates even when (ex-ante) managers want to commit to do otherwise.

Two other papers are not close examinations of a particular firm or firms, but rather careful descriptions and analyses of phenomena of interest. One is the Milgrom and Roberts (1990) paper on modern manufacturing systems. These authors describe how manufacturing industries have evolved from the times of Ford's Model T car factory to the present. The evidence collected on how such firms as General Motors and Caterpillar organize factory work pushes Milgrom and Roberts to hypothesize that optimally changes in the production chain must take place not in isolation but in groups. They use this anecdotal evidence to guide the development of a theory of complementarities between inputs, outputs, and methods of production.

The other paper is Asanuma (1989). Asanuma documents a large amount of informal interaction taking place between auto makers, electric component makers, and their input suppliers in the Japanese auto and electric component industries. Moreover, Asanuma describes in detail how ex post contractual changes and contractual renegotiation are resolved. The evidence in Asanuma's paper is some of the earliest on the impact of relations on business practices and economic outcomes. As the Fisher Body and General Motors story did with make-or-buy theories, Asanuma's study inspired many to pursue theory on the nature and consequences of relational contracting.

We also note that there were many social scientists outside economics undertaking in-depth clinical studies decades before economists started contributing to this type of research methodology. For example, there are the classic sociology works by Philip Selznick (1957) and Michel Crozier (1964) that studied organizations and Alfred Chandler's (1962, 1977) books in business history. To illustrate work in this tradition, we include one example of an in-depth clinical study from outside the economics literature—the early and influential paper in the sociology literature by Donald Roy (1952).

Roy's detailed account of piece-rate workers in a machine shop on the south side of Chicago in the 1950s provides tremendous insight into the inner workings of a shop floor. Roy was a graduate student in the Sociology Department of the University of Chicago, and he spent 11 months as a (clandestine) participant-observer in a machine shop near the university. This gave him access to worker "inside talk and activity" and allowed Roy to document the motivations of individual workers, the social interactions among workers, and their coordinated efforts to get the most out of the compensation scheme implemented in the plant. We discuss this paper more fully in Section 2.3.

Complementing the studies just discussed, we also find in-depth clinical studies roughly in the middle of the qualitative-quantitative spectrum, such as Blanchard et al. (1994). Motivated by existing theories of asymmetric information and agency, they ask: what do firms do with cash windfalls? They use a narrow selection criterion to choose 11 firms that received significant amounts of cash, for reasons (winning lawsuits) that should not affect their rate of return on future investment. By examining what firms actually do with this money, they can look at (test?) whether managers are acting in the best interests of shareholders or in their own best interest.

The paper bristles with tables, virtually all with 11 rows. Blanchard et al. (1994) show tables that reveal the characteristics of the firms, the characteristics of the cash windfalls, the historical investment behavior and returns of the firms, and the performance of the firms after they received the money. The text is sprinkled with stories about individual firms, but the real story is in the tables, which show the remarkable consistency with which the firms' managers waste the windfall to ensure the survival of the firms under their command. Although the quantitative result could be consistent with managerial information asymmetry theories, the detailed (and colorful) descriptions of the waste of the windfalls, especially on dividend payments and executive compensation, leave little doubt about the accuracy of the agency-theoretic explanation.

Another example of a similarly quantitative in-depth clinical study is by Cutler and Summers (1988). In this paper, the authors examine the costs of financial distress and look to see whether these costs have an effect on firm productivity. They do so by comparing the losses in market value suffered by Texaco and Pennzoil with the actual legal and administrative costs of the litigation in their fight over the Getty Oil takeover. They show that the loss of total value during litigation was much higher than even the most generous estimate of litigation costs. Their evidence suggests that the soft costs of financial distress—diversion of managerial time, loss of strategic focus and direction—appear to be real, at least in this case, and that financial markets take these costs into account. The meticulous recollection of events and information in this paper shed light on how economists ought to model financial distress episodes and their implications for firm performance.

The industrial organization literature has also provided several works that fall into this category of in-depth clinical papers, for instance, Joskow's (1985) paper on the contractual and institutional arrangements between coal-fired power plants and coal mines. Joskow documents coal supply arrangements between electric utilities and coal suppliers, focusing on the structure of vertical relationships for mine-mouth generating plants. He compares the characteristics of transactions for mine-mouth plants to those of plants located farther from coal supplies. Although the sample sizes are small by the standards of traditional empirical work, the richness of the descriptive results (the actual contracts are analyzed in detail) provides real insight into the importance of asset and locational specificity for organizational form and contract type. Paradoxically, it is the overwhelming amount of detail in this paper that allows the reader to understand the foundations of contracting costs in this industry and to apply this understanding to other settings facing the same economic trade-offs.

This paper shows the value of deep institutional knowledge when studying contracting arrangements between firms since the examination of data may not tell the whole story. As Joskow (1985: 34) put it:

Detailed knowledge of a variety of characteristics of buyers and sellers seems essential for applying and testing transactions cost theory empirically. . . . Furthermore, in part because they are regulated, there is a lot of information available about particular utilities, their power plants, and their coal supply arrangements. It is even possible to obtain a large set of actual coal supply contracts and related documents. The opportunity to analyze data at this level of microeconomic detail is extremely rare.

Finally, and farther toward the quantitative end of the spectrum, there are clinical studies that look like large-sample empirical work but use data from a single (or very small number of) firms. The first of two such studies that we discuss uses large proprietary panel datasets with no apparent exogenous variation in the data. These papers are not trying to test, or even really explore, any particular causal mechanism or hypothesis. Rather, they allow the authors to establish a set of facts for which economists may not previously have had a good grasp or understanding. The two studies—Baker et al. (1994) and Lazear (1992)—both follow individuals across different jobs within the same firm over a large number of years. By doing so, they are able to study the empirical cross-sectional relationships among jobs, job levels, wages, and changes in each of these. We come back to these papers in Section 2.1.

Two other studies in roughly this style are the analyses of peer effects by Ichino and Maggi (2000) and Mas and Moretti (2009). Ichino and Maggi explore the causes behind regional disparities in shirking behavior in a large Italian bank. By focusing on movers within the bank across offices in different regions, they were able to assert that cross-regional differences in shirking behavior were mainly due to individual taste for shirking, peer effects, and workers sorting into branches with similar shirking habits.

Mas and Moretti (2009) study cashier productivity at a large supermarket chain. They find that high-productivity checkout clerks have a positive impact on the productivity of other clerks working at the same time, through some type of peer effect, and that this effect on worker productivity is stronger in the presence of high-productivity co-workers with whom workers interact often. More interestingly, Mas and Moretti are able to exploit precise information about the physical arrangement of the cash registers to show that this productivity effect only occurs if the high-productivity clerks can see the lower productivity ones: when the more productive clerks are located in front of the less productive cashiers, and therefore the former cannot see the latter, there is no peer effect.

A second type of large-sample clinical studies consists of those that study events or changes that occurred inside firms or industries. In these papers, the authors attempt to show the consequences of such changes for the inner workings of the organization under study. An example of this type of paper is Lazear (2000), which is an event study of the change in compensation system at a large auto glass company, Safelite Glass Corporation. Between 1994 and 1995 the company changed its compensation system from hourly wages to piece rates.¹ Lazear calculates that this change in compensation system was associated with a 44% gain in productivity at the firm. He further documents that this productivity gain has two sources: increase in the

1. Lazear (2000) never mentions, and seems unconcerned with, the possible endogeneity of this change. However, the results are sufficiently striking and abrupt that the possible explanations involving endogeneity seem implausible.

productivity of individual workers who stay through the change and a selection effect (the more productive workers stay with the firm and the less productive ones leave). Lazear also documents that both average pay and firm profits increase after the change in compensation system.

Two papers along similar lines by Paarsch and Shearer (1999, 2000) examine the response of workers to piece rates using personnel records of a British Columbia tree-planting company. Their careful examination of changes in worker productivity stemming from changes in compensation allows Paarsch and Shearer to show that more aggressive piece-rate systems are associated with larger output yield per worker, but that the gain in output comes at the expense of quality. They also highlight the potential gains of sorting workers by productivity type but provide evidence suggesting that workers strategically choose how much effort to exert to prevent revealing their type, which reduces the productivity effect of sorting.

Knez and Simester (2001) offer another example of an event study, one that explores the role of social relations within firms. They examine the impact of firmwide bonus compensation system at Continental Airlines established in 1995. Conventional economic logic would predict that the scheme, which paid all workers a bonus based on firmwide profitability, ought to be plagued by a serious free-rider problem, because each worker has an indistinguishable impact on overall profits. Surprisingly they find that this bonus system increases firmwide productivity despite free-riding concerns. After carefully considering a number of alternative sources of individual incentives that could be spurring productivity, Knez and Simester attribute their result to the organization of workers into distinct autonomous work groups that enabled mutual monitoring among employees. Similarly to other clinical studies described in this section, it is this paper's attention to the detail and internal organization (carefully exploiting what is not in the quantitative data) that provides an understanding of the source of the increase in productivity and the lack of free riding.

2. What Purposes Do Clinical Papers Serve?

The traditional model of the scientific method describes a process that begins with observation and proceeds through hypothesis generation, formal modeling, and hypothesis testing. The third and fourth of these steps are well-trodden grounds in economic research; the first two rarely appear in journals. But observation and hypothesis generation are no less important parts of the process of understanding and testing the world: they just do not generate published papers very often. Clinical papers represent the tangible product of observation and hypothesis generation. It teaches us what to model, how to model things, and whether the models that we build are sensible. Each of these purposes of clinical studies is explored in this chapter.

2.1. Knowing What to Model

A clinical study can provide a highly detailed set of facts that may cry out for a more formal and general explanation (or a more thorough empirical analysis) than exists in the current literature. The story of Fisher Body proved very useful in providing enough detail about hold-up to allow theorists like Oliver E. Williamson, Sanford J. Grossman, and Oliver D. Hart to construct models, of varying degrees of formality, of this phenomenon.

The two papers on personnel economics mentioned in Section 1.4—Baker et al. (1994) and Lazear (1992)—have had a similar type of effect. These papers differ from others mentioned in this chapter in that they lack narrative structure, and therefore they cannot be classified as stories in the traditional sense. Yet these papers describe facts that are informative to organizational researchers about the inner workings of internal labor markets unclear to economists (not so much to other social scientists) up to that moment. By revealing the workings of two large firms, these authors prompted numerous theoretical papers on wages, learning, and careers within firms. Gibbons and Waldman (1999) pose the puzzle that they are trying to solve based on the observations of Baker et al. (1994).

The still-unidentified (despite the best efforts of several of the authors' colleagues) firm studied by Baker et al. (1994) was no mom-and-pop operation: it was a large and established firm in the financial services industry. This fact, combined with many others in the paper that “rang true” to those familiar with personnel systems in large firms, leads to the conclusion that these facts were important enough to model, and that these models would prove useful in predicting human resources practices in other firms.

The Baker et al. (1994) dataset contained data on 7,000 employees over 20 years. The data that the authors studied included information for each employee-year observation on the employee's salary, job title, and other demographic information. The paper documented some previously explored facts and found some (at the time) puzzling results that organizational economists had no solid explanations for. In particular, they found that wage changes at promotion are much smaller than cross-sectional differences in wages across levels. In addition, real wage declines were common, but nominal wage declines and demotions were rare. Baker et al. also found evidence for “fast tracks” in promotion and showed serial correlation between wage increases and promotions. They found that wage changes are a good predictor of promotions. The results in Baker et al. (1994) are still prompting theorists and empiricists to study the nature and robustness of their findings. In fact, these authors added dimensionality to an existing literature in internal labor markets (wage variation in organizations) and linked different literatures pertaining to different fields in the social sciences when relating wages (labor economics) to sequence of jobs in careers (sociology). Some examples of recent papers in economics referencing the work in Baker et al. (1994) are another by Gibbons and Waldman (2006) (explaining the presence of cohort effects in firms through the introduction of task-specific human capital) and Moldovanu et al. (2007), who explore why firms tend to have ports of entry primarily at low levels in their hierarchy.

The description and analysis provided in the Dial and Murphy (1995) account of GD provides similar grist for the theorist's (and empiricist's) mill. They show that tremendous value can be created, even in industries characterized by excess capacity and shrinking demand. This account of how the new CEO of GD (William Anders) developed and implemented a strategy to downsize and liquidate the defense contracting giant uncovers some important insights about the nature of organizational change and value creation. What was clear to Anders after the fall of the Berlin Wall was that there was far too much capacity in the defense industry. Most industry participants developed a strategy of expansion, trying to build up their capabilities so that they would weather the inevitable shake-out. Anders led GD on a totally different path, recognizing that efficiently liquidating the firm was the best thing to do from society's (and his shareholders') perspective.

Implementing Anders's strategy would prove to be difficult, however. The firm would need a management team with experience and knowledge of the firm and industry, who were committed to create value for GD's shareholders and were willing to make difficult and painful choices to shrink the firm. And Anders would have to recruit and retain this management team to a task that was virtually guaranteed to put them out of a job. His solution—a highly leveraged compensation plan that awarded very large bonuses and stock options to management based on the firm's market value—worked from the standpoint of motivation and results, but it proved to be a public relations nightmare. Every time the firm announced a move that reduced capacity from the industry, through either the sale of a division or the closing of a plant, GD's stock price would rise, and the managers who caused this pain and dislocation to workers would receive huge bonus payments! In spite of the firm's public relations problems (Anders was featured on *60 Minutes* as an example of outrageous executive pay—he was accused of graduating from the Marie Antoinette School of Management), GD was the best-performing company on the New York Stock Exchange for the 3 years from January 1991 to January 1994.

The insights from the GD clinical study are both obvious and profound. At one level, the story demonstrates nothing more than the tautology that moving resources to their highest valued use creates value—value that can be captured by the agents who develop and implement the strategy to do so. The GD story is enlightening in showing how this tautology holds even in situations that look like recipes for value loss and destruction.

2.2. Showing How to Model Things

A second important role that clinical studies play in the development of theory is to uncover and clarify the mechanisms at work in complex and poorly understood situations, so that theorists and empiricists can model them better. The authors of such studies do so by getting closer to the phenomenon and collecting qualitative data and anecdotal evidence. This often implies investing in such time-intensive activities as interviewing firm managers and employees, industry observers, and consumers. The object of these interviews is to understand the motivation and thoughts as well as the opportunities and constraints of economic agents and therefore to better understand how they make decisions.

It is important to recognize that a good understanding of the phenomenon under study is just as important to empirical research as it is to theory building. An incorrect empirical model can lead to specification errors that result in drastically misleading empirical results. An obvious example of such misspecifications occurs when empiricists leave out important variables from a regression, either because they do not understand that such variables are important or because collecting this variable is too difficult or costly. The problem is that variables that have no relevance whatsoever for the research question, but are coincidentally correlated with the relevant omitted variable, will have great statistical significance in this misspecified regression. An empirical investigator who understands what the important variables are would never even run this regression, recognizing that she has to either abandon the project or bear the costs of collecting the data to allow her to model the situation correctly. Qualitative detail in a clinical study will often guide empirical researchers to what the "right" regression model is.

An early example of this type of clinical paper is the Baker and Wruck (1989) study of the LBO of O. M. Scott & Sons. This paper followed several large-sample studies (DeAngelo and

DeAngelo 1987; Kaplan 1989) about the nature and consequences of LBOs. In their study Baker and Wruck take as a starting point the conclusions of Kaplan (1989) and DeAngelo and DeAngelo (1987) that LBOs create substantial value. Their task is to understand why. Baker and Wruck identify in detail the organizational changes that took place in O. M. Scott & Sons that led the firm to increase performance after the buyout: changes in organizational structure and governance, creation of new performance metrics, and implementation of new incentive plans. Whereas the literature previously hypothesized that changes in governance and incentives lead to the observed value increases, Baker and Wruck both document these changes and show (in this one case) how the changes lead to an increase in firm performance and value.

2.3. Assessing “Possibility Theorems”

In the editorial note introducing the clinical papers section in the *Journal of Financial Economics*, Jensen et al. (1989) lobby for the growing importance and role of clinical studies in the effort to improve existing and future theoretical and empirical research. Jensen et al. (1989: 3–4) warn us about the danger of “possibility theorems” in finance:

The unique and well-defined perfect market theory provides a useful standard of comparison as the limit toward which unencumbered markets move. There are, however, an infinite number of imperfect market theories corresponding to the limitless combinations of alternative assumptions. Unfortunately, most of these theories are irrelevant to understanding the world. In this sense they are “possibility theorems”—propositions that, while logically correct, have little or no probability of explaining any real phenomenon. The imperfect market theories that interest us are those that have a reasonable probability of explaining reality.

Possibility theorems start from a fact and then develop a model that explains this fact. The problem is: how does one assess the validity of this new model? To simply “check the math” to be sure that the model is solved correctly, and to make sure that it does indeed predict the initial fact, seems less than a thorough validity check. The chemist Manfred Eigen (1973: 618) states the problem succinctly: “A theory has only the alternative of being right or wrong. A model has a third possibility—it may be right but irrelevant.”

The standard method for assessing models that “predict” known facts is to demand that they make *new* predictions—perhaps with greater precision, or in realms outside those of the original fact. Thus, when Isaac Newton delivered the theory of gravity after sitting under the (proverbial) apple tree, that prediction that apples fall from trees does little to substantiate Newton’s theory of gravity. It is the fact that Newton’s theory of gravity, derived from observing apples falling, accurately predicts the movement of celestial bodies that validates this theory.

But a second method exists for validating possibility theorems: we can consider whether the model is sensible. To do this, we must understand the phenomenon with enough richness and detail to be able to say whether the model captures the trade-offs that agents and organizations face when making decisions. It is as part of this second method that clinical studies play a very important role. Clinical studies should provide this type of richness and detail and therefore help theorists produce better, more accurate, and more sensible models.² As discussed above,

2. This idea—that models in economics should reflect the underlying thoughts, motivations, and capabilities that agents have—is not universally accepted. Milton Friedman, using his famous analogy to billiard players, argued

the same goes for empirical models and empirical analyses that build on a well-known set of stylized facts.

There is an excellent historical example of how an in-depth study of a particular situation “tested” the sensibility of a perfectly plausible theory in the realm of incentives and motivation. Despite the widely accepted belief among economists that employee incentives raise productivity, there is much evidence that piece rates lead to shirking and restrictions in output by workers. Much of the early evidence on this phenomenon comes from the famous experiments, conducted by Elton Mayo and Fritz Rothlisberger, at the Hawthorne Works of the Western Electric Company.

Mayo (1946: 120) offers a theory in his book *The Human Problems of an Industrial Civilization* to explain how piece rates lead to shirking and output restriction:

Human collaboration in work . . . has always depended for its perpetuation upon the evolution of a non-logical social code which regulates the relations between persons and their attitudes to one another. Insistence upon a merely economic logic of production . . . interferes with the development of such a code and consequently gives rise in the group to a sense of human defeat. This . . . results in the formation of a social code at a lower level and in opposition to the economic logic. One of its symptoms is “restriction.”

Mayo had stated that workers were not obeying the will of their employers, because they were unable to process the set of incentives presented to them. He (and others) went a step further and claimed that the economic “logic” imposed on the workers made them feel disoriented, discouraged, and distracted from achieving their true potential, and therefore, they attained a new “lower social code” as described in his book.

Roy’s (1952) observations at the machine shop in Chicago suggest a very different theory. He notes that when the workers on the floor exceeded a specific “bogey” for a particular part, management (using classic ratchet logic) would conclude that the piece rate for this part was too high and would instruct the time-study department to retime the work and reset the piece rate. Thus, exceeding the bogey led to a short-run gain for the worker who worked hard, but a significant reduction in welfare for himself and all of his co-workers in the future. Not surprisingly, workers developed social norms that discouraged co-workers from exceeding the bogey.

Based in his observations, Roy discusses Mayo’s theory of human motivation regarding “quota restriction.” Roy (1952: 430) refers in the following way to Mayo’s conclusions regarding the observation in the Hawthorne studies, and to his own results:

Mayo thus joins those who consider the economic man a fallacious conception. Now the operators in my shop made noises like economic men. Their talk indicated that they were canny calculators and that the dollar sign fluttered at the masthead of every machine. Their actions were not always consistent with their words; and such inconsistency calls for further

that all we ask for in economic models is that they make good predictions. It does not matter whether the billiard player is actually an expert in trigonometry. The model that assumes that he is will make good predictions about his shots; however, models of this sort tend to be fragile. The billiard-trigonometrist would have little trouble with a billiard table that was a parallelogram; one would expect that the real-world billiard player would have a very hard time.

probing. But it could be precisely because they were alert to their economic interests . . . that the operators did not exceed their quotas.

Roy's observation casts doubt on the empirical relevance of Mayo's hypotheses. By developing a careful understanding of the motivations of his co-workers (at least as he understood them), Roy is able to conclude that Mayo's theory, while in principle correct, is not a sensible one to explain the behavior of his co-workers, given his (and, one suspects, many others') understanding of the behavior of piece-rate workers. It is not that his co-workers did not understand the motivation of their employer in setting and resetting piece rates. They did: far better than their employers would have liked them to. As rational individuals, they were maximizing their own well-being and therefore obtaining the higher pay with lower effort.

Similar to the controversy over Mayo's (1946) hypotheses, Roy's (1952) careful observations may also allow us to reject some economic theories regarding the consequences of the ratchet effect. Take, for example, Lazear (1986), where he models the presence of the ratchet effect in a two-period model in which workers understand the consequences of showing high productivity in the first period on their pay for the second period. Under the assumption that workers do not contemplate employment in another firm, Lazear finds that workers actually operate at first-best effort through both periods, resulting in no loss of efficiency. The accounts in Roy's passages, however, suggest that workers very much take into account their outside opportunities and therefore consider outcomes, such as being fired, laid off, or changing jobs. Following Roy's accounts accurately, Gibbons (1987) shows that the ratchet effect does indeed create inefficiency and that workers may not be producing the first-best effort when strategically responding to ratchetlike incentive schemes.

This particular set of cases makes clear the usefulness of clinical studies. Clinical studies allow outsiders to put themselves in the shoes of the agents and organizations involved in the decisionmaking process under study, and to discard improbable explanations that may yield the same set of observed well-established facts.

2.4. Clinical Studies as Evidence

In assessing the validity of a theory and the role that clinical studies play, we must ask the question of what can confirm and what can disconfirm a theory. Strict adherence to the scientific method would suggest that a single case can be used to declare a theory invalid. In practice, of course, such a strict interpretation rarely holds sway. Nonetheless, clinical studies can be useful as evidence to support or weaken theoretical conclusions.

Several excellent examples of this sort of insight from clinical studies have already been mentioned. Lazear's (2000) study of incentives and sorting at Safelite Glass Corporation provides a compelling example of the potential for piece-rate incentives to increase productivity. The Knez and Simester (2001) study of group incentives at Continental Airlines provides a similar benchmark for the use of group-based incentives. Both these papers not only provide evidence on the sign of the impact on productivity of the implementation of an incentive system but can also measure the magnitude of the impact. The Blanchard et al. (1995) paper on cash windfalls provides insight of a similar nature, as does the Cutler and Summers (1988) estimate of the total wealth loss stemming from litigation between Texaco and Pennzoil.

3. Should Economists Write Clinical Studies?

Clinical studies in economics are still a rare form, which means that few of us are doing them. We can think of three reasons that scholars can, and should, write clinical studies. The first is, of course, to aid in teaching. Teaching with cases generally enriches the pedagogy and makes concrete concepts that may otherwise be sterile or overly theoretical. Of course, the standards for what makes a good teaching case may differ from those for publishable clinical studies: more on this below.

A second reason to carry out clinical studies is to enrich one's own research. Most authors of clinical studies are also producers of standard economics research. From their perspective, beginning a research stream with something akin to a clinical study is a preliminary step to devising better models and conducting more sensible and relevant empirical analysis (even if the clinical study and consequent analysis appear in the same study). Take, for example, research by Arruñada et al. (2001) on allocation of decision rights across firm boundaries in the Spanish car retailing industry, or Baker et al. (2008) on strategic alliances in the biotech industry. These are examples of papers that detail patterns in organizations and then use that institutional knowledge to inform subsequent empirical and theoretical work.

Similarly, Gil's (2013) work studying contractual practices in the Spanish film industry documents the interplay of formal and relational contracting between Spanish movie distributors and a large exhibitor. Interviews with industry managers and practitioners revealed that contractual renegotiation of each one of the weekly revenue-sharing terms takes place after the movie is pulled from the theater. This is a fact impossible to identify from just looking at the data, and yet it is key for understanding the nature and source of renegotiation in this industry. The exhibitor (theater owner) is not holding up the movie distributor to get the latter to show the movie an extra week. Instead, the distributor is compensating the exhibitor for keeping the movie on screen even in weeks for which it would not be profitable for the theater alone to do so, but it is jointly profitable for both exhibitor and distributor to do so. Knowledge of this institutional detail drives not only the understanding of contracting in this industry but also the way to approach the data and the empirical analysis.

A third reason is to provide information and data for others. As we commented before, clinical studies may be the spark for further research by providing a thorough description of a poorly understood phenomenon. Helper (2000) argues that clinical studies are beneficial to everyone when paraphrasing the New York Yankees philosopher Yogi Berra: "You can observe a lot by just watching." The benefits of "observing" are highest when focusing attention on areas with little data or theory and when paying attention to the motivations and constraints of the economic agents. She also points to the value of providing vivid images that aid the reader by developing economic intuition.

Even if we accept that clinical studies should be carried out, and that we all benefit from them, we can ask the question of whether we *economists* should spend time and resources on writing clinical studies. The answer is ambiguous. Economists may not have a comparative advantage in doing this kind of work. Although economists are not trained to do this kind of intense and time-demanding data collection, some sociologists and psychologists do have the training. Perhaps economists should leave the writing of clinical studies to other social scientists.

Letting others do this job for us comes with its own set of advantages and disadvantages. One advantage is that other social scientists, by virtue of their different training and theoretical

approaches, will tend to observe and report facts that economists might have missed entirely. An excellent example of this is sociologist Robert Eccles's book *The Transfer Pricing Problem* (1985). Although economists (up to that time) believed that the purpose of transfer pricing was to allocate resources within firms, Eccles points out that few transfer pricing systems employed in firms actually do so. Eccles instead focuses on the conflict and political wrangling that transfer pricing systems cause in organizations.

However, this same strength—that clinical studies conducted by other social scientists may provide observation on things that economists would miss—may also be a weakness. When we borrow studies from other disciplines, the studies may fail to report on or even observe phenomena that are critically important to an economic theory. For example, a clinical study of almost any phenomenon inside an organization that fails to report on the incentives presented to the agents by the compensation system is likely to frustrate an economist's thorough analysis of the situation.

4. Standards for Clinical Studies

Good clinical studies ought to be interesting and compelling. Obviously, these two properties are especially important if clinical studies are intended for teaching purposes: less so if they are targeting a research audience. What other characteristics would we expect clinical studies to have to be effective in communicating those details and institutions that will enable economists to do better research?

Generally, good clinical studies will contain a detailed and rich description of the situation. Clinical studies without this detail are more like examples: useful for illustrating existing theory, but much less valuable as a tool for generating new theory. In addition, a good study ought to be generalizable, in the sense that insight derived from a particular situation is useful elsewhere. Without this characteristic, it is hard to see the point and relevance, other than pure entertainment.

In a similar vein, a clinical study should also address a topic that is, or eventually will be, modelable. This does not mean that the topic can be modeled with current technology: a good example is the description of the ratchet effect of piece rates in Donald Roy's machine shop. This phenomenon was not adequately modeled for 35 years until Gibbons's (1987) dissertation.

In this regard, we observe that many clinical studies and teaching cases about organizations, especially those by noneconomists, highlight the importance and relevance of corporate culture and leadership to corporate success. These are concepts that economists either failed to notice, or at least found too difficult to model, for decades. The Kreps (1990) paper—"Corporate Culture and Economic Theory"—was among the first to attempt this. Since that time, some economists have taken on the challenge of modeling these concepts (see Hermalin [1998] on leadership or Van den Steen [2006] on corporate culture).

One final standards question still looms: accuracy. It would seem that accuracy is a key ingredient of high-quality clinical studies. But is this really true? The legacy of Fisher Body again is relevant. Although this story has been central to theory development for more than 30 years now, the actual chain of events that led to the acquisition of Fisher Body by General Motors is very much in dispute. Papers by Casadesus-Masanell and Spulber (2000), Coase (2000), Freeland (2000), and Helper et al. (2000) dispute most, if not all, of the central factors

playing a role in the Klein et al. (1978) version of the story. However, controversy over the facts notwithstanding, no one can dispute the usefulness of the story of Fisher Body to the field of organizational economics and the generation of theory in the field. Given the usefulness of the case as related by in Klein et al., should we care about any lack of accuracy and discount the scholarly contribution of the work?³

4.1. Areas of Concern

Several criteria that are standards for empirical research in economics are problematic for clinical studies. These include representativeness, bias, and replicability.

4.1.1. *Representativeness and Bias*

There is, and we believe there should be, real concern that the body of knowledge that results from a set of clinical studies will not be representative of any set of real-world settings that scholars might choose. This is because one of the main impediments to clinical studies, at least inside organizations, is access. Scholars must get permission from organizations to go inside them, talk to people, look at potentially sensitive information, and report what they believe is a complete picture of the phenomenon under study. This problem introduces a kind of sample selection bias that is very difficult to get a handle on, but it is surely important. We can speculate on the types of organizations that are likely to allow this type of work: those that care about knowledge generation, those that seek publicity, those that are successful, and those that use academics as consultants.

Perhaps the most troubling of these biases is that favoring success. Clinical studies and business teaching cases tend to be about successful organizations and their strategies rather than about failed organizations and the factors that led them to failure. Why is this the case? A first reason is that the reigning teaching philosophy in business school, law school, and other professional and graduate schools is more about the “Dos” than it is about the “Do Nots.” A second reason is that firms going through failures that are worth writing about are also more likely to cease to exist. Finally, given that organizations must generally give their consent to allow a clinical study to be performed, it is human nature that those involved in success are more likely to agree to be the subject of a clinical paper than are those involved in failure.

4.1.2. *Replicability*

Another source of concern when evaluating the validity of clinical studies is the lack of replicability. Replicating most clinical studies is extremely costly, if not impossible, mainly because clinical studies often cover scenarios that are unusual and generally involve permissions and access that are hard to obtain. Later scholars’ likelihood of finding additional sites and circumstances that replicate the original setting is low. However, there is a serious question of whether replicability is necessary for a study to be acceptable. Because the situations described in clinical studies are often helpful precisely because they are unusual, and because much of the value is in

3. Along these lines, it is interesting to note the disclaimer printed on the first page of every Harvard Business School case: “HBS cases are developed solely as the basis for class discussion. Cases are not intended to serve as endorsements, *sources of primary data*, or illustrations of effective or ineffective management” (emphasis added).

the high content of institutional and situational detail, replicability is probably not a criterion that we may want to apply to clinical studies, even though we may want to apply it to all other empirical studies.

5. Conclusion

Although this chapter has focused on clinical studies in organizational economics, many of the arguments for (and against) the usefulness of clinical papers are relevant to all of economics. However, we believe that clinical studies are particularly useful and important to building good theories and designing sensible tests of these theories in the field of organizations.

It is easy to forget that the neoclassical theory of the firm was all we had as recently as 30 years ago. Indeed, in many introductory and even intermediate microeconomics classes, the firm is still treated as a black box that transforms inputs into outputs through some monotone mechanical relation called the production function. Thanks in part to the work of psychologists and sociologists, economists now recognize that organizations are complex in their workings and that many aspects of organizational design and function are still beyond the scope of our modeling technology.

Because organizations are such rich and complex systems, understanding this complexity as completely as possible is important to building good models of how organizations work. In addition, much probably depends on the subtle and “soft” mechanisms that are best understood by the direct and careful observations provided by clinical studies. Understanding how relationships are managed both within and between firms, the role of corporate culture that mediates these relationships, and the role of leadership and personalities are best understood, we believe, by the slow and meticulous work involved in performing clinical studies.

Indeed, it is difficult to imagine how we could make much real progress on the issues that are central to the study of organizations without clinical studies to help and guide us. Even considering their costs in terms of time and money, clinical studies seem a necessary, though certainly not sufficient, condition for progress in this field. We hope that they will become more common, and more valued.

Experimental Organizational Economics

Colin F. Camerer and Roberto A. Weber

1. Introduction

This chapter is about experiments that study aspects of organizational structure and economic performance. Relative to field studies using empirical data, experiments often have obvious advantages, especially that of control and randomized assignment to implement theoretical assumptions that can only be imperfectly measured or controlled econometrically when using field data. Despite these advantages, the range of organizational hypotheses studied in experiments is small, although it is growing rapidly.

What makes an experiment organizational? The working definition we use to define the scope of this chapter is the following.

Definition *In an organizational experiment, two or more subjects engage in a productive enterprise (usually a highly reduced-form model of a more complex organization) where the impact of the structure of the organization and incentives on productivity, through the characteristics and choices of subjects, are the variables of central interest.*

This definition is crafted to exclude (for brevity) consideration of many experiments relevant to organizations but not unique to them and those that do not vary structural variables of most interest in the economic study of organizations. One prominent class of such experiments is those that aim to use simple interactions to estimate the prevalence, characteristics, or consequences of social preferences on behavior (e.g., dictator, ultimatum, and trust games). Although valuable, this research is not unique to organizations, because the games also apply to market bargaining, groups, households, and other contexts (for reviews, see Camerer 2003: 336–407; Cooper and Kagel, in press). Another prominent class consists of experiments on negotiations studied by scientists interested in organizational behavior. We exclude these important experiments, because they do not typically alter incentives or hierarchical structure to test particular

ideas in organizational economics, and their results are well reviewed elsewhere (e.g., Bazerman et al. 2000). Finally, we also exclude a considerable number of relevant research studies due to the sheer volume of experiments that one could consider “organizational”—even using our definition.¹

An obvious concern about using experiments to study organizations is that the organizations that are the typical focus of theorizing—such as large firms—are complicated. Experiments are necessarily much simpler and are usually constrained in the numbers of agents and length of time that can be studied in a way that is both inexpensive and well controlled. This mismatch in scope naturally leads to heightened concerns about generalizability (which we discuss in Section 2.1).

The chapter is organized in seven sections. Section 2 presents an introduction to experimental principles and some early history of organizational experiments in psychology and sociology. The central sections discuss experimental research in four important organizational areas: basic theories of incentives and worker effort (Section 3), voluntary effort and reciprocity (Section 4), coordination (Section 5), and leadership and hierarchy (Section 6). Section 7 concludes and discusses some types of organizational experiments that could potentially provide valuable insights into organizational economics.

2. Experimental Principles and Some History

2.1. Basic Principles of Experimentation in Economics

Experiments are useful in all sciences. The experimental environment is one carefully designed and controlled by the researcher to provide the cleanest possible test of a theory or hypotheses. For instance, an experiment can allow researchers to measure the outcomes of both an event and its counterfactual (e.g., an institutional change or a merger), when the counterfactual is typically not observed outside the lab. An experiment also allows a researcher to avoid the endogeneity biases present in much empirical field research, by providing the researcher control over what is exogenous. Experiments also allow the researcher to distinguish among and test different explanations for an observed phenomenon (by controlling for transactions costs, risk aversion, beliefs, etc.) that are hard to separate parametrically in field data. Thus, the key feature of any experiment, and the central quality that makes experiments valuable, is control—over factors that are important in the theory being tested and over those that need to be excluded from the environment to properly test theory.

Good experiments typically satisfy four basic criteria: control over all relevant factors in the experimental environment, internal validity (the treatments work as intended and for the reasons claimed by the researcher), statistical integrity (using standards applicable to other empirical work),² and likely generalizability to naturally occurring settings with similar

1. We direct the reader interested in a more comprehensive review to other reviews that overlap considerably with ours in focus (Camerer and Malmendier 2007; Charness and Kuhn 2011; Kriss and Weber, in press).

2. In economics experiments with interacting groups and repeated behavior, it is generally inappropriate to treat individual observations as independent identically distributed (iid) draws. Instead, the appropriate tools

features.³ It is usually easy to evaluate these criteria. But even when it is not, the threat of direct replication (and actual replication) disciplines researchers and gradually weeds out unreliable effects that might result from weaknesses in the basic criteria.

Really good experiments have other properties that are more difficult to define than the basic ones but are just as important. For example, an “interesting” experiment grabs attention by producing a result that is both surprising—Davis (1971: 327) calls it “denying assumptions of the audience”—and comprehensible after the surprise wears off. A “fruitful” experiment creates a paradigm (and sometimes tools, like software) and a result that piques curiosity and leads to natural extensions of the paradigm. One component of fruitfulness is the capacity of an experiment that rejects a theory to suggest an alternative theory and new experiments worth doing.

2.2. Organizational Experiments and Generalizability

The canonical organizations of most interest in economics—large firms—consist of agents who are both self-selected and selected by organizational promotion tracks, highly motivated by financial incentives, often highly experienced in their roles, and familiar with other organizational members. The typical laboratory experiment uses random assignment of inexperienced subjects (often college students), who are unfamiliar with one another, to simple organizational settings (often a single, abstract task, e.g., a number choice representing effort) with relatively modest incentives. Despite the obvious challenge of generalizing from such simple experiments, there are three arguments in favor of doing simple laboratory experiments on organization.

First, in science it is usually surprisingly useful to start with the simplest cases and then generalize (much as in producing formal theory). Basic genetics were first understood by studying fruit flies, which are much simpler than humans. Earthquakes are understood by using slider block models that study wooden blocks connected by metal springs (representing tectonic plates). Such simple experiments can produce an understanding of basic phenomena of significant importance. At this point, organizational experiments are similar in complexity to fruit fly studies of genetics and slider block models of earthquakes. Fortunately, there is plenty of future opportunity to create experimental organizations that are larger in scale, complexity, and temporal scope than the simple ones we describe.

are those used for time-series panel data with some specification of interaction effects among agents and over time. Controlling for various levels of clustering is one approach (see Frechette, in press). In practice, researchers often report tests using both incorrect iid assumptions and overly conservative assumptions (e.g., treating behavior averaged across an entire session as a single data point and testing across sessions).

3. However, it is important to note that generalizability is simply one criterion on which many experiments can be evaluated and is not a litmus test that must be applied to determine the usefulness of every experiment. Testing theories often requires creating environments that are different from what we typically observe in the natural world but contain all the key elements of a theory (Falk and Heckman 2009; Camerer 2011). In the physical sciences theoretically motivated experiments similarly often use environments that are atypical, dissimilar from where the theory is usually applied, and do not exist naturally (e.g., in particle accelerators, zero gravity, or a vacuum). Camerer (2011) also carefully reviews data from the closest matches of lab and field settings and finds that in only one of several cases does lab data provide a different answer than field data. Thus, generalizability is quite good, despite concerns voiced by Levitt and List (2007).

Second, some organizations are simple, so simple experiments are good analogies. A start-up with a few inexperienced employees or a project team in a firm that involves a small group of strangers who interact in an unfamiliar production task for a limited period might be well modeled by simple experiments like those described in this chapter.

Third, the presumption in economic theory is that basic principles apply widely unless the theory explicitly contains variables that parameterize boundaries of likely empirical applicability. Nothing in principal-agent theory, for example, says the theory should apply to CEO compensation but not to a three-person law firm with one lawyer and two paralegals, or to a three-person lab experiment with the economic structure of the law firm. If obvious distinctions between large firms and small experiments—like incentives or experience and selection of agents—are expected to make a difference in behavior, then the way in which those distinctions matter should be part of the theory. If they are not, experimental findings can suggest how those distinctions should be included.

When judging the generalizability of organizational experiments, it is also important to distinguish the power of the experimental method with the progress made from experiments thus far. If there are doubts about whether worker reciprocity persists over long periods, for example, this is a criticism about the generalizability of specific short-run experiments to particular long-term settings, but it is not a criticism of the experimental method—because, in principle, experiments can be conducted over the long run. Moreover, field experiments in markets and firms, with some degree of control, can be powerful complements to laboratory experiments. Thus, where there is a doubt that a particular experimental finding will generalize, those doubts are most useful if expressed as a conjecture about how extending the criticized experiment in some feasible way would change the results, an endeavor we fully encourage that is compatible with the experimental approach.

2.3. Early (Noneconomic) Organizational Experiments

The earliest organizational experiments, as we define them, were simple social psychological experiments aimed at understanding how performance and productivity change in the presence of others. Early experiments on “social facilitation” (Triplett 1898) measured how the presence of other individuals can lead to increased effort and performance in simple tasks (e.g., pedaling a bicycle). Later experiments by management researchers and industrial psychologists (Taylor 1911; Mayo 1933) studied factors that influence productivity and performance. Most of this research took place in real firms. Researchers exogenously varied factors, such as incentives, task design, and environmental influences, and then measured performance under these varying factors. This early research demonstrated the value of experimentation for understanding organizations and influenced the development of management and organizations as areas of scholarly inquiry (March and Simon 1958).

Starting in the 1950s, organizational psychologists began using simple laboratory experiments to study social factors that might influence efficiency and productivity in organizations. For example, several experiments explored the impact of group structure or “communication nets” on productivity in simple tasks (e.g., Bavelas and Barrett 1951; Leavitt 1951; Guetzkow and Simon 1955). These experiments provided valuable insights into how communication and authority structures in organizations might influence performance, and they also demon-

strated the potential value of simple laboratory experiments for understanding organizational phenomena.

In subsequent decades, managerial and organizational researchers—usually trained as psychologists—continued to use experiments to understand organizations. In 1969, a special issue of a leading management journal was dedicated to experiments on organizations (see Weick 1969). This special issue addressed such topics as performance in hierarchical versus flat organizations (Carzo and Yanouzas 1969), internal resource allocation (Pondy and Birnberg 1969), and employee performance in response to varying levels of payment (Evan and Simmons 1969)—an experiment similar to recent “gift exchange” experiments in economics (see Section 4.1). The experiments varied in whether they took place in a laboratory or in the field, and as with many subsequent noneconomic organizational experiments, they also frequently involved deception of subjects by the researchers (a practice frowned on by experimental economists; see Ortmann and Hertwig 2002).

Following the abovementioned research, organizational and managerial researchers have since continued to rely on laboratory and field experiments to address similar questions (e.g., Argote et al. 1989; Greenberg 1990; Bottom et al. 2006). Although we omit this research to focus on experiments in organizational economics, this work frequently explores similar questions to those addressed in the work we review below.⁴

We now review experimental research in four areas of interest to organizational economists: (1) theories of incentives and worker effort, (2) voluntary effort and reciprocity, (3) coordination, and (4) leadership and hierarchy. Each of the next four sections reviews experimental research on one of these topics, focusing on a few key studies and cumulating regularity across studies.

3. Incentives and Worker Effort

The first wave of experiments we describe study the most basic propositions of incentive theory. The relationships among different kinds of incentives, effort, and productivity are central to organizational economics. Many of these experiments exploit the sharp precision of predictions that can be derived when cost of effort is induced experimentally and comparative statics make clear predictions about which types of contracts will work well or poorly.

3.1. Basic Incentives

Nalbantian and Schotter (1997) studied a variety of incentive schemes in simple lab experiments. In their setup, teams of six agents choose efforts e_i in the interval $[0, 100]$. Group output is a simple sum of effort plus a random term, $Y = 1.5(\sum_i e_i + \varepsilon)$, where ε is uniform in $[-40, +40]$. Revenue is equal to group output times a constant ($R = 1.5Y$). Agents' effort costs are $(e_i)^2/100$.

Optimal net revenue for the group (less effort costs) occurs at $e_i^* = 75$. Nalbantian and Schotter (1997) consider a variety of contracts that either induce this effort (in theory) or that

4. For example, the recent paper by Bottom et al. (2006) examines how employees respond to both financial and social incentives. This is similar in focus to the work reviewed in Section 3.1.

Table 1. Equilibrium and actual effort in various incentive schemes

Contract	Individual payoff to i	Equilibrium effort e^*	Equilibrium group profit	Mean effort
Revenue sharing	$Y/6 - c(e_i)$	$e^* = 12.5$	103.1	19
Forcing contract (75)	$Y/6 - c(e_i)$ if $Y \geq R^* = 450$; $B = 1.125$ otherwise	$e^* = 75$	337.5	16
Profit sharing	$(Y - Y^*)/6 - c(e_i)$ if $Y \geq Y^* = 75$; $B = 0$ otherwise	$e^* = 19.1$	150.0	22
Team competition	$(Y_1 + T)/6 - c(e_i)$ if $Y_1 > Y_2$; $(Y_1 - T)/6 - c(e_i)$ if $Y_1 < Y_2$; $T = 360$	$e^* = 75$	337.5	35 ^a
Monitoring ($p = 0.7$)	Earn $W = 112.5$ if $e_i = 75$, $W = 18.75$ if $e_i < 75$	$e^* = 75$	337.5	68
Monitoring ($p = 0.3$)	Earn $W = 112.5$ if $e_i = 75$, $W = 18.75$ if $e_i < 75$	$e^* = 0$	-506.25	4

Source: Data are from Nalbantian and Schotter (1997).

Notes: Mean effort is from the last 5 periods (out of 25) in phase I only. Means are estimated from plots.

a. Mean is from phase II, estimated from Nalbantian and Schotter (1997: figure 10) (corresponding mean for forcing contract with $e^* = 75$ is effort of 19).

theoretically induce lower effort due to shirking. These contracts and some basic results are summarized in Table 1.

Phase I experimental sessions begin with a 25-period revenue-sharing segment, followed by a switch to another scheme. Phase II experiments used the opposite order. Two experimental sessions used monitoring schemes, reversing the order of two different probabilities ($p = 0.3$ and 0.7) of being monitored.

The baseline contract is simple revenue sharing, in which players earn $R/6$ and pay their own effort costs.⁵ This contract should induce shirking and does so reliably; mean efforts start at about 35 and drift down to 18, toward the equilibrium of 12.5. A related contract, profit sharing, involves players sharing revenue only if average output exceeds the equilibrium quantity. This treatment also works roughly as predicted and generates little effort.

In a Holmström-type (1982) forcing contract, players share revenue only if total revenue is above the efficient level of 675 (corresponding to $e_i^* = 75$); otherwise, all players earn a low penalty wage $B \leq 1.125$. This forcing contract does badly because it is so fragile: mean efforts start at about 45, but all groups fall below the threshold output requirement, everyone earns the penalty wage, and efforts then fall. A forcing contract that is inefficient, inducing effort of

5. Revenue-sharing contracts are interesting because many firms use variants of group-based performance schemes (e.g., employee stock ownership plans). In theory, these schemes should not work well, because in large teams, workers should free ride if their shirking cannot be monitored and punished. Yet group-based performance schemes often work surprisingly well in practice (Nalbantian 1987; Blinder 1990), which motivates an interest in understanding when teams do not fail as badly as they should in theory.

40 in theory rather than 75, actually works much better in practice than the efficient forcing contract, as it is more easily met.

The contracts that work best, both at producing high effort and in the accuracy of theoretical predictions, involve team competition and monitoring. In the competitive teams treatment, firms consist of two six-person teams, and efforts create team output and revenue as in the revenue-sharing treatment. However, the lower output team in each pair of teams pays a transfer of $T = 360$ (shared equally among team members) to the team with higher output. In theory this contract should induce equilibrium effort of 75. Actual mean efforts are about half that level (with low variance across subjects).

Monitoring contracts works best of all. Players choose effort and are monitored with probability p . If they are monitored and chose effort of 75 or more, or are not monitored, they earn a high wage $W = 112.5$. If they are monitored and chose $e < 75$, they earn 18.75. When the monitoring probability is $p = 0.7$, they should choose $e^* = 75$, and monitoring indeed works incredibly well—median effort is 75 in about 90% of the experimental periods. When $p = 0.3$, they should shirk and choose $e^* = 0$, and median efforts are indeed very low.

More recent research studies how worker self-selection between different incentive schemes can affect firm productivity. For example, Dohmen and Falk (2011) use a real-effort task, in which subjects multiply one-digit numbers by two-digit numbers, and correctly entered answers constitute the worker's output. Subjects initially performed the task under no incentives and piece rate incentives, to provide measures of baseline productivity. They were then given the option to continue the task for 10 minutes under either a fixed-pay contract or one with pay dependent on performance. The variable-pay schemes varied by treatment and included piece rate, tournament, and revenue-sharing incentives. Across treatments, between 50% and 60% of subjects opted for variable pay. The main finding in the experiment is that output is higher under variable pay, with subjects completing roughly twice as many problems (about 60) under the variable-pay schemes than with fixed pay. Moreover, this result is driven mainly by more productive subjects opting for the variable-pay schemes. For example, when the variable-pay incentive was a piece rate, subjects who chose this option had completed, on average, 27.3 correct problems in the first part of the experiment, while those who opted for the fixed payment had completed only 13.8. Thus, different pay schemes not only affect productivity because of the effort they induce but also because of the different kinds of people they attract.

3.2. Tournaments and Sabotage

Lazear and Rosen (1981) note that many labor markets, particularly internal competition for promotion in firms, are organized as tournaments. In the simplest tournament model, individual workers exert costly effort e_i , their individual output (y_i) is a combination of (unobserved) effort and a measurement error term θ_i , and workers are ranked by total output $y_i = e_i + \theta_i$. Workers with rank r earn a pre-announced prize $M(r)$. Ranking workers is often cognitively easier than measuring their absolute outputs. Lazear and Rosen show conditions under which tournaments elicit maximum effort and are better incentive schemes than piece rates and other individual-specific wage packages.

Explicit tournaments are often used in sports (e.g., Ehrenberg and Bognanno 1990) and some areas of the economy (e.g., Knoeber 1989; Lambert et al. 1993). Generally, however, it is difficult

Table 2. Predicted and actual behavior in two-player tournaments

Treatment	Equilibrium prediction	Effort in rounds 7–12	
		Mean	Variance
Piece rate	37	38.91	87
Baseline	37	38.75	499
High effort equilibrium	74	69.91	892
Wide random number ($a = 80$)	37	33.41	286
Asymmetric costs	70, 35	73.60, 56.91	708, 905
Medium information (output)	37	48.91	442
High information (output, e_i)	37	33.48	552
Automaton opponent	37	44.62	276
Twenty-five-round experiment	37	48.00 ^a	362 ^a

a. Data are from the last half of the experiment (rounds 13–25).

to test the sharpest predictions of tournament theory with field data, because it is difficult to measure or influence key variables, making the laboratory a valuable testing ground.

Bull et al. (1987) did the first such tournament experiment. Subjects chose effort $e_i \in [0, 100]$ in two-player tournaments, with output $y_i = e_i + \theta_i$ determined by effort and an iid stochastic term θ_i drawn from the uniform interval $[-a, +a]$, with $a = 40$, and convex effort costs $c(e_i) = e_i^2/K$, where K varied from 10,000 to 25,000. The winning prize $M(1)$ varied from \$1.02 to \$1.45, while the second (losing) prize $M(2)$ varied from \$0.43 to \$0.86.

Table 2 gives results from the last half of the 12-period experimental session. The piece rate incentive produced outcomes very close to the theoretical prediction under risk neutrality. Although aggregate behavior in the first three tournament sessions (baseline, high-effort, and wide random number) converges toward the respective theoretical predictions, the variance in effort is quite large (much higher than for the piece rate) and does not decline across the session.

The results of providing additional information are a little puzzling. Providing ranks (baseline), or ranks and opponent effort (high information) produce efforts close to the equilibrium prediction, but supplying only rank and outputs (medium information) produces efforts that are much higher. Subjects appear to overreact to learning that their opponent's output is high, even though they realize that high output could be due to luck.

Sessions with automated opponents choosing Nash effort levels generally produce efforts close to equilibrium and lower variance than sessions with human opponents, which shows that strategic uncertainty when playing other subjects may increase variance.

Bull et al. (1987) also conducted one session with asymmetric costs, in which one player's cost function was twice that of the other player. Both players chose effort levels above equilibrium, which is important, because most naturally occurring tournaments do have cost asymmetries.

Schotter and Weigelt (1992) studied asymmetric two-player tournaments with two kinds of handicaps for player 2. In uneven tournaments the disadvantaged player has effort costs that are $\alpha > 1$ times larger than the advantaged player. In unfair tournaments the disadvantaged player must have output that is $k > 0$ units higher than the advantaged player in order to win.

Table 3. Predicted efforts and actual efforts (periods 11–20) in asymmetric two-player tournaments

Type of tournament	Cost handicap α	Effort advantage k	Advantaged player effort		Disadvantaged player effort	
			Equilibrium	Mean (standard deviation)	Equilibrium	Mean (standard deviation)
Baseline	None	None	73.8	77.9 (24.8)	n.a.	n.a.
Unfair	None	25	58.4	74.5 (19.9)	58.4	58.7 (37.9)
Uneven	2	None	74.5	78.8 (21.8)	37.3	37.1 (28.9)
Affirmative action	2	25	59.0	64.2 (32.3)	29.5	36.4 (27.7)
Affirmative action	4	25	60.2	85.8 (19.6)	15.1	32.4 (25.7)

Source: Data are from Schotter and Weigelt (1992).

Note: n.a., not applicable.

With a cost handicap α and the evaluation bias k , the equilibrium efforts for players 1 and 2 are $e_1^* = \alpha e_2^*$ and

$$e_2^* = \frac{[(1/2a) - (k/4a^2)] c(M - m)/2\alpha}{1 + [(1 - \alpha)/4a^2] c(M - m)/2\alpha}.$$

These tournaments have interesting properties. If there is no cost handicap ($\alpha = 1$), then even when there is a bias k , both players should exert the same effort ($e_1^* = e_2^*$). When there is a bias k , both players' efforts are decreasing in k . Intuitively, when there is a bias, the advantaged agent does not have to work too hard (because the marginal impact of effort on winning probability is lower) and the disadvantaged agent should not bother to work too hard (because extra effort probably will not overcome the bias). In addition, in the presence of a cost handicap α , a bias k in evaluation can raise total effort. This provides a possible rationale for affirmative action, adding a handicap to even a tournament where one player has a cost advantage.

Table 3 summarizes predicted efforts and mean efforts in the last 10 periods of Schotter and Weigelt's 20-period sessions. With no asymmetry ($\alpha = 1$, $k = 0$), average efforts of 77.9 are close to the predicted effort of 73.8, replicating the Bull et al. (1987) result. When asymmetries are introduced, all the comparative statics move in the right direction. However, both a cost handicap and evaluation bias lead to more effort by both advantaged and disadvantaged players than is predicted by theory.

The experiments described above all use two-player tournaments. However, organizational tournaments typically involve more than two workers. More recent experiments study multi-person ($n > 2$) tournaments.

Orrison et al. (2004) used the paradigm and parameter values in the experiments above. They varied the size of the tournament ($k = 2, 4$, or 6 players), the proportion of players to be awarded the high prize, and the symmetry of the competition (by varying the handicap k between 0 and 25).

In their symmetric treatments, predicted effort is always the same (73.75). As predicted, Orrison et al. (2004) find that behavior is insensitive to tournament size when half the players win the high prize. However, the proportion of large prizes influences behavior in a way that is not predicted by theory. In six-player tournaments, when two or three of the players earn the highest prize, effort is close to that predicted, but when the large prize is awarded to four players, mean effort drops to 59. In the asymmetric treatments, predicted effort is higher in six-person

groups than in four-person groups, as predicted. But contrary to the theoretical predictions, two-person groups do not produce lower effort—and often even have higher effort than the larger groups.

Müller and Schotter (2010) study a more complicated tournament in which four workers have private costs parameters and there are two prizes V_1 and V_2 , with a fixed total $V_1 + V_2 = 1$ (based on Moldovanu and Sela 2001). Theoretical predictions are sharply confirmed with two interesting exceptions. Low-cost workers should win all the time, but the predicted winners win only about half the time. And when costs are low, subjects typically exert too much effort (“workaholics”); when costs are high, subjects often drop out and choose $e_i = 0$.⁶

Although tournaments have many advantages—chiefly, they require only relative comparisons of output—they have a major drawback: workers may have an incentive to spend effort sabotaging perceptions of the output of other workers. If sabotage is cheap and effective, heightened incentives to work hard from tournament bonuses may be undermined by both the diversion of effort into sabotage and by the withdrawal of effort in anticipation of sabotage (see Milgrom and Roberts 1988).

Carpenter et al. (2010) conducted a clever experiment on sabotage with actual effort. Groups of eight subjects privately filled out forms and hand-addressed envelopes for 30 minutes. This simple activity permits differentiation of the quality of output, because envelopes can be either clearly or sloppily addressed. The quality of each envelope was rated on a 0–1 scale of deliverability by an actual letter carrier from the U.S. Postal Service. Measured output is the sum of these quality ratings across all the addressed letters. In addition, after finishing the task, all the workers looked at the output of other workers, selected one envelope at random to inspect, and rated its quality.

There are three experimental conditions: piece rate (\$1 times output), tournament (\$25 bonus for highest output), and tournament with sabotage. In the tournament with sabotage, the quality-adjusted output of a worker is determined by the average of the other worker’s quality ratings (like a “360-degree evaluation” system). Opportunistic workers should work hard, but they should also sabotage their peers by underrating the quality of the latter’s work. Hiring the postal carrier to rate objective quality provides a clear way in which to address whether peer-rated quality is lower than objective quality (i.e., whether there is sabotage).

Table 4 summarizes raw and quality-adjusted output in the three experimental treatments. In the piece rate treatment, workers addressed 12.8 envelopes, but both peers and the expert adjusted the output downward by about 20% for quality of handwritten envelope addresses. In the tournament with no sabotage (where peer ratings do not matter for payoffs), output goes up in raw terms and as judged by the expert, compared to the piece rate, but peers still rate quality as lower (even though underrating their peers does not benefit them). Carpenter et al. (2010) interpret this result as an automatic affective response to competition. In the sabotage treatment, where workers might benefit from underrating peer quality, peer-rated quality is about 40% lower than in the piece rate baseline—there is strong sabotage—and expert-rated quality falls as well. That is, when workers can have a direct influence on how their peers’ work is perceived, there is both substantial sabotage of high-achieving peers and a drop in effort (judged by expert

6. These deviations could be explored with newer models of stochastic response (McKelvey and Palfrey 1998) or limited strategic thinking (Camerer et al. 2004); see Camerer (2003) for a review of these theories and others that incorporate players’ regard for the payoffs of others.

Table 4. Average raw output and quality-adjusted output (peer and expert ratings) in piece rate and tournament conditions

Quality adjustment	Piece rate	Tournament output minus piece rate output	
		No sabotage	Sabotage
None (total letters)	12.8	+1.4	−1.3
Peer rated	11.0	−0.6	−5.3
Expert rated	10.5	+1.3	−1.4

Source: Data are from Carpenter et al. (2010).

Note: Outputs are envelopes stuffed and addressed. Quality adjustment is output times a 0–1 measure assessed by peer ratings or expert (letter-carrier) ratings.

quality ratings) in anticipation of sabotage. The drop in effort is so strong that output is higher in the piece rate condition than in the tournament with sabotage.

3.3. Anomalous Response to Incentives

Several experiments show responses to incentives that are theoretically surprising and counter-intuitive. These studies are important for understanding when incentives in organizations are likely to have unintended effects.

3.3.1. Incentives Do Not Necessarily Produce More Effort (Crowding Out)

One of the simplest predictions of labor economics is that the supply of labor should increase in response to a transitory increase in wage. Studies of temporary wage increases (e.g., Mulligan 1995) suggest this law of supply is often true. However, using field data on cab driver hours, Camerer et al. (1997) found that labor supply of inexperienced drivers slopes downward, because inexperienced drivers act as if they establish a daily income target and quit when they reach the target.⁷ In a field experiment with bicycle messengers, Fehr and Goette (2007) found that hourly effort of messengers decreased with temporary wage increases (though they also worked more hours, which led to an increase in the amount of labor supplied under the wage increase). These studies suggest that labor supply and effort are sometimes sensitive to a point of reference in income.

This sensitivity is more directly tested in a laboratory experiment by Abeler et al. (2011), which studies how productivity varies in a real-effort task. In the task, subjects counted the number of zeros in tables consisting of 150 ones and zeros, with each completed table counting as output. They could quit the task and leave the experiment whenever they wanted and were paid either a piece rate for their performance or a fixed wage, but they did not know which of the two payment mechanisms would apply until the end of the experiment. The key treatment variable manipulated the size of the possible fixed payment. Consistent with effort provision being influenced by reference levels, subjects worked harder when the fixed payment was higher, and they often worked until their earnings from the piece rate equaled the possible fixed earnings.

7. Farber (2005) finds a stronger effect of hours than of cumulative daily income but does find evidence consistent with targeting in three of six drivers for which he has many days of data. Using a different approach, Farber (2008) finds clearer evidence of targeting, although inferred targets are statistically imprecise.

This experiment nicely demonstrates how the control afforded by the laboratory can allow researchers the ability to conduct carefully specified tests of a theory while controlling for myriad possible confounds that are difficult to rule out in the field.

Another kind of reference point is a standard for a fair or reasonable wage. Gneezy and Rustichini (2000a) investigated effort in response to no incentive, very low incentives, and higher incentives, in performance on a 50-question IQ test. When pay is only 0.1 new Israeli shekels (at the time of the experiment, about \$0.03) per correct answer, the average number of questions answered correctly is lower than when there is no pay, mostly because several subjects quit and did poorly on the test (like a labor strike; see also Frey and Jegen 2001; Heyman and Ariely 2004).

Such crowding out of intrinsic incentives can also occur when people exert effort out of moral obligation, and pay drives out moral obligation. Gneezy and Rustichini (2000b) studied this effect in a field experiment at 10 private daycare centers in Israel. Before the experiment, parents were told to pick up their children on time. During the experiment, a modest fine was instituted for late pickups and was then rescinded. When the fine was introduced, late pickups actually increased (compared to control groups with no new fine). When the fine was rescinded, late pickups dropped but settled down to about twice the rate of late pickups before the fine. Gneezy and Rustichini (2000b) suggest the fine is a price—the moral obligation of picking up your children on time is driven out by a new low price you can comfortably pay for being late; and when the price is removed, the moral obligation is not restored (e.g., Lepper et al. 1973).

3.3.2. *Higher Effort Does Not Necessarily Improve Performance*

The standard incentive model assumes that higher incentives lead to higher effort, which improves performance. Psychologists, however, have long suspected that at very high levels of arousal, performance can suffer because of arousal and distraction (e.g., “choking”). Yerkes and Dodson (1908) initially demonstrated this effect by testing the ability of rats to discriminate between safe and dangerous (i.e., shock-inducing) areas in a cage. The rats learned to do so most quickly when the shocks were at an intermediate level of intensity and actually learned more slowly when shocks were stronger. Camerer (1998) noted this effect and reported data from NBA playoff free-throw shooting. Players make significantly fewer shots in the playoffs than in the regular season (about 75% versus 73%), presumably because of the heightened pressure during the playoffs.

Ariely et al. (2009) demonstrated the Yerkes-Dodson pattern with a high-stakes experiment in a poor town in India, using six games that require concentration and physical skill. The highest performance level in each game earned 400 Indian rupees, about a month’s worth of consumer spending. Subjects reached the highest performance in only 6% of games with high stakes, compared to 22% and 26% for low and medium stakes. The highest stakes seem to create nervousness, or choking, which actually lowers short-run performance.

3.4. *Field Experiments on Incentives and Monitoring*

Some interesting experiments on the effect of incentives on employee effort and productivity have been conducted in the field. These studies serve as a valuable complement to laboratory experiments.

Nagin et al. (2002) report an interesting field experiment that tests the effect of monitoring on employee moral hazard. Their experiment was conducted by a company that hires people to solicit donations to nonprofit organizations over the phone. The experiment varies the likelihood of detecting low effort on the part of employees (as in the monitoring treatments of Nalbantian and Schotter 1997).

The workers earn a piece rate wage that increases with the number of successful solicitations. As a result, there is a moral hazard incentive to claim that people who were called had pledged donations over the phone, when those people actually had not. The employer tried to limit moral hazard by independently calling back a fraction of the people who had allegedly pledged to give money and identifying “suspicious bad calls” (SBCs), or cases indicative of misrepresentation by the employees. SBCs were deducted from the original piece rate pay but were not directly linked to firing or other sanctions.

Because the callbacks are expensive, the company was interested in whether lowering the rate of calling back would lead to many more SBCs. They designed an experiment in which the monitoring (callback) rates were varied across 16 separate call centers and across time, from 0 to 25%. At four sites, the actual rate of calling back was 25% during the experimental period, but only a fraction of those monitored call results were reported to the employees. For example, at one site, 25% of the successful calls were called back, but only 8% of those results were reported back to the employees, so the employees were getting feedback as if they faced a 2% callback rate. This design enabled the firm to measure whether employees who were actually making a lot of SBCs but thinking that they were “getting away with it” most of the time would increase their SBC moral hazard in the future. (The design was double-blind, so that both supervisors and employees did not know the percentage of monitored calls.)

Table 5 shows the marginal effect on the number of per-week SBCs for week t , based on the monitoring percentage observed by employees in the previous week $t - 1$. For example, employees who were subjected to no reported monitoring in the previous week had 0.031 SBCs (per employee, per week) more than the baseline category (25% monitoring). Very low rates of monitoring (0–5%) produced substantial jumps in SBCs, although the numbers are still rather low. Most of the aggregate effect is due to a jump in later SBCs among employees who had earlier made an SBC that was not reported back to them. For example, in the four 0–10% groups, about a third of employees made an SBC in week 61 that was not reported back to them. The SBC rate for those employees in the subsequent week 62, across the four experimental sites, was 5.29, 1.33, 2.73, and 0.47.

There is a remarkable amount of heterogeneity in moral hazard. In the weeks when reported monitoring was 0, the median number of SBCs per employee is 0.25. The 80th, 90th, and 95th percentiles of the cross-employee distribution, however, are 1.99, 3.80, and 6.45, respectively. The top tenth of cheaters are cheating 15 times higher than the median. In a distribution with such a long right tail, the basic managerial challenge is to prevent moral hazard among that minority who are inclined to cheat a lot, if they can.⁸

8. Nagin et al. (2002) also used surveys to compare the influence of psychological and economic factors on generating SBCs. Measures of difficulty of finding a comparable job and expected tenure with the firm (typical economic variables) were not correlated with SBCs, but employee attitudes toward their employer did have a significant effect, consistent with pure reciprocity.

Table 5. Effect of frequency of call monitoring in week $t - 1$ on suspicious bad calls (SBCs) in week t

Monitoring in previous week $t - 1$ (%)	Change in SBCs per week, week t	
	Coefficient	t -statistic
0 (no monitoring)	.031	2.69
2	.006	2.81
5	.019	6.29
10	.002	1.36
15 (high monitoring)	.002	1.20
25 (constant term)	.002	0.44

Source: Data are from “OLS” column 1 in Nagin et al. (2002: table 2).
Note: Constant additional hours and call center fixed effects are included in the regression but omitted from this table.

Several other field experiments have studied the effects of simple changes in incentives on worker productivity. For example, Bandiera et al. (2007) report the results of a natural field experiment on incentive change on a British farm where workers either pick fruit or do other tasks. Increasing bonus pay for managers who supervise workers increased fruit-picking productivity of workers, due to both closer monitoring and managerial selection of more productive workers to pick fruit and less productive workers to do other tasks.

3.5. Summary

The experiments on basic incentives described above are mostly supportive of basic theory, with interesting exceptions.⁹ Effort in piece rate and experimental tournaments are close to those predicted. However, when there is a deliberate tournament bias, all workers work too hard, and when workers can sabotage others (through peer-rating of quality), they do so. Field experiments that increase high-powered incentives among managers increase productivity, due to more work effort and selection of harder workers by managers. In experimental team production (with no communication), forcing contracts—which penalize all workers if a team goal is not reached—work very poorly, and team competition does not work much better. The most robust experimental institution is the threat of monitoring. A field experiment with phone callers also shows that when monitoring drops to zero, shirking rises sharply, but mostly among a small number of workers; the effect is smaller if employees like their employer.

4. Voluntary Effort and Reciprocity in Organizations

Employment contracts typically have some degree of contractual incompleteness. Incompleteness raises the prospect of moral hazard (hidden action)—that is, when workers are expected to

9. For further discussion of theoretical approaches to employee motivation, and particularly how these have evolved to reflect “nonstandard” preferences demonstrated in some of the experiments we review, see Rebitzer and Taylor (2011).

exert effort that is costly for them, but valuable to the firm, firms should not expect much effort (absent reputational concerns and contractual requirements or penalties). Several experiments explore the conditions under which organizational members voluntarily exert effort absent any extrinsic incentives for doing so.

4.1. Simple Worker-Firm Gift Exchange

A potential constraint on moral hazard is reciprocity: if A feels B treated her well (badly), then A may sacrifice to help (hurt) B. Moral hazard by reciprocity-minded employees may be limited, leading employees to exert costly effort that is valuable to firms if employees feel firms have treated them well. Akerlof (1982) called this phenomenon “gift-exchange” and used it to explain the persistence of above-market wages and associated unemployment.

Gift-exchange is an ideal topic to explore in experiments, because the crucial economic variable that is typically unobservable in field data—worker effort—can be observed by the experimenter, even if subjects acting as employers cannot contract on effort. It is hard to imagine how one could possibly collect these data in a typical firm, because any component of effort that cannot be measured (and contracted upon) by firms would typically also be unmeasurable by an economist.

The gift-exchange labor market paradigm was pioneered by Fehr et al. (1993). Their study was modified and expanded by Fehr et al. (1998). Because the Fehr et al. (1998) design became standard in many subsequent studies, we will describe it in detail.

In their paradigm, firms offer a wage w . Workers who accept a wage then choose an effort in increments of 0.1 ($e \in \{0.1, 0.2, \dots, 0.9, 1.0\}$). Firms earn $(120 - w)e$, and workers earn $w - 20 - c(e)$, where $c(e)$ is a cost-of-effort function that is convex (with $c(0.1) = 0$ and $c(1) = 18$). Note that the gains from gift-exchange are large. In markets where effort is low ($e = 0.1$), the market-clearing wage is 21, so firms earn 9.9 and workers earn 1.0, a total surplus of 10.9. But if $e = 1$ could be achieved, firms would earn $120 - w$ and workers would earn $w - 20 - 18$, for a total surplus of 118. The gains from obtaining high effort are therefore very large.

Fehr et al. (1998) use explicit labor market language to describe the experiment.¹⁰ They compare three market institutions. One institution is one-sided oral bidding by firms with an excess supply of labor (a gift-exchange market), another is a bilateral market (workers and firms are matched individually, firms offer a wage to their worker, and their worker takes it or leaves it). The third institution is a complete contract condition in which effort is fixed at $e^* = 1$ and workers' cost at $c(e) = 0$.

In the standard gift-exchange markets and bilateral matching markets, wages and efforts are persistently above the competitive level and do not decline over time, and efforts are strongly correlated with wages. Under the complete contract condition, at the mandated effort $e^* = 1$, firms earn $120 - w$ and workers earn w , so a wage offer is essentially an ultimatum offer of how the surplus of 120 is to be divided. In simple ultimatum games, average offers are about 40%, which would predict a wage offer of 48. Wages in these experiments are close to that figure

10. In Fehr et al. (1993) the labor market is described in plain buyer-seller language. Switching to explicit labor market language does not seem to make much difference.

although clearly lower. In this complete contract condition, wage offers of military subjects are higher (average 44) than those of students (average 32), and the student offers decline over time more strongly than do those of the soldiers.

Fehr and Falk (1999) ran experiments with double-auction institutions, in which firms and workers both offer wages (subject to an improvement rule: firms must outbid, and workers must underbid, standing offers on their respective sides of the market). There is a large amount of underbidding by workers, but firms often take the highest wage bids and reject lower ones (as occurs in the field, too; see Agell and Lundborg 1995). This strategy turns out to be profitable for firms—profits increase in higher wages, because higher wages elicit greater effort from most subjects.

4.2. Replication and Robustness of Simple Gift Exchange

The apparent strength of gift exchange surprised experimental economists and inspired many replications and extensions designed to establish the boundaries and robustness of the phenomenon. Several of these studies are summarized in Table 6. Three questions that immediately arise concern the effects of experimental procedures and subject demographics, the influence of trading institutions and other components of economic structure, and the persistence over time of reciprocity. Estimates with individual fixed effects show that there certainly is heterogeneity, although most individual workers' efforts respond positively to higher accepted wages.

Charness et al. (2004) find that when the possible payoffs from various (w, e) combinations are presented in a table form, wages and efforts are lower, although the effort-wage relation is still strong. Hannan et al. (2002) explored differences in subject pools, using University of Pittsburgh undergraduates and MBA students.¹¹ The mean wages and efforts of MBAs are close to those observed in Fehr et al. (1998), but the undergraduate wages and efforts are substantially lower. However, the effort response to wages is comparable in magnitude and significance across both groups.

Hannan et al. (2002) also conducted sessions in which firms both offer wages and request effort levels; this change seems to raise effort. Interestingly, regressions of actual effort choices that include both wages and effort requests show that MBAs respond to requests but not to wages, and undergraduates respond to wages but not to requests. This difference may reflect some socialization in workplace norms (or other differences in MBA and undergraduate groups).

Fehr et al. (2002) did experiments in Russia with very high stakes (about one week's income per trade) and found similar results to Fehr et al. (1998).

Brandts and Charness (2004) experimented with four changes in structure. First, they varied the degree of excess labor supply from four extra workers to four extra firms. Wages and efforts are lower, but insignificantly so, when there is excess labor, which suggests that excess labor supply is not that important. Second, they had sessions with one-shot matches in the bilateral market institution; in these sessions, wages and effort are substantially lower, which shows a role for repeated-market effects (even though matches are anonymous). Third, in one treatment, they

11. Hannan et al. (2002) also varied the value of effort to firms, comparing profit functions $(120 - w)e$ with $(90 - w)e$. There are not large differences, except that the low-value firms pay lower wages in the MBA sessions and request higher effort levels.

a. Figures are reported in Charness et al. (2004).

b. Figure is estimated from binned histogram (Fehr et al. 1998: figure 1).

c. Mean effort is estimated from effort at mean wage in Hannan et al. (2002: figure 1).

d. Figures are normalized to 0–1 for effort, 0–100 for wages.

e. Mean efforts are estimated by multiplying average wage and period in effort-wage regression in Hennig-Schmidt et al. (2003: table 4).

f. Effort is normalized by subtracting minimum (1) and dividing by range $(6 - 1) = 5$. Unnormalized mean effort is 1.64.

g. Correlation is between wages and effort minus best reply effort (Engelmann and Ortmann 2009: table 9), excluding corner-equilibrium treatment.

required a minimum wage equal to the midpoint between the highest and lowest wage. Accepted wages are very similar when the minimum wage is instituted, and efforts are a little lower. There is also a sharp downturn in wages, a drop of about half, in the final (tenth) period (except for the minimum wage condition).

The reciprocity account of these patterns depends on workers knowing that firms intentionally shared surplus with them. Charness (2004) explored this aspect by comparing three treatments: firms intentionally choose wages; or wages were either clearly drawn randomly from a bingo cage or were “preselected by an experimenter.” In the latter two treatments, wages were actually drawn from a distribution matched to the wages chosen by firms in the first condition (although subjects did not know this). The hypothesis is that effort response to wages will be higher when firms intentionally choose wages. Overall effort is slightly lower in the intentional-wage condition, but the response of efforts to wages is significantly higher (0.0120 versus 0.0088).

Hennig-Schmidt et al. (2010) explored the effect of incomplete information on the profitability of worker effort for firms. Incomplete information could undermine reciprocity, because it limits workers’ confidence that firms are sharing surplus generously. The authors used a firm profit function $(120 - w)ef$, where f is equally likely to be 0.5 or 1.5. In one condition, neither side knows the value of f ; in the more interesting condition, firms know f , but workers do not (and the asymmetry is commonly known). In the firm-knows- f condition, wages are about 15 points lower but do respond to the profitability factor f (increasing f from 0.5 to 1.5 raises average wages by 6.67), as if firms were willingly sharing surplus. Efforts are modestly lower when f is unknown. Overall, the information asymmetry has a small corrosive effect on wages and effort (and hence, on efficiency).

Healy (2007) explores the possibility that even with random rematching and excess labor supply, reputational considerations might generate cooperative behavior. He derives conditions for a “full reputational equilibrium,” in which firms pay the highest wage and workers reciprocate with the highest effort (until the last period, when workers shirk by giving low effort). He derives a threshold probability that workers are reciprocal that supports full reputational equilibrium. Parametrically, this probability is often rather low when the marginal profit from hiring shirking workers is low relative to the gain to firms from high effort at high wages. Importantly, Healy notes that if workers believe that firms think reciprocal types are correlated, then workers are more inclined to reciprocate. Intuitively, when types are uncorrelated, then a worker who is lucky enough to get a high wage in one period can shirk and not suffer direct consequences from low wages in the future. But when types are correlated, the worker’s shirking affects the firm’s perceptions of all workers, which may affect the shirking worker’s wages in the future. Incorporating stereotyping of this sort expands the range of beliefs about the proportion of reciprocal workers that supports full reputational equilibrium.

Healy (2007) then conducts experiments in which the threshold is low—replicating the original Fehr et al. (1993) design (Healy treatment; LA) and then changing the design so that worker ID numbers are known to everyone, so that firms can keep track of who shirks and who works hard (LP). In these designs there is substantial gift exchange and a strong correlation between wages and effort until a sharp dropoff in the last period. In another treatment (HP), firm profits are quasi-linear in effort, approximately $0.275 + 0.0725e$, rather than the multiplicative function $(v - w)e$ used in earlier designs. Healy shows that the threshold probability of reciprocal

workers necessary to sustain full reputational equilibrium with these parameters is much higher, which implies that unless firms are very sure many workers are reciprocal, gift exchange will not emerge. Indeed, wages and efforts are much lower in this treatment, where the value of effort to firms has much lower marginal product, although there is still a strong effort-wage relation.

Rigdon's (2002) parameters and design provide a boundary case in which gift exchange is likely to disappear and does. She uses linear effort costs (efforts 1–6 have cost $c(e) = 2e - 2$) and firm profit is linear in effort, $v(e) = 27 + 8e - w$ (with a minimum wage of 10). Because $v(e)$ is linear in effort, the gains from gift exchange are much smaller than in other designs (25 at the self-interest equilibrium versus a maximum of 65). She also uses a double-blind procedure (subjects receive keys to a box in which their payoffs are deposited). There are $T = 16$ periods, and only one is chosen for payment. The probability that the last period is chosen for payment is 0.5 (all earlier periods are equally likely), so there is a strong economic emphasis on the last period. The trading institution is a sealed-bid offer market, and employers request effort levels. Employers request 3.5 units of effort and receive 1.64 on average (see Table 6). Wages and efforts decline over time until they are very close to the competitive equilibrium in the last period. This example shows that gift exchange does not survive a combination of procedural factors (double blindness) and design parameters that make the gains from gift exchange small and the economic value of the last period large.

Engelmann and Ortmann (2009) varied the efficiency gains from gift exchange and implemented a design with an interior wage-effort equilibrium (assuming self-interest). Creating an interior equilibrium is important, because when a predicted equilibrium is at the boundary (like zero effort), any confusion or deviations from equilibrium create positive effort, which could look like reciprocity. (This concern is allayed, because every study reports that wage-effort relations show a strong response of effort to wages, which suggests high-effort choices are typically deliberate.) To create an interior equilibrium, Engelmann and Ortmann (2009) used efforts in the interval $[1, 3]$ and a worker utility function of $1.5w - c(e)$ for $e \leq 2$ and $(e + 1)w/2 - c(e)$ for $e \geq 2$. Profit functions are $em - 1.5w$ for $e \leq 2$ and $em - (e + 1)w/2 - c(e)$ for $e \geq 2$. Values of $m = 50$ and $m = 80$ create high and low efficiency gains from effort with an equilibrium of $w^* = 21$ and $e^* = 1.8$. The authors also compare abstract and worker-firm experimental framing (which has only a small positive effect when $m = 80$ and the efficiency gains are large). Efforts are close to those predicted under self-interest, although wages are above the equilibrium level, and there is a relationship between effort and wages.

4.3. A Second Wave of Gift-Exchange Experiments

Other experiments explore how institutional changes designed to enhance the power of reciprocity affect behavior. Fehr et al. (1997) study the influence of types of reciprocity on wages and effort. In their weak reciprocity treatment, firms offer a wage w , a requested effort $\tilde{e}$, and a fine f . A worker who accepts the offer chooses a costly effort e . If $e < \tilde{e}$, the worker is fined with probability s , and earns $w - f - c(e)$ rather than $w - c(e)$. In a strong reciprocity treatment, the firm can also punish a worker who shirks and is fined, at a cost $k(p)$, by multiplying the worker's total payoff b a shrinkage factor $p < 1$. The firm can also reward a worker who chooses effort $e \geq \tilde{e}$, at cost $k(p)$, by multiplying the worker's payoffs by a multiple $1 \leq p \leq 2$.

The results are simple. In the weak treatment, efforts are low (about 0.1), even though firms offer substantial job rents $w - c(\tilde{e})$ and efforts do respond to offered rents. However, strong reciprocity works very well. Efforts are about 0.8, and workers only shirk about 20% of the time. Shirkers are typically punished by the firm, and workers who choose the requested effort are rewarded about half the time.

Brown et al. (2004) examined the effect of allowing implicit long-term contracting by announcing ID numbers of workers and allowing firms to offer contracts to specific (identified) workers. Their session had $L = 7$ firms, $N = 10$ employees, and $T = 15$ periods.

Firms pay wages $w \in \{1, 2, \dots, 100\}$ and workers choose efforts $e \in \{1, 2, \dots, 10\}$. Firms earn $10e - w$, and workers earn $w - c(e)$, where $c(e)$ is convex (as in Fehr et al. (1998) and other studies). In the specific-contract condition, about two-thirds of the offers are earmarked for a specific employee, wages are higher, and wage offers depend on previous effort. For example, if the worker provided the maximum effort in period $t - 1$, the probability of getting a new contract in t is close to 1. However, the probability of renewal falls to 0.2 for effort levels below 7. As a result, efforts are generally higher when offers are specified for particular workers than when worker IDs are not provided. Both employees and firms in the specified-offer condition earn more per round the longer they have been in a relationship. Firms initiate long-term relationships by initially paying relatively high wages, and employees can signal their trustworthiness by meeting or exceeding the firm's effort expectations. These results have been replicated and appear to be robust to change in excess worker supply (Brown et al. 2010) and to random worker layoffs (Linardi and Camerer 2011).

4.4. Field Experiments

Four field experiments on gift exchange shed light on how long reciprocity persists. Gneezy and List (2006) recruited a small sample of 19 undergraduate students (who were unaware they were participating in an experiment) for a one-time 6-hour job entering information from library books into a computer. Ten of the subjects were paid the \$12/hour wage offered during recruitment ("no gift" condition) and nine were paid \$20/hour instead ("gift" condition), with no explanation given for the increased wage.

Figure 1 presents the mean number of books catalogued by subjects in the gift and no gift treatments averaged over 90-minute intervals. There is a significant difference in output in the first 90-minute period, consistent with the gift exchange hypothesis, but the difference decreases over time. A second field experiment used 23 participants in a door-to-door fundraising task. In that study, the effect of the gift wage is sensitive to how effort and output are measured, and to whether demographic subject controls are included (which are known to have a large effect on output).

Kube et al. (in press a) ran a close replication of the Gneezy and List (2006) field experiment on cataloging books. Their study consisted of 68 participants in three conditions who all expected initially to earn €15/hour: neutral (paid €15), kind (paid €20), and unkind (paid €10). The results are also shown in Figure 1. There is a little (insignificant) evidence of positive gift exchange from the kind wage increase (compared to a baseline), and the effect does not decline with time as in the Gneezy and List (2006) experiment. Pooling the two datasets, there is little

Figure 1. Mean output (books catalogued) in Gneezy and List (2006; GL) and Kube et al. (in press a; KMP) experiments. The GL “gift” and “no gift” conditions correspond to the KMP “kind” and “neutral” labels, respectively.

clear evidence of a persistent positive gift-exchange in several hours in the field, compared to shorter (2-hour) laboratory experiments, at least when it comes to cataloging books.

In the unkind treatment of Kube et al. (in press a), however, participants produced significantly lower output throughout the 6 hours, and this difference was always statistically significant. Therefore, this experiment presents clear evidence of persistent reciprocity in worker output, with a stronger negative reaction to a below-expected (unkind) wage than the positive reaction to the kind wage. Taken together, the experiments show little evidence of positive reciprocity but strong evidence of negative reciprocity. (Of course, the fact that subjects worked at all could be thought of as evidence in support of the gift-exchange hypothesis, because nothing prevents them from shirking completely.) The field experiments therefore demonstrate at least one way in which the main laboratory phenomenon extends to the field, but they also raise questions about when and precisely why they do so.

Bellemare and Shearer (2009) describe a gift-exchange experiment in which British Columbian tree planters were awarded a 1-day bonus, which was said to result from unpaid wages negotiated for a different purpose. Workers plant about 1,000 trees/day and usually earn a piece rate of \$0.20/tree (about \$200/day). The work is hard and varies with terrain and weather. The 1-day bonus raises productivity by about 100 trees/worker-day and is highly significant. The effect is also stronger for longer tenured workers, and long-tenured workers showed a productivity boost in the Monday after the week in which there was a 1-day gift.

The results from these three field experiments do not all agree. In one book-cataloguing study the effect of the wage gift appears to wear off after 90 minutes. The other book-cataloguing

study finds the opposite: there is no difference initially, but those workers receiving a gift learn more quickly. A 1-day bonus for tree planters has a day-long effect.¹² In all cases there is at least some effect of the gift wage.

Reciprocity is probably most strongly activated if workers feel that employers are sharing surplus with them voluntarily (the book-cataloguing experiments said nothing to the study subjects about why the wage was higher than originally offered). The type of gift provided by the employer also appears to affect worker performance. A recent study, also by Kube et al. (in press b), demonstrates this by varying the type of gift. Workers again catalogued books for an hourly wage. The gifts, which varied by treatment, included an unexpected additional payment (€7, on top of an expected €12 wage) and a thermos worth the same amount as the monetary gift. Although the monetary gift has little effect, confirming the null or weak findings in the abovementioned studies on book cataloguing, the nonmonetary gift increases effort by approximately 25 percent. This result holds even when workers are made aware of the gift's monetary value. Moreover, when workers are given the choice between money and the thermos, most choose the former but work harder, as if they had received the nonmonetary gift. Finally, a €7 monetary gift that is arranged—with effort—in the form of an origami figure similarly elicits high effort. Thus, the experiment reveals that the thought and effort that an employer puts into a gift determine its effectiveness.

The notion that how an employer treats employees can affect their effort and cooperativeness is also addressed in a large literature on procedural justice and its effect on organizational outcomes (e.g., Lind and Tyler 1992). One of the best early studies was done in two aerospace/car parts plants by Greenberg (1990). The company determined that it needed to cut wages for 10 weeks by 15% to avoid laying off workers. It randomly assigned to each plant one of two methods of explaining the pay cuts to workers. In one plant the company's president spent 90 minutes explaining the decision and expressing remorse; he then answered questions for 60 minutes. In the other plant a vice-president spent 15 minutes explaining the decision and wrapped up the meeting by saying "I'll answer one or two questions, but then I have to catch a plane for another meeting." Compared to the short speech, the longer and more remorseful explanation lowered the number of resignations in the subsequent paycut period from 27% to 2%, and it lowered employee theft from 8.7% to 5.7% (though both theft rates were higher than the rate of 3% before and much after the pay cuts).

4.5. Compositional and Sorting Effects on Voluntary Effort and Reciprocity

The research discussed above shows that the social and financial incentives presented to a particular set of employees can be a powerful determinant of the effort they exert. However, employees are often free to select between organizations with different incentives and composed of different kinds of people. Experimental research also studies how the process by which groups are formed can impact cooperative behavior and productivity. This research studies how group formation and individuals sorting among environments (organizations) can help produce groups that are more or less cooperative and likely to exert voluntary effort. We have already

12. Field data from police union arbitration (Mas 2006) and a long tire company strike (Krueger and Mas 2004) also suggest very long-term effects linked to perceptions of fairness and reciprocity.

reviewed one paper (Dohmen and Falk 2011) showing that sorting by employees between incentive contracts can affect productivity. Here, however, we particularly focus on how it can affect cooperative behaviors, such as voluntary effort.¹³

4.5.1. Voluntary Cooperation and Endogenous Group Formation

Public goods experiments and n -person prisoner's dilemmas are a useful model for some kinds of organizational processes, such as voluntary effort for production with group incentives or revenue sharing. Experiments using the voluntary contribution mechanism, in which individuals contribute linearly to a public good, show that contributions typically begin at about 50% and steadily decline to close to the inefficient Nash equilibrium level, with a small percentage of "moral exemplars," who always contribute regardless of what others do (see Ledyard 1995). When the game is unexpectedly or randomly restarted, contributions tend to jump back up to high levels and then decline again over further periods (Andreoni 1988; Ambrus and Pathak 2011).

Although these experiments typically assign individuals to groups randomly, organizations and groups within them are usually formed endogenously, based on individuals' preferences, past behaviors, and what they know about the past behaviors of other potential group members. A handful of recent studies explores how contributions vary by allowing such endogenous group formation. Page et al. (2005) explore the influence of endogenous selection of group members on cooperation in a linear public goods game with a voluntary contribution mechanism. In one treatment, group members are allowed to rank others in all groups according to their match desirability every three periods, but ranking is costly. Most subjects (80%) choose to rank others and generally rank others who contributed most highly. Subjects are then regrouped in an assortative-matching scheme, creating groups of players who matched one another most closely. Regrouping based on costly ranking has a huge effect (compared to a no-rank, no-regrouping baseline), doubling overall contributions (70% versus 38%). In the most "selective" groups (i.e., among those who were most frequently chosen), contributions approach the maximum.

Ahn et al. (2008, 2009) show similar effects of endogenous grouping in public goods games. Allowing subjects to determine who enters their group increases contribution rates (though only by about 10%). Thus, the ability of people to sort endogenously into groups—a key feature of organizations—can help mitigate free rider and incentive problems.

4.5.2. Endogeneous Sorting among Organizations

A central question in organizational economics is how workers sort (or self-select) themselves into different economic environments. Lab experiments typically assign subjects to roles and environments, whereas most firms use various kinds of nonrandom sorting (including self-selection). However, it is easy to study sorting experimentally (e.g., Orbell and Dawes 1993). Indeed, the ideal way to study sorting is to assemble a pool of people, measure their characteristics and expectations, and then allow them to sort into economic environments and see what

13. Several experiments have studied endogenous sorting in market entry games (see Camerer and Lovo 1999; Rapoport et al. 2002; Duffy and Hopkins 2005), but those experiments are of limited interest in the study of organizations. Our focus here is on the kind of sorting that occurs within organizational contexts and deals with voluntary effort and reciprocity.

types of people sort into what opportunities (see Dohmen and Falk 2011). It is very difficult to infer this type of sorting from field data and extremely easy to do so in experiments. For example, Lazear et al. (2012) show the effects of sorting on the expression of social preferences. Subjects who can take a certain amount of money, or play a dictator game, often prefer to take the certain money rather than play.

An experiment on sorting that is central to organizational outcomes was conducted by Eriksson and Villeval (2008). Incentive theory predicts that higher performance-based incentives will raise the effort of all workers and also induce sorting of higher productivity workers into such a scheme, if workers could choose those incentives over a fixed wage (as in Bandiera et al. 2007; see also Lazear 2000). It is also conceivable that when reciprocity plays a strong role, even highly productive employees might prefer high-fixed-wage contracts to performance-based incentives if the high wages indicate an employers' trust in the workers' willingness to work hard even without extrinsic incentive. It is therefore helpful to understand how sorting into different incentive systems works, and the lab provides a good measure of control.

In the Eriksson and Villeval (2008) experiment, there are eight firms and eight workers. Effort is less costly for some (high-skilled) workers and more costly for other (low-skilled) workers. Firms either post contract offers to all employees each period (a market condition) or offer contracts to the same employee each period (a matching condition). In the first eight periods, firms can only offer a fixed wage and stipulate a desired (but noncontractible) level of effort. Employees either agree to a contract or reject all contracts (earning nothing in that period); those who agree to a contract then choose their level of effort. In the last eight periods, each firm offers a fixed wage and offers a piece rate wage, specifying a marginal wage for each unit of effort. In these periods, employees who agree to work with a particular firm also choose among the two offered fixed-wage and piece rate contracts, and they also choose an effort level.

In the market condition, firms initially offer wages above the minimum, but workers do not reciprocate with high effort, so wages and efforts rapidly disintegrate to a low-wage/low-effort equilibrium. However, when piece rate contracts are allowed, average effort increases substantially, because high-skilled (i.e., low-effort-cost) workers sort into the piece rate contracts and low-skilled workers choose fixed wages. This sorting parallels a field study in which an auto-glass installation firm switched to piece rates, increasing effort by all employees and also causing less-productive workers to leave the firm (Lazear 2000).

In the matching condition, firms offer higher fixed wages than firms in the market condition, and employees reciprocate with high effort. When piece rates are allowed, high-skilled workers are more inclined to continue working for fixed wages than are high-skilled employees in the market condition.

Together, these results show that high-productivity workers often sort into piece rate work environments in a market condition. However, when repeated matching is possible, as with relational contracting, sorting is less important, because the long-term contract generates effective reciprocity and high effort even when wages are fixed. Sorting across piece rates, and long-term contracting, are therefore substitutes in creating high worker effort.

4.6. Summary

Many experiments explore conditions under which reciprocity and voluntary worker effort occur or do not occur. The existence of such reciprocity, in the context of labor relationships,

seems to be robust to trading institutions and to variables that should matter in theory (e.g., excess supply of labor and time horizon), but results are sensitive to other procedural details of experiments.

The clearest result is that when the gain to gift exchange is largest, with multiplicative productivity $(v - w)e$, gift exchange is substantial and robust across time, but when productivity is linear in effort, $ve - w$, or has an interior equilibrium, there is much less gift exchange. However, every study reports a strong response of efforts to wages, even when wages and efforts are low (e.g., see Section 4.2, HP treatment). Moreover, nonpecuniary factors, such as how wages are communicated and the kind of gift provided by an employer, appear to be important as well. Field experiments involving temporary wage increases that last a day yield mixed results.

Finally, sorting and voluntary association can be important determinants of voluntary effort and cooperativeness. Sorting can work very well in creating cooperative groups. In a labor-market experiment, allowing workers to sort into high- or low-incentive contracts (piece rates or fixed wages) does create strong sorting, but sorting is much weaker when there is long-term contracting (even with fixed wages) because of reciprocity.

5. Coordination

The need for coordination arises when interdependence among organizational agents requires them to act consistently with one another but there is strategic uncertainty about what others are likely to do (see March and Simon 1958; Schelling 1960; Thompson 1967). Coordination is central in games with multiple equilibria, creating strategic uncertainty about which equilibrium will be played (Mehta et al. 1994; Bacharach and Bernasconi 1997; Cooper 1999).

From an organizational perspective, coordination problems are important, because they create the possibility of inefficiencies when agents' behaviors are mismatched or when an organization is stuck in an inefficient set of practices that a small group of workers cannot change on their own. Heath and Staudenmayer (2000) highlight the importance and difficulty of solving coordination problems in organizations. They note that organizations often neglect the importance of coordination and tend to focus excessively on partitioning tasks into specialized subtasks, without paying proper attention to the need to eventually integrate the specialized output in a coordinated manner.¹⁴ As a result, they argue, coordination failure is ubiquitous in organizations and is often quite hard to overcome.

The research below seeks to understand mechanisms and interventions that might help organizations overcome coordination problems. For an alternative review and discussion, see Devetag and Ortmann (2007).

14. Heath and Staudenmayer (2000) describe an experiment in which groups of MBA students have to assemble a "Lego man" consisting of arms, legs, and a torso. A long period of untimed planning is followed by a timed period of assembly. The goal is to assemble the Lego man properly in the fastest assembly time. Planning time spent on partitioning (dividing up tasks) and time spent on integration (discussing how to assemble the parts later) are equally valuable in speeding up assembly time, but groups tend to do more partitioning and less integration.

Table 7. Payoffs for weak-link coordination game

		Minimum choice of all players						
		7	6	5	4	3	2	1
Player's choice	7	130	110	90	70	50	30	10
	6		120	100	80	60	40	20
	5			110	90	70	50	30
	4				100	80	60	40
	3					90	70	50
	2						80	60
	1							70

5.1. Minimum-Effort (Weak-Link) Coordination

The coordination game applied most frequently to study organizational phenomena is the minimum-effort (or weak-link) coordination game (see Van Huyck et al. 1990).¹⁵ In this game, $n \geq 2$ players simultaneously choose numbers $a_i \in \{1, 2, \dots, K\}$ and earn $\alpha + \beta \min_{j \neq i}(a_i, a_j) - \gamma a_i$, with $\beta > \gamma$ (so that each player would prefer to choose a higher number only if it increases the minimum). The payoff is increasing in the minimum and decreasing in the player's own choice. A payoff function of this form used in many experiments is shown in Table 7 (corresponding to $\alpha = 60, \beta = 20, \gamma = 10$).

In this game, all outcomes in which players select the same number are pure-strategy Nash equilibria. The equilibria are Pareto-ranked, because equilibria in which all players choose higher numbers are better for everyone.

The game is appealing for organizational research because it captures situations in which strategic uncertainty creates a conflict between efficiency and security. Players would all prefer to coordinate on the equilibrium corresponding to a choice of 7, but uncertainty about what others are likely to do also creates an incentive to choose lower numbers. Situations like this arise frequently in organizations when the quality of a good depends on the lowest quality input or when the completion of a joint activity is determined by the slowest completion of any component activity (see Camerer and Knez 1997).

Initial experiments on weak-link games demonstrated that when players choose simultaneously without the ability to communicate before playing, coordination near the efficient equilibrium (in which everyone chooses the maximum payoff of 7) is almost impossible for groups larger than three (Van Huyck et al. 1991; see also Weber 2006). However, groups of two often coordinate on the efficient equilibrium if one player chooses 7 and patiently teaches the other player to learn to choose 7. Thus, coordination failure in groups larger than two raises an

15. See Hirshleifer (1983) for an early discussion of this game and Becker and Murphy (1992) for applications to economic growth and firm output. This game falls into a more general class of games known as order-statistic games, in which each player's payoff is a function of her own choice and some order statistic (e.g., the minimum or median) of all players' choices (see Van Huyck et al. 1991; Crawford 1995).

important issue for organizational research: given the prevalence of similar kinds of problems in real firms, how can we solve such coordination failure?

5.2. Incentives

A natural candidate for improving coordination is incentives. If adding incentives for coordinating efficiently works for the game in Table 7, then similar incentives might produce efficient coordination in real organizations. Of particular interest is the possibility that a temporary incentive increase might have long-term positive effects on efficiency by coordinating players on better equilibria, which are subsequently self-reinforcing, even after the incentive has been removed.

Goeree and Holt (2005) studied two-player versions of the game with continuous strategy choices. Their experiment varied the cost of selecting high choices (i.e., analogous to varying γ in the payoffs in Section 5.1), keeping the equilibria unchanged. They find that this parameter has a strong effect on behavior. Subjects' choices are significantly lower when the cost of choosing high effort increases.

Bornstein et al. (2002) created team competition. Players in two seven-person teams earn their own outcome and a bonus if their group's minimum is higher than the other group's minimum. This manipulation produces a slight improvement, raising the average minimum by about 1.5.

Perhaps the most dramatic demonstration that incentives can improve coordination in a setting mimicking organizational production is by Brandts and Cooper (2006). They use a five-action turnaround game (with strategies $\{0, 10, 20, 30, 40\}$), in which coordination failure occurs reliably in the first 10 periods. The reward for efficient coordination (β) is then increased for 10 periods to induce a change to an efficient equilibrium. The solid line in Figure 2 shows the effect of increasing the bonus during periods 11–20 (for 37 groups) and then reducing the bonus back to the original level (for 9 groups). The graph presents the average minima for groups in their experiment and also in a follow-up experiment by Hamman et al. (2007) that used a slightly different kind of incentive. Both lines report only groups that experienced coordination failure in the initial 10-period block.

In the Brandts and Cooper (2006) data, the increase in incentive improves coordination reliably: 70% of the groups move to a higher equilibrium and more than a third coordinated on the efficient equilibrium. When the increased incentives were removed, half the groups were able to maintain coordination above the minimum. This finding suggests that even temporary incentive increases can permanently draw firms away from inefficient equilibria.

Hamman et al. (2007) provide an interesting contrast to the Brandts and Cooper (2006) results. Their experiment used a very similar design to the latter, in which groups are first induced to fall to the lowest minimum. Then flat (all-or-none) incentives of the kind regularly used in real organizations are introduced: subjects receive a fixed bonus (or avoid a fixed penalty) if their group minimum reaches a certain threshold. Figure 2 shows that this flat bonus produces a large immediate improvement in group effort choices, as in the Brandts and Cooper design, but the long-term improvement is significantly smaller, by about half. One interpretation of the difference in the two designs is that the all-or-nothing incentive either works immediately or does not work at all, but the Brandts and Cooper linear bonus from increasing β allows groups

Figure 2. Average minima across periods in weak-link games: Hamman et al. (2007) versus Brandts and Cooper (2006) (initial failure only). For both experiments, periods 1–10 involved baseline incentives, periods 11–20 used increased incentives, and periods 21–30 returned to baseline incentives. Data from Hamman et al. (2007).

to slowly climb out of the bad equilibrium and obtain more efficient coordination. Thus, the latter kind of incentive is more effective at aiding long-run turnaround in firms coordinated on inefficient equilibria.

5.3. Communication

A natural candidate for increasing coordination is pre-play communication about strategies. Cooper et al. (1992) investigated one- and two-way communication in a two-player version of the weak-link game with strategies 1 and 2, and payoffs $\alpha = 600$, $\beta = 1000$, and $\gamma = 800$ (this two-player, two-action version of the game is frequently referred to as a “stag hunt,” or “assurance game”). Subjects playing without communication overwhelmingly choose strategy 1—the inefficient but safe strategy. With one-way communication, however, 87% of subjects say they will choose 2, and, conditional on receiving a message indicating action 2, the other subject chooses 2 76% of the time. The efficient (2, 2) equilibrium results roughly half the time. With two-way communication, subjects always indicate the intention to play action 2, and the efficient equilibrium results in 91% of groups.

Blume and Ortmann (2007) measured the effect of communication in nine-person weak-link games with the payoffs given in Table 7. In the baseline, subjects play eight times without any communication. Choices begin at about 6–7 and drop to 1–2 within five periods (as is typical in many studies). In the pre-play communication treatment, every subject also sends a message (1, 2, . . . , 7) before playing and observes the distribution of messages sent by others. Pre-play communication has a very strong positive effect on choices: the median message is 7 (the maximum choice), and the post-message choices have a median of 7 and an average of about 6.

However, Kriss et al. (2011) present a caveat to the Blume and Ortmann (2007) results by modifying the communication in two ways that are likely to apply to many organizational contexts. First, their experiment makes sending messages optional, meaning that players can choose not to send a pre-play message. Second, they make sending messages costly, with the costs equal to either 1 or 5 cents. They find that both levels of cost significantly decrease message use and lead to fewer groups coordinating on action 7 than in Blume and Ortmann's experiment. Thus, an employee's ability to forgo communication, coupled with very small costs for communication, can dramatically decrease the frequency with which people in an organization use communication to solve coordination problems and can therefore reduce its effectiveness as a mechanism for solving coordination problems.

Aside from pre-play messages, other forms of communication are generally less successful for inducing efficient coordination. For example, players' willingness to pay to play a coordination game should signal intentions to choose high numbers, through a forward induction-like argument: Players who pay a lot to play the game can only benefit by doing so if the profits from the game are also high. So, for example, someone indicating a willingness to pay 125 to play the game in Table 7 is signaling an expectation that the payoff from the game will be at least this amount. Cachon and Camerer (1996) find that although players opting to pay a fixed amount to play the game coordinate on higher (more efficient) equilibria, they do not converge to the efficient equilibrium in which all players select 7.¹⁶

Chaudhuri et al. (2009) also find many kinds of intergenerational communication ineffective. In their experiment, players in one generation provide advice on which strategies to play to members of a subsequent generation, as when members of a firm train their successors. Players earn payoffs from their own play and from that of their successor. Advice rarely improves the efficiency of coordination and often makes it worse. Advice only improves efficiency when it is public and commonly known (i.e., when the advice of all members of the preceding generation is read publicly to all members of the subsequent generation), a rather extreme form of intergenerational communication.

Taken together, the above results suggest that communication can help solve even the most difficult coordination problems—those with relatively large numbers of players and where the minimum effort determines the entire group's output. However, the most success occurs with very extreme forms of communication, in which players must all send messages and observe the messages sent by all others. Such communication is unlikely in many organizational contexts.

5.4. Managed Growth

Organizations might also achieve efficient coordination by obtaining it when they are small—when coordination is easier among a small number of members—and then maintaining it by growing slowly and ensuring that new entrants are aware of the group's history of success. Weber (2006) studied how a group's ability to maintain efficient coordination is influenced by the

16. Van Huyck et al. (1993) find that pre-play bidding works extremely well in coordinating activity efficiently in a game where the group payoff depends on the median choice rather than on the minimum, a version of the game with weaker interdependence between players. However, the kind of communication that occurs through other kinds of markets can decrease choices and efficiency by reinforcing pessimistic expectations (Kogan et al. 2011).

group's growth process and by the kind of entrants the group brings in. The experiment uses a 7-action game very similar to that in Table 7 (except that $\alpha = 20$).

The experiment compares groups that start off large (12 players) with those that grow to that size by starting small (2 players) and adding new entrants slowly. Replicating previous research (e.g., Van Huyck et al. 1990), groups that start off large converge to the inefficient outcome—all five 12-person groups converge to a minimum of 1. Also replicating previous work, 2-person groups all coordinate at higher levels of efficiency (minima of 6 or 7) than do large groups.

The two-person groups then grow slowly—usually by adding only one person at a time. Two treatments differ in the information provided to new entrants. In a history condition, new entrants observe the full history of outcomes (minima) obtained by the group, and this history is common knowledge. In a no-history condition, however, entrants are completely unaware of the minima obtained by the group prior to entry.

Groups without history all converge to the lowest minimum. However, although several groups in the history condition also fall to the lowest minimum as they grow, several groups do not. In fact, more than half of the groups maintain coordination on minima greater than 1, and two of nine groups remain coordinated on the efficient equilibrium (minimum = 7) throughout the entire growth process. This result presents one reason we might observe large efficiently coordinated organizations—they start off at a small size, when coordination problems are easier to solve, and then maintain efficiency by growing slowly and exposing new entrants to the group's history.

5.5. Coordination and Organizational Culture

Organizational economists have noted organizational culture as a potentially important concept for understanding behavior in firms. Much of their work focuses on the relationship between culture and equilibrium selection in coordination games (see, e.g., Kreps 1990; Crémer 1993; Hermalin 2001; see also Arrow 1974). Culture can serve as a means for resolving strategic uncertainty or selecting among equilibrium behaviors by individual members of a firm. Thus, a strong organizational culture might be one way to prevent coordination problems. (One way to interpret the above results on firm growth is that the efficient coordination obtained in small groups is similar to the strong culture that might develop in a small firm, and that such strong culture helps maintain efficient coordination as the firm grows.)

An important property of organizational culture is that it is sensitive to changes to the organization's size and boundaries, such as during a merger. Given the difficulty in identifying organizational culture and its effects on performance in real firms, the laboratory presents a useful domain for isolating the effects of changes to an organization on its culture.

An experiment providing insights into what happens when firms with different cultures merge was conducted by Knez and Camerer (1994). They studied what happens when two groups playing the weak-link coordination game are combined into a single larger group. In their experiment three-person groups play the weak-link game in Table 7 for five periods. Three-person groups playing this game exhibit a large degree of heterogeneity in outcomes—some coordinate efficiently (4 of 20 groups obtain a minimum of 7 in the fifth period), others fall to the inefficient outcome (6 of 20 groups have a minimum of 1), and several end up in between (minima of 2, 3, or 4). Two three-person groups were then combined into six-person groups for

another five-period block. The minimum in the larger combined group usually fell to that of its component three-person groups (or lower), and eventually to the global minimum of 1 in 80% of the cases. Thus, maintaining efficient coordination (or a successful culture) while merging small laboratory groups into larger ones appears to be difficult.

Weber and Camerer (2003) further studied difficulties in merging firms with distinct cultures and how such difficulties might be underestimated by firm members. Their paper introduced a paradigm for studying organizational culture using simple laboratory experiments. In the paradigm, groups of subjects develop a code to jointly identify sets of complex pictures as quickly as possible. More precisely, in every period a manager receives some information regarding an exogenous state of the world (some subset of a batch of pictures that the group must identify during that period) and must verbally communicate this information to get employees to respond appropriately by selecting the correct pictures. To do so, the manager and employees must develop a shared understanding of what words or phrases will be used to identify each picture (i.e., a code). This code is a shared understanding that allows firm members to solve coordination problems while minimizing the need for costly communication. As Cr  mer (1993) notes, such code shares many features with organizational culture. Much as with organizational culture, each firm's code is likely to be idiosyncratic, history dependent, and reflect the firm members' jointly developed shared perspective. Moreover, each code is likely to be well suited for that firm's performance, but different firms are likely to have codes that differ.

In each experimental session, two two-person firms develop code/culture independently over the first 20 periods. As the left part of Figure 3 indicates, firms initially lack a shared understanding, and it takes them a long time to complete the picture identification task. However, with repetition, both two-person firms develop a code/culture that allows them to perform the task efficiently.

Following period 20, the two firms in each session merge, with one firm taking over the other and eliminating the redundant manager. The new firm therefore comprises one manager, one familiar employee (who previously worked with the manager), and one new employee. The merged firm performs the same task as before (using the same set of pictures) for 10 additional periods. Prior to merging, members of both firms forecast the performance of the merged firm (with an incentive for accuracy).

As the right side of Figure 3 reveals, the merger has a detrimental effect on the performance of both employees. The manager and new employee find it very difficult to integrate their distinct codes/cultures, and this miscoordination negatively affects the performance of the familiar employee. Therefore, integrating two distinct codes/cultures—which had been equally efficient at solving the coordination problem before the merger—proves quite difficult. Moreover, subjects significantly overestimate postmerger performance, indicating unawareness of the difficulty of integrating the two firms' codes. Finally, questionnaires in which subjects rate the ability and competence of other subjects in the experiment reveal that the postmerger integration difficulties are attributed to perceived incompetence on the part of the individual(s) from the other pre-merger firm. Taken together, this study provides an illustration of the pitfalls present in real-world mergers that are often discussed anecdotally after a highly touted merger ends in failure but that are difficult to demonstrate conclusively using nonlaboratory data.

Feiler and Camerer (2009) replicated the Weber and Camerer (2003) experiment using a computerized interface and endogenous mergers. Subjects in the separate groups (students from

the University of California, Los Angeles, and the California Institute of Technology identifying pictures of their own campuses) bid for payments demanded to join a mixed-picture (cross-campus) group (rather than staying in a same-campus group) in a first and a second “merger.” The central question is whether bids to join a merged group correctly price the economic loss from the merger (similarly to the pre-merger estimates in Weber and Camerer). In the first merger into mixed groups, the average bids to join the mixed groups are too low by \$0.32/period (using Vickrey auctions, which in theory are demand revealing).¹⁷ There seems to be an organizational winner’s curse, in which the successful bidders do not recognize how relatively optimistic they are about the profit that can be produced in the merger.

5.6. Summary

The experiments discussed above analyze different ways in which activity in firms might be effectively coordinated. The results show that the process of coordinating choices, even when there is a clearly payoff-dominant equilibrium that everyone in the organization prefers, is not straightforward. The degree of coordination success can depend critically on such factors as incentives, communication, and how the organization undergoes transitions. For example, the experiments show that some kinds of communication are effective for coordinating employee

17. Feiler and Camerer (2009) also conducted regular auctions in which successful bidders pay their bids (in this case, because bids are demands for payment, successful bidders are paid what they demanded). As these bids are not, in theory, the same as actual valuations, an inferential procedure is used to estimate from bids the true willingness to accept. Both raw bids and inferred valuations suggest that winning bidders are too optimistic about the merger.

effort, while others are not. Similarly, a growing organization needs to be aware of the need for managed growth that brings in entrants slowly and exposes them to the firm's history, to maintain efficient coordination. The studies on merging groups reveal that coordination among newly integrated units might be difficult, and the difficulty is underestimated.

6. Leadership and Hierarchy

Organizations of almost any scale have some hierarchical structure in which authority relations substitute for price mechanisms and contracts. Hierarchical superiors typically have residual control rights and authority over what subordinates do. A special aspect of hierarchy is leadership, in which values and broad strategic direction are espoused by a leader in an implicit contract. These topics are also a natural meeting ground for rational theories (based on information and contracting) and behavioral theories (in which leaders inspire and serve symbolic functions).

The experiments discussed below explore how hierarchy and leadership affect organizational behavior and productivity. Experimental control has a special power in these studies, because experimenters can randomly assign firms to be either flat or hierarchical, can assign subjects to leadership roles, and can also allow self-selection to estimate the power of sorting and selection.

6.1. Hierarchy and Incentives

Alchian and Demsetz (1972) were among the first to recognize the advantage of an organization's members hiring a supervisor to monitor them. In an experimental analogue of this process, van der Heijden et al. (2009) studied the effect of supervisory power in a simple public goods game with predicted free riding. Subjects in groups of four choose simultaneously to either shirk or work (a binary choice, $e_i \in \{0, 1\}$). Shirking enables a worker to keep his endowment of 120; working means he loses the endowment but contributes to group output, determined by $Q = 60(\sum_i e_i)^2$, which is shared equally. If all four work, the net total payoff is $60(4)^2 = 960$, which is higher than the net total payoff when all shirk (480).

In a baseline (revenue-sharing) condition, group output is shared equally. As is typical in repeated public goods experiments—and in the experiments by Nalbantian and Schotter (1997) reviewed above—total effort begins at a high level (three workers chose to work) and shrinks to an average total group effort of 0.5 in 15 periods. There is substantial variation across groups, showing that local cooperative norms can emerge.

In a hierarchical (leader-determined sharing) condition, one person is randomly chosen to both choose effort as a worker in the group and also to assign output to individual subjects after each round however she likes. Although this hierarchy could backfire (the manager can grab all the output), the manager typically divides output evenly among those who exert effort and gives nothing to those who shirked. Subjects learn this pattern and work, because free riding will earn them nothing. As a result, the mean group effort is about three until the last round, when there is a sharp endgame drop in effort.

This experiment nicely shows that cooperation is sensitive to institutional rules and to the willingness of some players to punish defectors, as in many experiments in which costly punishment reliably raises contributions in public goods games (e.g., Fehr and Gächter 2000).

Having a worker-manager who can allocate output to all workers coordinates punishment of all free riders, because of her ability to allocate group output to each worker, and leaders do not grab too much output (presumably because they know it would lower future effort). As a result, leadership works well enough to produce sustained cooperation close to full efficiency.

Hierarchy is also studied in a recent experiment by Fehr et al. (2010), who consider a manager's decision of whether to delegate a decision right to a subordinate. Following from a model by Aghion and Tirole (1997), their experiment includes situations in which it may be optimal for a manager to delegate, because of the incentive this creates for the subordinate to acquire costly information concerning the best action to take. The key finding in their experiment is that managers delegate less often than they should, appearing to value authority inherently. Moreover, the extent to which they underdelegate is related to the degree of loss aversion they exhibit. Thus, managers in an organization may hold on to power excessively, even when it benefits them to let it go, because of some inherent value they place on possessing authority.

6.2. Leadership and Public Goods

An important aspect of leadership in organizations is signaling (e.g., Hermalin 1998). Leaders signal private information about desirable collective outcomes through observable announcements or through their behavior, or by changing economic incentives. Recent experiments explore this phenomenon in public goods.

Güth et al. (2007) explored the effectiveness of leadership for improving cooperation in public goods games. In their experiment, groups of $k = 4$ subjects play a public goods game under the voluntary contribution mechanism. Endowments are 25 tokens, which have a private return of 1 and a public return of 1.6 (so the marginal per capita return is 0.4).

In the baseline condition, contributions begin at about half of the 25 tokens and decline to about 6 after $T = 16$ periods, a typical pattern (e.g., Ledyard 1995). In the weak-leader condition, one player moves first, and her contribution is visible to others. In this condition, average contributions are about 3 units higher and exhibit the same typical decline over time. In the strong-leader condition, the leader can also penalize free riders by excluding one player from the group in the following round (the excluded player earns nothing). In this condition, average contributions start at 18 tokens and rise slightly (until a sharp drop in the final period). The strong and weak leader conditions together show that the ability of one player to establish a norm by moving first has a small effect, but combining that with the ability to "lay off" a free rider increases contributions substantially.¹⁸

Potters et al. (2007) examined contributions to a public good when the value of the good is only known by an early-moving leader. In this case, the leader's action can signal information about the value of the public good. In their experiment, subjects play a public goods game in pairs, composed of players 1 and 2. Each player can choose one of two options: A or B. Choosing A gives the individual a private return of 0.4 (in £). Choosing B gives each of the players a return

18. In a second part of the experiment (periods 17–24), groups voted on whether to have a leader (with unanimity required). Only 40 percent of the subjects voted to have leaders, but groups with leaders obtained significantly higher contributions and earnings. This raises the interesting question of why a structural change that benefits the group as a whole is not more popular. Subjects might not like ceding authority to a leader, or they may underestimate the leader's economic impact, which helps everyone.

of 0.0, 0.3, or 0.6. The exact return from choosing B was randomly determined. For the small return (0.0), choosing A maximizes both individual and collective payoffs. The medium return (0.3) is a prisoner's dilemma (A is privately better but two choices of B are best for both). For the highest return (0.6), choosing B is both individually and collectively better.

The design is fixed-role, random rematching with $T = 18$ periods. Choices are either made simultaneously or sequentially. Additionally, either both players observe the return rate prior to making a choice (full information) or only player 1 is able to do so (asymmetric information). Under full information, the order of play should not matter, and leadership should have no effect. However, under asymmetric information (when the leader observes private information), sequential play should implement efficient behavior (B choices by both players) when the return rate is 0.3 or 0.6, which is not predicted under simultaneous play. The interesting case that might show an effect of leadership is that of the sequential leader information with a return of 0.3. Suppose the leader knows the return is 0.3. If she chooses the cooperative B in those cases, a follower should infer that the leader's observed B choice either means the return is 0.3 or 0.6; the mean inferred return is therefore 0.45, which makes the marginal public return above the private return, so the follower should contribute. A leader contributing when she observes a return of 0.3 therefore coaxes followers, in theory, into contributing, which is mutually beneficial.

As predicted, under full information, both subjects rarely contribute when the return is 0.0 (less than 5%) and almost always contribute when the return is 0.6 (more than 90%). When the return is 0.3, leaders contribute a little more when playing sequentially (27%) than when playing simultaneously (16%). However, followers in the sequential treatment mimic leaders only a third of the time (and therefore contribute 9% of the time).

In the asymmetric information treatment, when the return is 0.3, player 1 does lead by choosing B 75% of the time when choosing sequentially, as theory predicts, compared to only 15% in the simultaneous condition. Followers contribute 81% of the time when leaders contribute, so the efficient outcome occurs more than half of the time.

These experiments highlight the significance of leadership in organizational settings when obtaining cooperation and voluntary effort is important. In both cases, leadership has beneficial effects, inducing higher contributions and generating greater earnings for the group as a whole (see also Moxnes and van der Heijden 2004; Gächter et al., in press). However, experiments of this kind also shed light on when leadership is likely to work and what characteristics make it effective.

6.3. Leadership in Coordination

Another way in which leadership might be valuable for organizations is in coordinating members' activity. When interdependent agents are faced with the problems of strategic uncertainty and equilibrium selection that we described in Section 5, having a leader direct behavior toward an efficient equilibrium through public statements might help produce efficient coordination (Foss 2001). Understanding when statements by a manager can induce a change in behavior to a new (more efficient) equilibrium is important for understanding the role of leadership in organizations.

Van Huyck et al. (1992) studied the effectiveness of public statements directing players toward one equilibrium in coordination games (see also Brandts and MacLeod 1995). In their experiment, pairs of subjects play three-action games with multiple equilibria, as in the game

Table 8. Coordination-game payoffs and influence of recommendations

		Column's choice		
		A	B	C
Row's choice	A	$5 + X, 5 + X$	0, 0	0, 0
	B	0, 0	5, 5	0, 0
	C	0, 0	0, 0	$5 - X, 5 - X$
		(X = 4)		
Recommendation		Players' choice of option (%)		
		A	B	C
None		97	2	1
A		99	1	0
B		51	48	1
C		62	0	38
		(X = 1)		
None		100	0	0
B (from experimenter)		50	50	0
		(X = 1) ^a		
None		39	61	0
B (from interested third subject)		37	63	0
B (from disinterested third party)		19	81	0

a. The third subject received \$5 for successful coordination on option B by the other players.

in the top panel of Table 8, which, for numerical values of X satisfying $0 < X < 5$, has three pure-strategy equilibria (the outcomes along the diagonal). In the Van Huyck et al. (1992) experiment, in which $X = 4$, most subjects (97 percent) select the action that corresponds to the efficient equilibrium (A) when there is no advice (see the second panel from the top in Table 8).

The experimental treatments vary whether there is a recommendation from the experimenter to play a particular strategy. As the row “A” indicates, advice is strongly followed (99 percent of the time) when it coincides with efficiency. Recommendations to play the Pareto-inferior equilibrium strategies B and C produce mixed behavior, and are followed 48 and 38 percent of the time, respectively. Thus, public statements by leaders in settings involving coordination can change behavior, even toward actions that are inefficient from the players’ perspectives. For example, a manager who wants employees to adopt and use a new communication technology or bookkeeping system may produce an impact through public statements, even when employees do not prefer the change.

Kuang et al. (2007) used payoffs similar to those of Van Huyck et al. (1992), with $X = 1$, and compared the effectiveness of recommendations from the experimenter, from an disinterested third party, and from a self-serving third “player” who earns \$5 if the two players in the

coordination game follow her recommendation to play B (although the third player does not play). As the bottom panel in Table 8 reveals, the mere presence of the third party, who receives a payoff of \$5 if the players coordinate on action B, makes B the modal choice even when there is no recommendation. (That is, concerns for equity and the third party's payoff appear to be important for equilibrium selection in this modified game.) However, when the interested third subject makes a recommendation of B, it is largely ineffective, and increases the frequency of B play by 2% (from 61% to 63%) relative to when there is no recommendation. But the recommendation of a disinterested third party—who does not benefit from the recommendation being followed—produces a significant increase. Thus, recommendations are more likely to be followed when they are impartial.

In Section 5, we discussed weak-link coordination problems (see Table 7). Given the difficulty of obtaining efficient coordination in such games, understanding the effectiveness of leaders' recommendations to play the efficient equilibrium is important. Can a leader urging players to move away from the secure but inefficient equilibrium toward the efficient but risky equilibrium convince them to do so?

Brandts and Cooper (2007) explored this question. In their experiment, firms of four subjects play a weak-link coordination game. Worker subjects choose among five possible effort levels $e_i \in \{0, 10, 20, 30, 40\}$. Worker i 's payoff $u_i(e_i)$ is $200 - 5e_i + (B \min_{j=1-4}(e_j))$; that is, each unit of effort privately costs 5 units, and the group payoff is B times the lowest effort, where $B \in \{6, 7, 8, \dots, 15\}$. Each firm also has a fifth subject, who plays the role of manager. In the first 10 periods, the manager is a passive observer (B is fixed at 6). In these first 10 periods, firms typically sink to the inefficient equilibrium in which efforts are close to zero.

In the remaining periods of the experiment (11–20), the manager takes control of the firm and attempts to induce coordination on the efficient equilibrium. The manager sets the bonus and receives the payoff: $100 + (60 - 4B) \min_{j=1-4}(e_j)$. This payoff function means managers benefit if the firm coordinates on higher minimum effort, but they also prefer to pay the lowest B that increases effort. In different treatments, managers had the ability to send natural language messages to employees (one-way communication) and receive messages back from employees (two-way communication).

Figure 4 shows the average minimum effort across the manager-run periods, using only those firms that experience initial coordination failure (i.e., firms in which the manager could “turn things around”). “Computer manager” refers to a treatment in which the role of manager is played by a computer who always selects $B = 10$. (This bonus is very close to the average bonus set by human managers across all treatments.)

Managers who are unable to communicate (but who set the bonus) produce very little improvement in efficiency, as do computer managers. However, communication improves the firm's performance, and two-way communication produces the greatest improvement. Thus, allowing better channels of communication between managers and employees improves the efficiency of coordination, suggesting a critical motivational role for managers when coordination is important in organizational settings.

Brandts and Cooper (2007) also explored the content of messages from managers to employees. Managers who ask employees for greater effort, who draw their attention to the bonus, and who describe a long-term plan for improving efficiency obtain the greatest improvements in efficiency. Communication is a complement to incentive change.

Figure 4. Average minimum effort (group output) in different conditions, for firms with initial coordination failure. From Brandts and Cooper (2007).

In a follow-up paper, Cooper (2006) used the one-way communication treatment described above to explore differences in the effectiveness of student subjects and actual managers (executive MBA students). Actual managers are slightly more effective than student managers, particularly at obtaining a rapid improvement in group outcomes, because they are more likely to employ the communication strategies found to be effective by Brandts and Cooper (2007).

6.4. The Illusion of Leadership

The abovementioned studies show that leaders, by recommending particular equilibria to organizational members, can improve the efficiency of coordination. Another study, however, highlights that such leadership may have limits to its effectiveness, and that such limits may be detrimental to the followers' perceptions of the leader's ability.

Weber et al. (2001) examined the ability of large and small groups to coordinate efficiently in the weak-link coordination game under a simple form of leadership. As mentioned in Section 5, previous studies using this game show a consistent group-size effect: small groups almost always coordinate successfully, while large groups never do (Van Huyck et al. 1990). Weber et al. (2001) examined whether simple leadership in the form of one subject addressing the group and urging them to coordinate efficiently would improve the ability of large groups to coordinate.

Each session consists of nine or ten subjects playing in one of two conditions. In the large-group condition, all nine or ten subjects play a four-action version of the weak-link game together. In the pairs condition, subjects are randomly and anonymously paired with one of the other nine people in the room and play the same game with this person only. The game is played eight times.

Figure 5. Average choices by treatment and session. From Weber et al. (2001). Reprinted by permission. Copyright © 2001 the Institute for Operations Research and the Management Sciences, 7240 Parkway Drive, Suite 300, Hanover, MD 21076 USA.

Prior to the first round, a leader is randomly selected and told that she will, after the second round, address the entire group (or all pairs, in the pairs condition) to organize and prepare the players for the remaining rounds. Leaders are given a simple message to guide their statements, highlighting the efficient equilibrium and the mutual gains from selecting it

Figure 5 shows the average effort choices (which were framed in the context of a “fee” voluntarily contributed to the group) for three sessions each of large groups and pairs. As expected, the pairs coordinate efficiently in the first two periods, but the large groups begin to fall toward the inefficient equilibrium.

After period 2, the leaders address the groups. The effectiveness of leaders’ statements can be seen in period 3: in both treatments, average choices are close to the maximum. However, for the large groups this is not enough to overcome coordination failure, and these groups subsequently begin to converge again toward the lowest choice. Thus, even though Brandts and Cooper (2007) showed that simple leadership in the form of public statements is effective at inducing turnarounds in groups of four individuals, this is not the case here for larger groups (of nine or ten) and when the leader only has one chance to speak.

Weber et al. (2001) were primarily concerned with what effect the different situations have on followers’ perceptions of the leaders’ abilities. Immediately after leaders speak, subjects in both treatments rate the leaders’ speeches and leadership ability equally highly (means ratings of 5.8 (pairs) and 5.9 (large groups), on a 9-point scale). However, when the same questions are asked again at the end of the experiment, subjects in the large-group condition rate leaders as significantly less able (4.5) than do subjects playing in pairs (6.2). Thus, even though the situation in which subjects were placed (i.e., the size of the group they were leading) determines their outcomes—and subjects even recognize that leading small groups is easier than leading

large ones in separate questionnaire responses—followers mistakenly attribute good outcomes to good leadership and poor outcomes to poor leadership. An additional experiment replicated these results and showed that subjects are even willing to act on their perceptions of leadership quality by casting a costly vote to replace the leader.

6.5. Summary

The experiments discussed in Section 6 all study the extent to which hierarchy and leadership yield efficient organizational outcomes. In each case, there is some inefficiency that obtains in flat organizations—because of either moral hazard or coordination failure. The experiments explore the extent to which efficiency is improved by assigning differential roles and giving some roles greater information, power, or prominence. In most cases, there is some beneficial effect of hierarchy and leadership on efficiency. However, the success of these treatments is not always perfect, even when theory predicts it should be. They may even produce perverse effects, as in the misattributions of leadership ability in weak-link games with small and large groups.

7. Conclusion

Laboratory and field experiments are a useful method for addressing important organizational questions, such as how worker effort will respond to different kinds of monetary and social incentives and how hierarchy and communication can help improve the efficiency of firm outcomes. In each of these cases, laboratory experiments provide very high degrees of control, which is helpful for testing theoretical predictions and comparing institutions and which is typically difficult to obtain in the field.

The results vary in what they tell us about organizations. In some cases, the results are highly supportive of theory. For example, worker efforts are close to those predicted in tournaments, and workers do respond to piece rates and monitoring. However, sabotage in tournaments with peer rating of quality is strong, and team-forcing contracts do not work.

Many of the results do not refute or confirm theory *per se* but instead illustrate empirical effects of variables that have ambiguous theoretical effects. For example, communication typically expands the set of equilibria, so data are helpful in determining whether communication leads to better outcomes. It appears that large-group coordination is difficult, but extensive types of communication and leadership can solve coordination problems, though the extent to which they actually do so in more practical situations remains an opportunity for further study.

An advantage of the lab is that it is often possible to clearly measure heterogeneity in responses and its influence. For example, the field experiment on monitoring by Nagin et al. (2002) showed that reducing monitoring increases moral hazard but usually only among a small set of workers (and the effect is moderated by workers' attitudes toward their employer). Heterogeneity is also evident in experiments on gift exchange: even though a minority of subjects are self-interested and shirk if they can, a majority of subjects' efforts reliably respond to wages (indicating positive reciprocity), although procedural details and economic structure matter, too.

When some results are surprisingly consistent with theory, and others are not, one hopes for a generalization of standard theory that could explain both kinds of evidence. In game theory, models that assume equilibrium beliefs but relax best response or assume a hierarchy

of cognitive sophistication have proved useful in explaining when standard theory works well and when it does not (e.g., McKelvey and Palfrey 1998; Camerer et al. 2004). Models like these, along with specifications of reciprocal or altruistic preferences (Fehr and Schmidt 1999) or of employees motivated by concerns for image or esteem (Bénabou and Tirole 2006; Ellingsen and Johannesson 2008), might be able to unify many disparate results and make interesting new predictions.

In reviewing this research, we were struck by how many interesting topics have been understudied or completely unstudied. Most of what is discussed in a modern doctoral-level course has never been studied experimentally. Employment contracts are usually surprisingly simple and incomplete (and relative performance evaluation is rare for executives), job design is crucial when multitasking makes it difficult to incentivize the optimal mix of activity, and sorting is presumably important. But all these topics are rarely studied, even though it is arguably even easier to study them in a lab experiment than with naturally occurring data. And in many cases, there is a clear complementarity of theory and experimentation, because an obvious experimental design walks right off the pages of a theory paper into the lab (particularly in game theory).

There are also many opportunities for entirely new experimental directions. Web-based software and the reasonable availability of funds for subject payments (and the capacity to do experiments with highly literate subjects in low-income countries) mean that experiments that are much more elaborate than most of those described in this chapter are feasible. Such experiments could explore how results scale up to larger groups and longer spans of time. Some topics that are ripe for additional and more thorough experimentation include the following.

Multitasking. When workers perform multiple activities, it is generally impossible to find contracts in which performance-based incentives induce agents to provide the mix of activity levels across tasks that firms would like. This fact shifts attention from single-activity contracts trading off risk and incentive to an incentive system including job design and monitoring (Holmström and Milgrom 1994). But there are only a handful of experimental studies of multitasking (e.g., Fehr and Schmidt 2004). This paucity of research presents a ripe empirical opportunity, because it is conceivable that studies would find that heterogeneity, sorting, and reciprocity could limit problems that appear to arise in theoretical multitasking models, or they could guide job design in an unexpected direction.

Social networks. Recently, economists have caught up to sociologists, who have been taking empirical snapshots of networks and studying their properties and influence on behavior (e.g., Jackson 2010). Networks are clearly important inside organizations. And because naturally occurring networks are both created by and influence behavior, experiments that assign networks exogenously are scientifically useful to establish causality. Experiments have been used to study the influence of network structure on solving combinatorially explosive operations research problems (Kearns et al. 2006), financial contagions (Corbae and Duffy 2008), and other topics (see Kosfeld 2004), but none of these experiments deals with the central questions in organizational economics.

Virtual worlds. Commercial firms have developed online gaming virtual worlds, in which players inhabit personal roles, interact socially, and develop economic exchange for scarce resources that enable players to succeed (e.g., SimCity and Second Life). These games represent a mouthwatering empirical opportunity, because they attract large numbers of players who spend

hours playing. Experimental control could either come from collaborations with designers or from running true experiments inside the virtual world (see Bloomfield 2007).

More broadly, we advocate richer, more complex—and therefore often more informative and realistic—experiments on organizations.

Insider Econometrics

Empirical Studies of How Management Matters

Casey Ichniowski and Kathryn Shaw

1. Introduction

Survey data and casual observation suggest that there are striking differences in management practices among firms and establishments that operate within the same industry. Human resource management (HRM) practices—such as types of compensation, teamwork, job design, or training activities—vary across firms. Decisions about the scope of the firm, such as the extent of outsourcing or vertical integration and about adopting new technologies, are among the many management policies that vary across firms.¹ Industries are not populated by homogeneous firms having a single set of optimal management practices. Why do some firms within the same industry look so different from one another? Are some management practices more productive than others?² Do differences in management practices help explain large differences in productivity that exist among firms and establishments within the same industry?³ Can one set of management practices be the right choice for some firms, while a different set of practices is appropriate for other firms that compete with them?

Researchers are now going inside firms and industries to answer these questions. With firms increasing their use of new software to track the productivity of their employees and operations, managers in these firms are looking for new ways of using these data to elevate the performance of their firms. As economists obtain access to these data, they can identify more detailed determinants of productivity and test richer theories of the firm than was previously possible.

In this chapter, we describe an empirical research strategy for investigating these questions about the effects of management practices on productivity and the determinants of the choice of

1. See Osterman (1994, 2000), Ledford et al. (1995), and Lawler and Mohrman (2003) for surveys on HRM practices. See Bresnahan et al. (2002) for data on computer technologies and other management practices.

2. For survey articles on personnel economics topics, see Lazear (1999), Ichniowski and Shaw (2003), Lazear and Shaw (2007), Oyer and Schaefer (2011), Rebitzer and Taylor (2011), and Lazear and Oyer (this volume).

3. Haltiwanger (2008) documents very large differences in productivity across establishments within narrowly defined industry categories.

management practices. We refer to this research strategy as “insider econometrics.” The term “insider” refers to the use of rich micro-level data on workers or work groups inside firms that share a common production function. “Insider” also refers to the use of insights from insiders—from managers and employees—that inform almost every facet of the research. The term “econometrics” refers to the use of rigorous statistical tests of the effects of management practices on workers’ performance, or tests of why some firms adopt one set of management practices rather than an alternative set. In sum, insider econometric research combines insiders’ insights with econometric techniques applied to the right data to reveal when and why management practices matter.

2. The Distinctive Characteristics of Insider Econometric Research

Five characteristics are common in insider econometric studies. We first list these features and then describe them in more detail. Insider econometric studies

1. estimate a productivity regression in which productivity is a function of some management practice;
2. identify why management practices raise productivity and where the practice has larger and smaller effects on productivity;
3. model the adoption of the management practices;
4. analyze micro-level data on production units (e.g., individual employees or teams of employees) or larger work groups (e.g., establishments) that share a common production process; and
5. use field research and interviews from industry insiders to formulate testable hypotheses, interpret results, and provide additional evidence of the mechanisms behind the econometric results.

The first three features identify the objectives of insider research—what questions do insider econometric studies try to answer? The last two features are two defining methodological features of insider econometric research—asking what are the main methods used to answer insider questions?

The first question insider econometric research tries to answer is: does a new management practice raise productivity? Thus, the first step is the estimation of the treatment effect in a productivity regression. While the treatment effect literature in economics has often been concerned with estimating the effects of changes in public policies, such as that of an increase in unemployment compensation on labor supply,⁴ insider econometric studies analyze the effects of management policies. Therefore, the *treatment is the adoption of a new management practice*, and the *treatment effect is the effect of the new practice on workers’ performance*.

What are examples of the management treatments in insider studies? Because insider studies focus on a single production process, treatments are often changes in how workers are managed. Treatments therefore include changes in personnel and HRM practices; changes in interactions

4. For a discussion of the evolution of treatment effect research in economics, see Levitt and List (2009).

among co-workers, such as new shift assignments; changes in employees' social networks; and many other people management practices implemented in firms. Other insider studies examine differences in technological features in a given production process, such as the adoption of new computer technologies. Treatments also include changes in the scope of the firm's activities, and thus in the boundary of the firm itself.

Throughout this chapter, we refer to the treatment effects as the effects of the new management practice on productivity, but the term "productivity" is really shorthand for different measures of performance that are relevant for the given production process. The performance outcome is more accurately defined as any variable that the firm monitors and the worker controls that affects the firm's profits. Examples of productivity outcomes in insider studies include product quality, production line downtime, number of customers processed per hour, patents granted to research teams, speed of order fulfilment, worker absenteeism, or worker turnover. The performance variable is rarely profits, because profits are measured at the level of the firm, and insider studies use samples below that level. Management practices are typically not the same across all workers in a firm. Production workers are not covered by the same practices as managers, and employees in one site may be covered by different practices than those at another site.

The second question addressed by insider econometric research is a natural extension of the first. Why does the new management practice raise productivity? To build richer theories of the firm, researchers must find out why a management practice is or is not effective. One way insider studies address this question is by identifying reasons why the treatment effect of a management practice varies across workers, work groups, or establishments in the same industry. Productivity may increase considerably after a new practice is adopted among some workers or work groups in the study, while for others, the productivity effect is negligible. This variation can help identify the mechanisms and behaviors that explain the productivity increases. Insider studies allow workers and work groups to respond differently to a management practice; therefore, these studies almost always estimate the production function with heterogeneity in the management treatment effect.

The third question that insider econometric research addresses is why and where is the new management practice adopted? Insider studies document systematic answers to the questions about why management practices change and why management practices are not universally adopted for all workers and plants, even among seeming competitors. First, best management practices evolve over time. For example, new information technologies are invented. New technologies may also call for the adoption of new management practices. Second, the profitability of practices varies across firms. For example, the expected productivity gains depend on subtle differences in the production functions of competing firms. They may also depend on other management practices in the firms. The expected profitability of a new practice also depends on the costs of adoption, which can vary across firms because of differences in managers' and workers' resistance to change or differences in managerial knowledge about the existence or effects of new practices. The expected profitability can also depend on the firm's strategy.⁵

5. See Section 6 for a systematic discussion of causes of adoption.

Even if the researcher does not have the data to estimate the full adoption equation, reports on managers' views of the reasons for adoption can be very helpful in interpreting results from the productivity equations.⁶ These three questions—about the effects of management practices on productivity, the mechanisms behind the estimated productivity effects, and the reasons for adopting different management practices—are the focus of insider econometric research.

The fourth feature of insider econometric research is the analysis of micro-level data from one narrowly defined production process. The observations that form the dataset should be the natural production units for the single production process being studied. These production units can be individual workers (if employees work alone), small groups of employees (e.g., problem-solving or project-development teams), or relatively large groups of employees (e.g., retail stores or production lines in manufacturing plants). The focus on one specific production process helps isolate the productivity effects of new management practices, reduces concerns about omitted variable bias in the productivity regression, and allows the researcher to build and estimate an accurate production function. For example, by modeling one specific production process, the researcher can choose a logical dependent variable for that process, leading to the many different variables that insider studies use to measure productivity—sales volume for salespeople, calls for call center workers, flight delays for airline carriers, downtime for a production line, or student achievement in a classroom. The focus on a single production process also allows the researcher to identify the determinants of that specific measure of performance.

The last feature in the list is perhaps the defining feature of insider econometric research: consultation with industry insiders who have direct experience in the production process. These insider insights help identify practices and policies that are relevant to managers in the industry, the most appropriate measures of productivity, other determinants of productivity that might be correlated with the management treatment, reasons a management practice was adopted for one work group or plant but not another, how employees responded to the new management policy, examples of actual workers and plants that illustrate the productivity effects, and more. Insiders therefore are instrumental in identifying meaningful hypotheses about the effects of practices on productivity outcomes and on worker behaviors, and about the determinants of adoption of the practices. They also can help identify what factors need to be included in an accurate model of productivity or adoption and therefore what kinds of data are needed to estimate those models.

Insider studies usually cover four of the five features listed above. Specifically, insider datasets often do not permit the researcher to estimate both the productivity regression and the adoption regression (in features 1 and 3). As the examples below show, researchers often estimate the production function but carefully describe the likely conditions for adoption based on interview evidence. Other examples below show that researchers estimate the adoption regression and use interviews to describe the production function underlying the adoption decisions. Overall, all

6. However, many insider studies reviewed in this chapter do try to add up the broader economic and welfare effects of a given management practice beyond its effects on productivity outcomes, such as the effects on overall firm profitability or the prospects for future growth.

insider studies aim to marshal micro-level data and insights from industry insiders to study the effects of management practices on workers' performance; changes in worker behavior when new practices are adopted; the costs of the practices; and ultimately, the reasons for the adoption of the practices.

3. Illustrating the Challenges and Advantages of Insider Econometric Research

Researchers face analytical challenges and unique opportunities in undertaking insider studies. We illustrate both.

The key challenge is that firms are making optimizing decisions when they choose management practices, and therefore, the adoption of the treatment is not random.⁷ Therefore, our models of the effects of these practices on productivity face all the traditional problems of using nonexperimental data. There is likely selection bias and endogeneity in the choices of workers and managers. There is omitted variable bias in the production function. We cannot know the unobserved counterfactuals about what would have happened if nonadopting firms had adopted some new management practice or if adopting firms had not adopted.

There are advantages to modeling treatment effects in insider studies. The quality of the data, the information from industry insiders who adopt the practice or work under it, and the types of comparisons the researcher can make with the data all add more information than is typically available in traditional treatment effects research. Perhaps most important, access to knowledgeable insiders and to rich data on the operations of the actual production process can potentially address all the key challenges by providing insights into the decisions of workers and managers, by reducing the extent of omitted variable bias (by modeling a specific production process with real operating data), and through insiders' views about how a process would work without the given management practice.

To illustrate the challenges that selectivity in the adoption of a new management treatment poses and the opportunities to address those challenges through insider econometric research, we display the production functions and patterns of adoption for a hypothetical insider study in Figure 1. Figure 1 shows two age-productivity profiles. For convenience, we refer to these productivity profiles as the profiles for two groups of establishments, such as plants in a manufacturing industry or stores in a retail industry. However, insider datasets focus on a single production function, and thus the data can also be observations on workers, work teams, or parts of an establishment. Many of our examples are insider studies with worker-level datasets from a single firm, and so Figure 1 could also represent the age-productivity profiles of different types of workers in the firm.

The two hypothetical productivity profiles in Figure 1 reflect several assumptions that are made or tested in insider econometric studies. First, despite being in the same industry and

7. The case of random adoption is relevant for some insider applications, such as those studying personnel records for a single firm that adopts a new work practice for all employees, because universally applied practices are not applied selectively (for that firm's population). Also, field experiments in developing countries can impose random assignment—see Bloom et al. (2011b) for a random treatment in textile firms in India. Doyle et al. (2010) examine the performance of different kinds of physicians through random assignment of patients.

Figure 1. Productivity effects of adopting a new management practice: a hypothetical age-productivity profile for treated and nontreated groups. Note that t^* is the time that the treatment, such as an organizational change, occurs.

even having the same basic production process, differences still exist between the two sets of plants; the Type 1 group has a higher level of productivity than the Type 2 group. Second, both productivity profiles are upward sloping, reflecting factors like learning-by-doing and experience. In this illustration, we let the basic growth rate in productivity be the same for the two types of establishments. Third, at t^* , management in the high-productivity Type 1 establishments adopts some new practice, for example, a new work practice or technological enhancement in their operations. Management in the low-productivity Type 2 establishments does not adopt. The new management practice causes a one-time increase in productivity by an amount equal to ΔP^T . Finally, productivity continues to grow in both types of establishments after t^* due to continued effects of experience and learning.

Figure 1 also displays assumptions about two unobserved counterfactuals. First, we assume that the change in productivity among Type 2 nonadopting establishments had they adopted (ΔP^N) would be positive but smaller than what was observed for the Type 1 adopters. Though the productivity gains for nonadopters, ΔP^N , are shown to be positive, these establishments still do not adopt, because the gains are insufficient to overcome the costs of adopting. Second, the post- t^* profile for the adopters would have continued along the same pre- t^* trajectory but without the one-time increase.

The hypothetical example in Figure 1 highlights the basic empirical challenges. Consider two types of data that could be used to estimate the treatment effect of the new management practice on productivity. First, consider the case where the researcher obtains true experimental data—data from a sample of organizations with random adoption of the new practice at time t^* . Figure 1 does not depict this case but rather the case of nonrandom adoption: organizations that would experience bigger productivity gains are the adopters in Figure 1.

If adoption of the management practice were randomly assigned across both Type 1 and Type 2 establishments as part of an experiment, the estimated gain in productivity from the new practice will be an average of ΔP^T and ΔP^N , because the group of adopters in an experimental design would include both types of establishments. As with any experiment, this estimated gain is an unbiased estimate of the average effect of the practice on productivity across all plants in this industry. However, in the real world, this estimate of the change in productivity due to the management practice will never be observed in any single establishment: a firm will never randomly adopt a new management practice. From the perspective of a manager in any of the organizations in the dataset, the experimental estimate of the productivity gain due to the adoption of the practice will not answer his exact question: what happens to productivity in my business if I adopt this new management practice?

Therefore, random assignment of the treatment does not offer all the methodological advantages one desires for studying productivity effects of new management practices. The manager wants to know what the expected productivity gain is for his operations. He would like to know the “treatment of the treated” and the “treatment of the nontreated” effects displayed by the Type 1 and Type 2 groups, respectively, and he wants to know whether his workers and plants are in the Type 1 or Type 2 group. Researchers want to know the same things. Insider studies—with good data and knowledge—test theoretical models of why and how Type 1 establishments benefit, while Type 2 establishments do not.

In what follows we use Figure 1 to frame our discussion of the insider econometric methodology. The examples provided illustrate the two distinctive methodological features of insider studies—analysis of rich micro-level data about one specific production process and access to insiders who are knowledgeable about their management practices and operations—that are instrumental in constructing convincing empirical tests of the effects of management practices on productivity.

4. Examples Illustrating the Methods of Insider Econometric Research

In this section, we review eight examples of insider econometric research to illustrate the common features of this research and to give the new researcher a true feel for both the methods and results from this body of work. After reading these examples, it is much easier for the researcher to understand the econometric methods, which we describe in Section 5, and the key decisions about more specific elements of the research design of an insider study (beyond the use of micro-level data on a single production process), which we describe in Section 7.

The review of each example follows a pattern: we describe the sample and the production process; the nature of the management practices; the basic empirical findings about adoption of the practice and its effects on productivity; and the results on why productivity does or does not rise due to management practices. Variants of the Figure 1 profiles are used to summarize the studies. These examples also illustrate a range of management treatments that insider studies investigate, from the adoption of a single new compensation practice, to the adoption of sets of HRM practices, to changes in the scope of the firm’s work tasks and activities. We conclude the

section with a broader review of insider studies, where we categorize a large number of insider studies according to the type of management practices analyzed.

4.1. Two Single-Firm Worker-Level Studies on the Productivity Effects of Incentive Pay

The first two studies use worker-level observations from a single firm. In both, the new practice adopted by management is an incentive pay practice that covers all employees in the firm. Despite these similarities, both confront their own unique methodological issues and each shows the importance of different insider insights.

4.1.1. *Incentive Pay at Safelite Glass*

Lazear (2000) studies the productivity of workers in one firm before and after the introduction of a new incentive pay plan. Lazear's study models automobile windshield installation for the Safelite Company. In this company, each employee drives a truck to the homes of people who need a new car windshield. The production function is worker-specific and measurable: employees work alone, installing about two or three windshields a day. The production unit is the worker. The data are monthly productivity data for some 3,000 workers for 19 months. During this period, the firm shifts from hourly pay to incentive piece rate pay, where pay is a function of the number of windshields the worker installs that day. After the move to piece rate pay, the average productivity of the Safelite workforce rises by 44%. Workers are highly sensitive to monetary incentives.

Why is this study interesting? The specific production setting is not important: the reader does not have to be interested in windshield installation per se. The management practice—piece rate pay—is of interest, because many firms use some form of individual performance incentive, even if incentive pay rarely takes the form of simple piece rates. Therefore, the evidence that monetary incentives raise workers' productivity is in itself valuable, though perhaps not surprising.⁸ What makes the result valuable is that the study identifies why productivity goes up. First, as expected, some of the overall productivity increase is due to the same worker increasing his or her effort and output. Second, about half of the increase in the mean productivity of all workers comes from self-sorting by workers: those workers who have low productivity levels leave the firm (or are not hired by the firm) after incentive pay is adopted. The most interesting result of the paper is that the firm's choice of its incentive pay practice induces sorting by workers, and the sorting itself has a big productivity impact.

Figure 2 illustrates these results. The productivity response to the incentive pay is heterogeneous across workers. Analogous to Figure 1, the Safelite workers are classified as types—in this case three types. The pay plan is changed at time t^* . The response to the treatment is heterogeneous across the three types. Type 1 workers are employed before and after the new pay plan, and these workers raise their productivity (by 22%, according to the actual estimates in this study). Type 2 workers quit in response to the new incentive pay. Type 3 workers are hired after t^* . They have higher productivity and earn more under incentives than those who

8. Of course, the adoption of the incentive plan cannot be considered exogenous. Safelite adopts the practice because it expects productivity to increase. In Section 6, we consider the question of why optimal management practices can change over time.

Figure 2. Incentive pay introduced in one firm (Safelite; Lazear 2000). Note that t^* is the time of the treatment: the introduction of piece-rate pay. The solid lines represent the observed productivity profiles for workers of Type 1, Type 2, and Type 3. The dashed lines represent unobserved productivity profiles for the different worker types.

left would have earned had they stayed. Together, productivity rises by an additional 22% from the selection effects of losing Type 2 workers and the hiring of Type 3 workers.⁹

Obviously, not all firms would achieve this exact productivity gain. This is just one firm that chose the practice, probably expecting it to be effective.¹⁰ Although one cannot expect the estimated productivity gains of this incentive pay plan to apply to other firms and production processes, the design of this study has several advantages that make the estimates of this particular treatment effect especially convincing. Because the production function is very simple with workers working alone, the unobserved counterfactual productivity paths are easy to model (based on the observed productivity paths, as shown in Figure 2). There is little likelihood of omitted variable bias, and thus, typical selection bias and endogeneity bias are not relevant to the study. In studies of the effects of management practices on performance using more heterogeneous samples of production units, one would be much more concerned that

9. The figure is not drawn to scale to capture this size of gain. Shaw and Lazear (2008) display this figure using the actual Safelite data and offer more detail on differences between employees who leave and join this firm after introduction of the new pay plan.

10. Note that the reason that the firm chose to adopt incentive pay at this time is that the firm had introduced new information technology software that kept computerized records of each employee's productivity. Thus, Lazear (2000) is estimating the joint impact of a change in the HRM practice and a change in information technology infrastructure. Other firms that introduce piece rate pay may have lower performance gains and may not find the use of piece rate pay optimal (for evidence from shoe manufacturing, see Freeman and Kleiner 2005).

unmeasured factors cause a selection bias, with some firms choosing the practice while others do not.

At the same time, in this study, there is still a different source of selection bias in the estimated treatment effects—workers decide whether to work at the firm or not, and that optimizing decision by workers affects the size of the productivity gain from incentive pay for the firm. But the study identifies and measures this self-selection, leading to the key theoretical point of the paper. An overall change in productivity can be decomposed into two components that are analogous to the intrinsic and extrinsic margins of each employee's labor supply decision. Some workers respond to the new incentive pay at the *intrinsic margin* by increasing the amount of labor (in this case, effort rather than hours) they supply. Other workers respond at the *extrinsic margin* by leaving their jobs, with different workers taking their place. The broader point for economic theory applies beyond the scope of the single firm in this study. When the firm selects its overall management practices, it must consider not only their effects as a motivation device but also their effects as a signaling device to sort specific kinds of workers into and out of the firm.

4.1.2. Incentive Pay among Fruit Pickers

Bandiera et al. (2005) analyze productivity of employees who pick fruit. The workforce in this study is hired only during the summer harvest season. The firm undertakes a series of experiments that change the payment schemes for these employees.¹¹ In one experiment, the firm introduces new piece rate pay, as in the Lazear (2000) paper discussed in the previous example. However, in Lazear (2000), the move was from hourly pay to piece rate pay; here the move is from a performance pay plan based on workers' relative performance to piece rate pay. In the relative output pay plan, the firm fixes the average pay for the field *ex ante* but pays each worker based on how much he or she does relative to other workers in his or her group (but keeping the mean pay fixed). In the second half of the picking season, the farm switches to simple piece rates: pay per unit of output is fixed *ex ante* and does not vary as a function of how co-workers perform. The panel data in this study cover 142 workers for 108 days spanning the periods in which different compensation plans are in place. After the switch to simple piece rates, the average productivity of workers rises by 58%. Nearly all workers increase their effort, and the variance of output also rises markedly with a jump in the number of high performers.

Figure 3 illustrates the unique results of this study. The productivity response to the incentive pay is heterogeneous across workers. Analogous to Figure 1, there are Type 1 and Type 2 workers, with a new incentive policy adopted at t^* . Unlike Figure 1, both types of workers are covered by the new incentive pay. Type 1 workers exhibit a bigger productivity jump after t^* than do Type 2 workers. The study identifies who the Type 1 workers are—employees who had been working with their friends under the initial relative pay plan. Prior to the piece rate pay plan, these workers probably withheld effort, because they knew that if they worked hard, they would

11. The experiment here does not randomly assign different workers at one point in time, but the timing of the change in compensation is exogenously determined by the analysts. For papers on their other experiments on managerial pay or on teamwork, see Bandiera et al. (2007, 2009).

Figure 3. Incentive pay introduced in one firm (fruit pickers; Bandiera et al. 2005). Note that t^* is the time of the treatment: incentive pay plan changes from a relative pay plan before t^* to a per unit piece-rate plan after t^* . Insider information identifies Type 1 workers as those with friends as co-workers; Type 2 are workers without friends as co-workers. The solid lines represent the actual productivity profiles for workers of Type 1 and Type 2; the dashed lines represent the unobserved counterfactuals for these worker types. After the move to piece-rate pay at t^* , productivity rises, and there is no difference in the performance of those with and without friends. (The variance in performance goes up after piece rates are introduced, but that is a function of effort, not friendship, so that increase is not displayed here.)

lower their friends' pay. The Type 2 workers have lower productivity gains, because they were not working with their friends and thus were more productive than the Type 1 workers when they were working under the initial relative pay plan. The researchers reach this conclusion about why productivity increases, because they gathered additional data on friendships among workers.

What makes this study interesting? The readers of this paper do not have to be intrigued by either the occupation of fruit picking or even this specific case of piece rate pay. Unlike the setting for Lazear (2000), where workers came and went, all workers in this study stay for the short fruit picking season covered in the data. Thus, we are looking only at workers who are employed before and after the change in pay policy (in the Figure 2 illustration of the Safelite study, these would all be Type 1 workers). Here, however, we are examining the heterogeneity in productivity responses among these workers. The more fundamental economic insight in this study of fruit pickers is that workers with certain characteristics internalize an externality—the externality that their effort harms others—during the relative payment scheme. Thus, social relationships determine productivity. More broadly, this example identifies the importance of peer effects and social networks in the determination of worker productivity. Other insider style

studies make related points about peer and network effects, including Ichino and Maggi (2000) for banking, Mas and Moretti (2009) for grocery stores, De Giorgi et al. (2009) for classrooms in education, Bartel et al. (2009a) for nursing, and Ingram and Roberts (2000) for hotels.

In the econometric treatment effects literature, it is widely acknowledged that treatment effects should vary across people.¹² But the design of this study is illuminating, because it solves other econometric problems associated with estimating treatment effects. In managing a firm, managers know that not all workers respond equally to a treatment. Often, a study would conclude that the variance in the treatment effects is from some unobserved abilities of the workers, but here the authors go inside the company and gather the data on friendships to identify the source of variance displayed across Type 1 and Type 2 workers. Even though the data pertain to the limited setting of one firm in one industry, the logic of the economic model applies more broadly. In settings where workers might withhold their effort because that effort can harm their co-workers, managers need to consider these peer effects in the design of compensation plans.

4.2. Two Cross-Company within-Industry Studies of the Productivity Effects of Innovative HRM Practices

In the next two examples, we contrast studies that examine the productivity effects of new HRM practices inside the steel industry. In both examples, the production process is a production line involving multiple employees. Despite these similarities, these studies analyze different segments of the steel industry and reach different conclusions about why these HRM treatments are or are not adopted.

4.2.1. *Human Resource Systems in Integrated Steel Mills*

In our third example of insider econometric research, two companion studies by Ichniowski et al. (1997) and Gant et al. (2002) analyze the productivity of finishing lines in integrated steel mills. The management innovation is the adoption of entire sets of new HRM practices in integrated steel mills, where the new HRM practices cover recruiting and selection policies, compensation, teamwork, communication, and employee training. The authors model production of one specific type of production line that finishes steel. These steel lines take a coil of very thin steel sheet, unwind it, and then chemically treat and coat the steel for use in products like auto bodies. In the 1997 study, the authors collect panel data on productivity outcomes for the finishing lines. The monthly productivity data for the rolling mill work groups in 36 steel mills cover several

12. In this study, there is no selectivity within the firm in the adoption of the practice, because all employees are covered by the change in pay policy at t^* . As in Lazear (2000), the treatment effects estimated are effects conditional on being employed in this firm. Even though the management policy change covers all employees in the dataset, there are still important unobserved counterfactuals; but in this case, these are outside the scope of the study's data. The workers' productivity profiles in Figure 3 come from only a subset of farms. As in the case of Figure 1, there are other farms, not in this particular study's dataset, that did not introduce incentive pay; these farms are analogous to the nontreated establishments in the bottom half of Figure 1. The fruit-pickers study shows us what would happen to the farming fields that adopt; we do not know anything about the nonadopters that are not covered in this study's data.

years for each line. The researchers identify four “systems” of HRM practices, ranging from the most innovative HRM system to the most traditional system with no such innovations.

Ichniowski et al. (1997) show that the mills with all the highly innovative HRM practices have the highest productivity levels. Yet some mills adopt the system of all the innovative practices and some do not. What accounts for the difference in adoption among a set of finishing lines that are competitors in a very narrowly defined industry and that are making very homogeneous products using the same machinery? Site visits to the finishing lines did not reveal any differences in product attributes, technologies, or demographic characteristics of the workers. Site visits did reveal that, even though older and newer vintage lines adopted the innovative practices, the only kind of older lines that adopted the innovative practices were old reconstituted lines—those that had been temporarily shut down and restarted by new owners. Based on this subtle distinction, the authors hypothesize that the difference in the adoption of innovative HRM systems is due to transition costs. Older continuously operating lines had higher transition costs; newer lines and those older mills that were restarted after a purchase by new owners did not have transition costs associated with changing their HRM systems (Ichniowski and Shaw 1995). All would have equal productivity gains, but older lines did not make the transition. Since the time of the study, more mills have adopted new HRM practices, but only after becoming reconstituted mills. One example is the private equity buyout by Wilbur Ross of multiple U.S. steel mills in 2002, which was followed by the introduction of new HRM practices in these mills, and then by the resale of the mills to Arcelor-Mittal in 2004 (Bose and Shaw 2008).

What makes this insider study interesting? Once again, readers of the paper do not have to be interested in the specific setting of steel finishing lines in this study. The authors not only show that HRM practices matter—that innovations in HRM practices produce tangible performance gains—they also show how such practices matter and why productivity goes up. Productivity increases only when a firm adopts a set of complementary HRM practices that together reinforce productive worker behaviors. Insider insights about why HRM practices are complementary lead the researchers to measure the management treatment as a set of practices rather than as a single HRM practice.

Moreover, research inside the finishing lines revealed why these bundles of HRM practices improve productivity. Gant et al. (2002) collect and analyze data on the communications patterns of workers in these lines and show that workers interact much more with one another as part of problem-solving activities in the high-productivity lines with innovative HRM practices. The lines with innovative HRM practices have much denser social networks and worker interactions, or higher levels of “connective capital” in the firm (Ichniowski and Shaw 2009). This difference in worker behavior provides another type of evidence—evidence on the work behavior of the employees in these lines—that helps explain why the treatment effect due to innovative HRM systems exists.

The evidence on the interactions among workers in Gant et al. (2002) also helps answer the question about why many lines do not adopt sets of new HRM practices that raise the productivity of other lines. Ichniowski et al. (1997) suggest that the productivity gains would be the same if nonadopters instituted the new HRM practices, but that nonadoption is explained by differences in the transition costs of adopting new HRM practices in older, continuously

operating lines.¹³ The evidence in Gant et al. (2002) suggests that changing the pattern of social relationships among workers could be a very costly process for any steel finishing line, and thus could be precisely the kind of transition cost that prevents older lines from adopting the new HRM practices.

4.2.2. *Problem-Solving Teams in Steel Minimills*

Boning et al. (2007) return to the steel industry but move to production lines in the minimill sector that use electric arc furnaces. Minimill lines produce steel bar products, like rebar used in construction and highways or large beams used in the construction of buildings. The mills melt steel scrap and cast it into the bar products. As in Ichniowski et al. (1997), the data here also come from one type of rolling line in these mills and thus pertain to very homogeneous production processes. The management innovation in this study is the adoption of problem-solving teams. Workers use problem-solving skills to increase the quality of the bars coming out of the mill by watching the production process as the bars roll through the mills and correcting problems as they arise. The authors collect panel data: monthly productivity data for the rolling mill work groups in 34 steel mills for about 5 years. In the beginning of the data, about 10% of the rolling mills had problem-solving teams; by the end, about half of the mills had teams.

Productivity regressions reveal significant productivity gains after problem-solving teams are adopted in minimills. However, some mills adopt teams and some do not. Once inside the mills, the reason for the difference was apparent. Some lines producing basic commodity bar products, like rebar steel, have fewer problems to solve compared to other lines making more complex products, such as thin steel wire or steel with intricate shapes. Using measures of product complexity, the authors show that 100% of the lines producing the most complex products adopt teams, and 23% of the lines producing the least complex products adopt teams.¹⁴

What makes this insider study interesting is that it identifies two broad economic principles. First, the study shows that product strategy decisions dictate the appropriate HRM or organizational design decisions. A strategy of making customized complex products requires HRM practices that foster more problem solving than does a strategy of making standardized products. The firm's product strategy determines its management practices. Second, firms do not benefit equally from teamwork. Here, it is complex production lines that gain the most; lines making simpler commodity products do not benefit from problem solving.¹⁵ Economic theory suggests that teams will not be adopted by all firms. The insider insights revealed that the team effect observed among complex production lines does not apply to commodity lines.

13. See Ichniowski and Shaw (1995) for evidence on the transition costs of nonadopters.

14. The productivity regression results reinforce this conclusion: the productivity impact of teams is greater in the complex lines than it is among commodity lines (where teams are rarely adopted).

15. The conclusion that complex production processes value teamwork is also generalizable to some other settings. Recent researchers emphasize that firms in developed countries have a comparative advantage at producing sophisticated products, rather than commodities, so organizational innovations like teamwork are more likely to be adopted in the United States than in other countries across all firms (Bloom and Van Reenen 2007; Bloom et al. 2011a). Bartel et al. (2009b) document a similar conclusion in the U.S. and British valve-making industries.

Figure 4. Innovative human resource management (HRM) systems introduced in steel finishing lines (Ichniowski et al. 1997). Note that t^* is the time of the treatment: introduction of the new HRM systems. Some steel mills are “adopters,” and others are “nonadopters.” The adopters and nonadopters are identical in their underlying production processes prior to t^* : there is one learning curve for both types. The one-time jump in productivity after adoption of new HRM systems at t^* is equal for these lines. For convenience in illustrating productivity profiles for different counterfactuals by line type, the nonadopters have lower learning than the adopters after t^* , but our model would state that they are identical.

We contrast the findings of these two establishment-level studies of the effects of similar HRM practices in the same industry in Figures 4 and 5. Figure 4 summarizes the conclusions reached by Ichniowski et al. (1997) that the adoption of innovative HRM systems at t^* raises productivity in integrated steel mills. Figure 4 assumes that productivity gains of the nonadopters would be the same as those experienced by adopters. Nonadoption is instead explained by higher transition costs of adopting the new practices in older, continuously operating lines.

Despite studying similar HRM practices in a different part of the same industry, the minimill study of Boning et al. (2007) reaches different conclusions than does the study of integrated mills by Ichniowski et al. (1997). Figure 5 illustrates these differences. This figure shows selection bias in the adoption of teams at t^* with complex lines (the Type 2 adopters in Figure 5) having larger productivity gains from teams than do the commodity lines (the Type 1 nonadopters in Figure 5). In both steel studies, an understanding of selectivity in adoption of the management treatment is critical.

4.3. Two Studies with Experimental Interventions in Management Practices across Multiple Worksites

Our discussion in Section 3 emphasizes studies in plants and firms where decisions by the firms or their workers lead to nonrandom assignment of the new management practices. Recent

Figure 5. Problem-solving teams introduced in steel minimills (Boning et al. 2007). Note that t^* is the time of the treatment: the adoption of teams. The complex mills make more complex products and therefore have lower levels of productivity pre- t^* relative to commodity mills, which make simpler products. Complex mills are more likely to adopt teams, because they experience large gains from teamwork and problem solving.

studies in the economic development literature measure the impacts of new management practices that have been randomly assigned to work sites or workers. We review two such studies.

4.3.1. *The Effects of Monitoring and Incentive Pay in Rural Indian Schools*

Duflo et al. (2012) examine the effects of the introduction of new practices to monitor and reward teachers in informal education centers in remote rural areas of India. The sample includes teachers in 56 control centers and 57 treatment centers. In the controls, teachers received a fixed monthly salary of Indian rupees (Rs) 1,000 and were reminded of the importance of regular attendance at work and possible consequences of not attending regularly, such as termination. In the treatment centers, teacher attendance was monitored using cameras to provide photographic evidence. Teachers were also paid according to an incentive pay plan in which they received Rs500 if they attended 10 days or fewer per month and an additional Rs50 per day for each day beyond 10 days. Performance effects were dramatic. Attendance rates were 21 percentage points higher in the treatment centers. Moreover, according to subsequent testing, student achievement increased by 0.17 standard deviations under the new monitoring and incentive pay practices.

The study and its results are interesting for a number of reasons beyond the implied social impacts of increased teacher attendance and improvements in student achievement in rural regions of India. The study's design overcomes concerns about selectivity in the adoption of the new management practices because of the random assignment and sample sizes. Therefore, this study estimates an average treatment effect of these management practices. The

implications of this particular point are worth emphasizing, given the overall themes of this review.

First, the average treatment effect can be expected to apply to the nontreated informal education centers, if the monitoring and incentive pay are instituted in the controls.¹⁶ The well-understood advantage of an experimental design with random assignment is that it allows the researcher to make strong causal interpretations about the changes in performance that followed the adoption of the new management practices. Second, consistent with the examples illustrated in Figure 1, there is also a limitation of studies in which the new practices are randomly assigned to workers or work sites—we cannot directly examine the factors that explain the adoption and nonadoption of the practices. This does not mean that studies using random assignment cannot provide insights about adoption of management practices. In particular, if experimental studies have large enough samples to identify differences in the size of the observed treatment effects among the treated observations, then we know that the adoption of treatment should vary across those subgroups.

4.3.2. *Modern Management Practices in Indian Textile Plants*

Bloom et al. (2011b) study the impact of implementing modern management practices in textile plants in Mumbai. Modern management methods refer to practices that have largely been adopted in manufacturing in developed countries. The steel industry studies in Section 4.2 focused on innovative HRM practices, but in India, much of the challenge is to adopt modern methods for operating the factory, including methods of lean production and total quality management. Specifically, the authors consider the productivity effects of detailed changes in the operations of these textile plants, such as cleaning the shop floor, conducting preventative maintenance for machines, monitoring quality defects, and meeting to shut down production when quality is poor.

The researchers employ an experimental design in a sample of textile plants. In particular, they use a management consulting firm working with 17 textile firms with 20 plants to measure and evaluate the management practices in the plants. The 20 plants are then randomly assigned to two different treatments: 6 receive a 1-month treatment involving a diagnosis of what kinds of practices they have and what additional practices might make sense to adopt; 14 plants receive the same 1-month diagnosis plus an added 4-month treatment in which the consultants continue to assist with the implementation of new practices. Management changes are measured by an index of the percentage of 38 modern management practices present in any month in the various plants. The researchers track changes in this index of management practices and in three performance indicators on quality defects, fabric output, and inventories.

Productivity rises sharply, as do other performance measures, in plants that implement the new management practices with consultants. Adopting innovative management practices matters. Performance does not improve in plants that only received the diagnosis of their management practices, even though the adoption of new management practices increased

16. In fact, Duflo et al. (2012) estimate a structural model of the effects of the new practices and changes in pay for different numbers of days the teacher attended using just the data from the treatment centers. They find that the model predicts well the attendance of teachers in the controls when it is evaluated for zero incentives.

considerably in these plants as well. The study considers several different models to explain the timing, magnitude, and incidence of the effects of these new management practices on the performance outcomes.

The empirical results of this study also highlight the question of why these innovative lean manufacturing practices are not adopted earlier in these plants. The researchers cite several possible reasons. First, many of the practices were not common in this industry, and so a lack of knowledge about them plays some role. Second, top managers of the plant work very long hours, and so without the help of consultants, investing in changes in management methods seems less important than meeting immediate requirements of managing daily operations. Finally, consistent with the discussion of Figure 1, performance effects of the same management practices may vary, as in the case of management practices adopted in plants with 1-month versus 5-month interventions. Managers' uncertainty about whether the performance effects would occur in their plants is therefore another barrier to adoption.

4.4. Two Within-Industry Studies of the Adoption of Management Practices That Affect Productivity

In the previous examples, the production processes were relatively well understood. The examples of fruit pickers and windshield installers were individual-level production processes, and the manufacturing processes in steel, although highly technical, are relatively well understood by engineers. In some sense, these settings were the laboratories in which to study the effects of incentive pay, problem-solving teams, or new HRM systems on productivity outcomes. In other settings, such as the productivity of research and development (R&D) activities, the outcomes from the production process are much less predictable, even by the expert insiders. Yet innovations from R&D are fundamental to economic growth. The next two examples of insider econometric research are studies that shed light on determinants of productivity in research activity in the pharmaceutical industry. These papers examine fundamental issues in industrial organization economics related to the size and boundaries of the firm—managerial decisions about the number of projects to pursue and about contracting out work versus doing the tasks in-house.¹⁷

4.4.1. *The Effects of Scale and Scope on Productivity in Pharmaceuticals*

Henderson and Cockburn (1996) study productivity of early-stage research activity in the pharmaceutical industry. Research personnel in this phase try to find a chemical compound

17. Industrial organization research offers many other examples of empirical studies that follow an insider econometric approach of going deeply inside firms in one industry. For other discussions using micro-level data to model industrial organizational issues, see Bresnahan and Levin (this volume) and Lafontaine and Slade (this volume). In this chapter, we define insider econometrics by its focus on the internal management practices of the firm in the context of a single production process. Some empirical industrial organizational research that examines firms in a single industry would not fit this description, for example, studies of a change in firms' pricing policies (Chu et al. 2011) or in how information is revealed to customers (Leslie 2004; Bollinger et al. 2011), or studies using data on products rather than on production processes. Other examples of empirical industrial organizational research would also fit this chapter's description of insider econometrics, for example, whether the internal management practices of stores in an industry look different if the store is run by a franchisee versus an owner-operator (Lafontaine and Shaw 1999, 2005).

that has a desirable effect by mimicking aspects of a human disease. In this study, productivity is measured by the number of patents awarded, and the management treatments are changes in the scale of the firm's research activity (expenditures per project, per firm, etc.) and scope of research (extent of other research projects in similar classes of compounds in the firm, in other firms, etc.). The authors analyze 5,000 observations on annual research projects. The data come from ten firms with up to 38 projects per year and up to 30 annual observations on any one project. The authors describe the dataset assembly as an extensive iterative process with knowledgeable scientists identifying accurate detailed measures of research outputs and inputs in firms.

Henderson and Cockburn (1996) find that a wider scope of the firm, as measured by the number of large research projects, improves the chances of success in a research project. More specifically, knowledge spillovers across research on similar classes of drugs within a single firm and spillovers among firms working on the same drug class both raise research productivity. Also, there is a positive effect of the scale of the research project on research productivity, where the scale is measured by research expenditures on a given project.¹⁸

What makes this insider study interesting? The authors document how firm size matters for productivity. Henderson and Cockburn (1996) aggregate their project-level data up to the level of the firm and replicate a common result in prior firm-level pharmaceutical studies—that measures of firm size have little impact on patenting. When they subsequently analyze the project-level dataset they had constructed after extensive field investigations, they show just how misleading the conclusion based on firm-level analysis is. New insights surface by modeling a specific research production function at the level of individual projects. Insider insights allow them to identify why firm size matters. In addition, this study puts the micro-level productivity results into the larger public policy discussion of regulation of the industry. Allowing larger firms in the industry may in fact lead to concerns about monopoly power, but these concerns must be balanced with efficiency gains from knowledge spillovers within large firms.¹⁹

4.4.2. Vertical Integration Decisions in the Pharmaceutical Industry

After basic research, several stages of clinical trials take place prior to the U.S. Food and Drug Administration's approval of a new drug. Azoulay (2004) offers insider econometric research about management policy decisions in this phase of drug research.

In this study, the treatment is the drug company's decision on whether to outsource clinical trials to contract research organizations. The hypothesis is that clinical trials that are very data intensive are likely to be outsourced, whereas those that are knowledge-intensive stay in-house.

18. In this study, Henderson and Cockburn (1996) do not model why the treatment varies—that is, why the firms have different numbers of projects or different expenditures per project. However, they do use detailed insider insights about the causal nature of the link between the scale and scope measures and research productivity. Although their panel data document increased patent productivity when measures of scope change, they acknowledge that the question of what is the optimal research portfolio for any single firm in the dataset is beyond the scope of their analysis.

19. Other insider studies cited in Table 1 in Section 4.5 provide insights into the determinants of productivity in other knowledge-based or research-intensive industries, such as biotechnology, education, health care, law, and financial services and venture capital.

In-house trials are hypothesized to involve more subjective performance evaluations, whereas the outsourced trials involve a narrower set of more easily monitored tasks that can be covered by explicit pay-for-performance contracts. The data are project-level data from 6,826 projects spanning all pharmaceutical firms from 1991 to 1999. Coupling these rich micro-level data with insider insights from extensive field work, Azoulay (2004) models outsourcing decisions. Outsourcing is the better decision when the testing tasks can be reduced to standardized data collection tasks; testing that involves the generation of new findings and knowledge are more likely to be kept in-house.

Why is this paper interesting? First, the results of the Azoulay (2004) study deepen our understanding of a basic economic question: what determines the boundaries of the firm's activities? Furthermore, the evidence from this industry-specific example is consistent with broader economic models in which multitask jobs (e.g., jobs involving both knowledge generation and data generation) can be better managed with low-powered incentives and more intensive monitoring. Conversely, when the work involves only data-generation tasks that are easier to monitor, explicit high-powered incentive arrangements (that can be outsourced) may be more appropriate. This vertical integration decision in pharmaceuticals is therefore similar to franchising: the in-house contractors will have more subjective performance evaluations and less sensitive pay for performance, whereas the outside contractor will have more explicit pay for performance (or high-powered incentives) based on a narrow set of easy-to-monitor tasks.

In this insider study, data are not available on the success, or productivity, of drug testing; the empirical analysis focuses exclusively on the adoption of the management practice—the decision to outsource or not. The conclusion that knowledge-generating tests would be less successful were they to be outsourced to firms using high-powered incentive contracts is not tested.

These studies highlight that aggregating data up to the level of the firm produces misleading results (Henderson and Cockburn 1996: 35). Insider insights suggested that productivity in this part of the pharmaceutical industry could best be studied at the level of individual projects, so that cross-project productivity could be identified. Azoulay's (2004) study then goes on to reveal important sources of heterogeneity even within the drug testing activities in this industry: some testing should be kept in-house, while other testing should be outsourced. Thus, one reason for heterogeneity in practices within a single industry is the fact that firms are managing many different production processes at the same time.

4.5. Additional Insider Studies

The previous eight examples include some of the early research papers that use insider methods to model management treatments effects. To illustrate a broader range of topics, practices, and data analyzed with this kind of methodology, we present a longer list of studies in Table 1. This table summarizes the management practices studied, the nature of the dataset, and a short description of conclusions about the economic mechanisms that explain why productivity changes when the practice is adopted. The studies reviewed in Table 1 suggest that the methods in the examples above are representative. We refer to details of the studies mentioned in Table 1 when discussing emerging themes from insider econometric research (Section 8) and sources of data (Section 9).

Table 1. Additional insider econometric studies, by management practices analyzed

Type of study/reference/data	Performance outcome	Reason for outcome
Sets of complementary management practices		
Ichniowski et al. (1997) Data: team monthly productivity, 5 years, 36 steel production lines (17 companies)	Productivity rises by 10% due to combined use of incentives, teamwork, careful hiring, and other practices.	When firms implement multiple HRM practices, the complementarities between the practices raises performance.
Bloom et al. (2011b) Data: 20 textile plants, 1 year, in India	Productivity rises by 18% due to modern management practices in textile firms.	Managers did not have the information to adopt modern practices before experiment.
Duflo et al. (2009) Data: 70 schools in Kenya, 35 randomly treated with school-based management initiative	Student performance improves when schools adopt a set of practices, such as greater parental involvement and new hiring methods for teachers.	Performance improves for a set of management practices and curriculum and does not increase with added funding.
Griffith and Neely (2009) Data: retail stores, monthly sales, 72 months, one company	Productivity rises when the multidimensional Balanced Scorecard performance evaluation is introduced.	When Balanced Scorecard incentive pay is adopted, productivity rises only if managers are experienced.
Chan et al. (2009) Data: daily sales for 85 cosmetics sales workers, 791 days, 11 companies	Individual incentive pay raises individual productivity, but lowers within-team cooperation and lowers group productivity.	Individual incentive pay raises personal productivity, but it reduces cooperation and overall productivity. Team-based incentive pay increases cooperation within teams and increases competition across teams (or firms).
Baron and Hannan (2002) Data: 200 technology start-up companies in Silicon Valley, annual data, 1995 and 1997	Sets of innovative "star" HRM practices raise growth by 140% and reduce the probability of firm failure by 210%, relative to autocratic HRM practices.	The initial set of HRM practices that the start-up firm chooses has a large effect on all measures of firm success: "star" firms recruit only top talent, pay them top wages, and give them resources and autonomy. In autocratic firms, "you work, you get paid."
MacDuffie (1995) Data: 62 auto assembly plants	Productivity and quality outcomes are higher in plants that have systems of innovative HRM practices. Effects are larger if the plant also uses management practices for flexible production systems.	The organizational logic of lean manufacturing production processes is not supported by individual HRM practices but by multiple such practices that are elements of a system.

Continued

Table 1. *Continued*

Type of study/reference/data	Performance outcome	Reason for outcome
Sets of complementary management practices		
Dunlop and Weil (2000) Data: 42 business units in the men's suit, shirt, and pants sector and in the women's jeans and undergarment sectors of the apparel making industry	Lead times are substantially shorter when team-based systems of HRM practices in modular assembly production processes are used.	The adoption of team-based HRM systems in modular production processes is driven by the adoption of new complementary sales-tracking information technologies by large retailers who require apparel makers to fill smaller orders more rapidly. The effects of new HRM practices on performance outcomes are dependent on the effects of the use of new information technologies.
Berg et al. (1996) Data: production records and worker surveys from more than 100 workers in four plants of two apparel-making companies	Systems of HRM practices associated with the module system of manufacturing exhibit lower production costs, reduced throughput production times, reduced work-in-process inventories, and increased variety of clothing styles than seen in firms using HRM practices under the bundle system.	Team-based HRM practices under module production allow greater coordination of workers' activities that eliminates production bottlenecks and solves production problems.
Incentive pay		
Lazear (2000) Data: monthly measures of average daily output for 3,000 workers who install car windshields, 19 months, one company	Productivity of individual workers rises 44% due to a switch from hourly pay to piece rate pay.	Higher efforts by workers stemming from incentive pay raises productivity by 22%. Better sorting or selection of workers to the job raises productivity by an additional 22%.
Bandiera et al. (2005) Data: daily output for 142 workers, 108 days, picking fruit, one company	Productivity of workers increases by 58% when wages are switched to piece rate pay from a relative pay scheme.	Efforts of workers increase due to piece rate pay, because workers were withholding effort when friends were on their work teams.
Nagin et al. (2002) Data: daily data, 16 call centers, one company	Daily productivity of workers rises by about 3% when pay is tied to call monitoring.	Monitoring reduces instances of workers reporting unsuccessful sales calls as successes. Perceptions of a fair work culture also reduce this unproductive behavior.

Table 1. *Continued*

Type of study/reference/data	Performance outcome	Reason for outcome
Incentive pay		
Misra and Nair (2011) Data: monthly sales, 87 sales agents for contractors for 38 months, one company	Total revenues rose 9% following the introduction of an incentive pay plan that has a linear incentive (no quotas) and pays out more frequently.	A pay plan that is highly nonlinear and pays out over long intervals (quarters rather than months) results in gaming the system and in lower productivity for current employees.
Lavy (2002, 2008) Data: student test scores, 1 year, 629 teachers in the Israeli school system	Productivity of students rose 3% after the introduction of tournament bonus pay for teachers; it rose 1–6% in other similar plans.	Students' test scores in English and math improved due to a change in teaching methods and an increase in teachers' efforts in response to incentives.
Lerner and Wulf (2007) Data: 140 firms, 700 firm-years, compensation for R&D heads matched to patent data	R&D group productivity increased by 26%, as measured by citations or patents, when long-term incentives (measured as a percentage of pay) rose by 50%.	Use of long-term incentives for corporate heads of R&D departments rose 50% from 1988 to 1998 and is likely to have improved R&D project selection.
Peer effects		
Ichino and Maggi (2000) Data: 28,642 retail bank employees, 442 branches, 20 years, one company	Productivity (measured by absenteeism) rises by more than 15% when employees are located with peer employees who work harder.	Worker productivity is strongly influenced by personal background and culture, but these influences are reduced when workers are paired with more productive peers.
Mas and Moretti (2009) Data: all supermarket transactions, six stores, 2003–2006, one company, checkout clerks	Within a 10-minute work interval, personal productivity rises 1.7% when working near a peer who is 10% more productive than average.	The productivity gains from peer effects show that low-productivity workers work harder when a high-productivity worker watches them work.
Teamwork		
Hamilton et al. (2003) Data: weekly productivity, 132 workers, 156 weeks, apparel sewing, one company	Team-based pay increased productivity 14% compared to individual piece rate pay.	Team-based pay increases team output through collaboration among workers with complementary skills. Highly productive workers raise team productivity even more.

Continued

Table 1. *Continued*

Type of study/reference/data	Performance outcome	Reason for outcome
Teamwork		
Bartel et al. (2009a) Data: 431 hospital intensive care units, monthly productivity, 48 months, one company	Hospital units with more “unit-specific” human capital have a 1.5% reduction in patients’ length of stay.	Teamwork in nurses’ work area combines nurses’ human capital, which raises productivity.
Boning et al. (2007) Data: 2,355 monthly productivity team-level observations for 34 steel minimills, 5 years, 19 companies	There is a 11–20% reduction in defective output when mills move to team-based problem solving.	Team-based problem solving is more valuable to the firm when the steel mill produces complex products than when it produces commodities.
Bandiera et al. (2009) Data: 407 fruit picking teams, 15 fields, 109 days	Productivity rises 24% when a team-based tournament reward system is introduced.	Workers of similar ability form teams in response to incentives; teams are not formed on the basis of friendship.
Social networks and information sharing		
Kalnins and Chung (2006) Data: 2,800 hotels, annual data for 1991–1999 on revenues, exit, and entry	Close social ties from same demographic group lowers the failure rate of hotels.	Employees from the same demographic group (Gujarati immigrants) share more information about management practices that work.
Bandiera et al. (2007) Data: daily worker output, 94 days, picking fruit, one company	Productivity increases by about 9% when workers are socially connected to managers who are paid incentives.	When the firm switches to incentive pay for managers, overall firm productivity rises, as managers allocate jobs to the most efficient workers rather than to their friends.
Gant et al. (2002) Data: daily communication ties among workers, 642 workers, 7 steel production lines	Direct communications for problem-solving is five times greater for workers on production lines with a set of innovative management practices.	Problem-solving activity, as measured by the amount of direct communications on operational issues, rises when workers are employed by firms using a set of management practices, such as teamwork, incentive pay, and careful hiring.

Table 1. *Continued*

Type of study/reference/data	Performance outcome	Reason for outcome
Hiring practices		
Autor (2001) Data: workers employed by 1,033 temporary help firms in 1994	The match quality of workers and firms is higher when workers self-sort in response to the firms' offers of general training.	Providing general human capital training induces workers to self-sort, so the most able are hired by firms offering the greatest amount of general training. (The temporary help firms then sell this worker-quality information to firms.)
Autor and Scarborough (2008) Data: 1,363 retail stores, one company	Productivity rises due to the switch from informal screening to test-based screening.	Testing yields more productive hires, resulting in a 10% increase in workers' average tenure.
Goldin and Rouse (2000) Data: orchestra auditions for 7,065 individuals, 508 audition rounds, 14,121 person-rounds	Promotion of women at each round of auditions increases by 50% when auditions are blind, and hiring of women increases substantially.	Better hiring techniques, such as reviewing orchestral auditions with a blind shield, substantially raises the percentage of women employed.
Lazear (2000) Data: monthly measures of average daily output for 3,000 workers who install car windshields, 19 months, one company	Productivity rises 22% when the most productive workers are hired and stay at the auto windshield installation firm.	Such HRM practices as incentive pay cause workers to self-select to the firms at which those workers are most productive.
Boundaries of the firm		
Forbes and Lederman (2010) Data: 2 million flights from 72 U.S. airports over 260 days	Flight delays at the same airport on the same day are significantly shorter for airlines that are vertically integrated (those with an owned, rather than independent, regional connecting partner).	Direct ownership of partner airlines promotes more efficient decisionmaking when airlines need to adapt to nonroutine conditions.

Note: HRM, human resource management.

5. Estimation of Treatment Effects and the Econometrics of Insider Studies

The kinds of productivity profiles shown in Figures 1–5 are typically estimated by analyzing panel data on workers or work teams. In this section, we consider issues that arise in applying econometric methods to obtain accurate estimates of treatment effects. Start with the simplest possible regression for estimating the impact of some management policy on productivity:

$$Y_{it} = \alpha D_{it} + \beta x_{it} + \eta_i + \epsilon_{it} \quad (1)$$

where i and t are subscripts for the worker- or work-group-specific observations and for time, respectively; Y_{it} is productivity;²⁰ x_{it} is a set of production function control variables; D_{it} is a dummy variable equal to 1 for the presence of the management practice; η_i is the worker-specific (or work-group) fixed effect; θ_t is the common time period effect; and ϵ_{it} is the transitory worker-specific effect. How should the insider econometrician elaborate on this simple model to estimate treatment effects of management practices on productivity?

A hallmark of insider econometric research is that it models the heterogeneity in workers' responses to the managerial practice. Even for workers within one occupation, there is heterogeneity in workers' responses to managerial treatments; for example, not all workers respond the same to incentive pay. This differential response is the reason management practices may not be effective. Translating this heterogeneity into the productivity regression, rewrite (1) to allow the treatment effect to vary across observations:

$$Y_{it} = \alpha_i D_{it} + \beta x_{it} + \eta_i + \theta_t + \epsilon_{it}. \quad (2)$$

The adoption of the management treatment D_{it} at time t^* is determined by its profitability:

$$D_{it} = \begin{cases} 1 & \text{if } \pi_{it} > 0 \text{ and } t > t^* \\ 0 & \text{otherwise} \end{cases} \quad (3)$$

$$\pi_{it} = \Gamma Z_{it} + v_{it}, \quad (4)$$

where the index π_{it} measures the expected profits from adopting the new practice; it is a function of observables Z_{it} and an error term.

Equations (3) and (4) imply that at time t^* , the treatment, some new management policy, is introduced. The treated group adopts ($D = 1$) when expected profits from adoption exceed zero. The nontreated group ($D = 0$) does not adopt, because expected profits after adoption are not sufficiently high. The treated group either has a different underlying production function or different underlying transition costs than the nontreated group. Because the adoption of the treatment is not random, selection bias arises.

20. Note we refer to Y_{it} as productivity, but the specific dependent variable used in any insider study is a measure of performance relevant to the setting of the specific study.

5.1. Estimating Treatment Effects

Insider econometricians typically estimate productivity regression (2)—a panel data regression with worker and time fixed effects. But what are the properties of the treatment effect estimated in this regression? To answer this question, rewrite the production function in a more general functional form in a switching regression framework.²¹ The treated group has production function (5a), with superscript 1 to indicate $D = 1$ for treatment. The nontreated group has production function (5b), with superscript 0 to indicate $D = 0$ for nontreatment.

$$Y_{it}^1 = g_t^1(x_i) + u_{it}^1 \quad (5a)$$

$$Y_{it}^0 = g_t^0(x_i) + u_{it}^0, \quad (5b)$$

where x_i are basic production function variables that are not affected by the treatment and are uncorrelated with error term u_{it} .

Define the treatment effect as the productivity gain due to treatment, given by $\alpha_{it} = Y_{it}^1 - Y_{it}^0$. Given the productivity functions (5a) and (5b), the treatment effect is defined as

$$\alpha_{it}(x_i) \equiv g_t^1(x_i) - g_t^0(x_i) + (u_{it}^1 - u_{it}^0) \quad \text{for } t > t^*. \quad (6)$$

Intuitively, the treatment effect is the shift up in the production function after adoption. The estimated treatment effect, given real world data with nonrandom adoption of the treatment, is biased if the difference in the residual in (6) is not zero.

Now, rewrite the productivity equations to identify types of selection biases in the treatment effect. To form one productivity equation across the treated and nontreated groups, combine (5a) and (5b) by weighting them by the treatment dummy D_{it} to obtain

$$Y_{it} = D_{it}Y_{it}^1 + (1 - D_{it})Y_{it}^0.$$

Then, substitute into this equation the definition of the treatment effect from (6) with $\alpha_t = \bar{t}(\alpha_{it}) = g_t^1(x_i) - g_t^0(\bar{x}_i)$ to obtain

$$Y_{it} = g_t^0(x_i) + \alpha_t D_{it} + \left[u_{it}^0 + D_{it} (u_{it}^1 - u_{it}^0) \right]. \quad (7)$$

Equation (7) identifies the potential selection biases in the estimated treatment effect. The expected value of the treatment is

$$E(\hat{\alpha}_t) = \alpha_t + E(u_t^1 | x_t, D_t = 1) - E(u_t^0 | x_t, D_t = 0), \quad \text{with } t > t^*. \quad (8)$$

The two expected error terms are nonzero due to selection bias in the treatment—only those firms that gain the most from treatment will adopt.

21. This structure for the specification of treatment effects follows Blundell and Dias (2002). For further discussions of treatment effects and their estimation, see Meyer (1995), Heckman et al. (1999), Imbens (2004), List et al. (2010), and citations therein.

Equation (8) and Figure 1 can be combined to easily picture the three types of treatment effects that the insider econometrician might want to estimate with insider data:

1. The *treatment of the treated effect* (TTE) is the expected treatment effect among treated observations, that is, the mean value of the observation-specific treatment effects across all observations conditional on treatment occurring (i.e., $D_t = 1$) and on the production function control variables x_{it} :

$$\alpha^{\text{TTE}} \equiv E(\alpha_{it} \mid x = x_{it}, D_{it} = 1), \quad \text{with } t > t^*. \quad (9)$$

In Figure 1, this hypothetical treatment effect is $\alpha^{\text{TTE}} = \Delta P^T$.

2. The *treatment of the nontreated effect* (NTE) is the expected value for those groups who are never treated:

$$\alpha^{\text{NTE}} \equiv E(\alpha_{it} \mid x = x_{it}, D_{it} = 0), \quad \text{with } t > t^*. \quad (10)$$

In Figure 1, this hypothetical treatment effect is represented by $\alpha^{\text{NTE}} = \Delta P^N$. To illustrate potential selection bias, we assumed in Figure 1 that the treated group has bigger expected gains than the nontreated group would have.

3. The *average treatment effect* (ATE) is the average gain in productivity if the treatment were applied randomly across all i .

$$\alpha^{\text{ATE}} \equiv E(\alpha_{it} \mid x = x_{it}). \quad (11)$$

In Figure 1, it is the weighted average (with weights equal to the percentages of treated and nontreated subjects) of α^{TTE} and α^{NTE} .

Thus, TTE, NTE, and ATE are mean effects among the always treated observations, never treated observations, or randomly treated observations, respectively.

5.2. Estimation of Treatment Effects with Panel Data in Insider Studies

How do insider studies typically estimate the alternative treatment effects using panel data? First, we describe the estimation methods for alternative treatment effects and then provide examples from the literature for research using these alternative estimators.

Rewrite the production function (7) as

$$Y_{it} = g^0(x_{it}) + \alpha_{it}D_{it} + \eta_i + \theta_t + \epsilon_{it}, \quad (12)$$

where η_i is the worker-specific fixed effect, θ_t is the common time period effect, and ϵ_{it} is the transitory worker-specific effect. Equation (12) matches the typical panel data regression presented in (2).

Depending on the exact nature of the panel dataset and the specific details of the treatment effect the researcher wants to estimate, there are four common options for estimating treatment effects in panel data.

5.2.1. First Differences

For this option, the researcher estimates the treatment of the treated, α^{TTE} , using data on only the treated group, before and after the treatment when the treatment is not randomly applied to workers or plants (i.e., the top productivity profiles in Figure 1). Estimate the production function (12) with first differences by introducing controls for the worker- or establishment-fixed effects and using only the before-after data for the treated group. The resultant α^{TTE} (for the Type 1 observations in Figure 1) is then equal to

$$\hat{\alpha}^{\text{TTE}} = \left[\bar{Y}_{\text{post-}t^*}^1 - \bar{Y}_{\text{pre-}t^*}^1 \right], \quad (13)$$

which states that the treatment of the treated effect is the difference in the conditional means of the treated group before (the pre- t^* period) and after (the post- t^* period) the treatment. Assuming we know the right functional form and specification of $g^0(x_i)$, the unobserved counterfactual for the treated group in the post- t^* period can be estimated. Avoiding the use of the nontreated sample eliminates the need to make assumptions about that subsample—about why it was not treated and about its unobserved counterfactuals. An obvious drawback is that there are fewer observations when the nontreated sample is omitted, and we assume that time effects θ_t are uncorrelated with treatment D_{it} .

5.2.2. Difference-in-Differences Estimator

Researchers estimate the α^{ATE} effect using the difference-in-differences option when the treatment is randomly applied to a subpopulation of workers, plants, or stores, or when one can assume that the only difference between the control group and the treated group lies in the fixed effect η_i .²² Given this assumption, the researcher has data on both the treated group, before and after the treatment, and on the nontreated group in Figure 1. Equation (12) is estimated with both the treated and nontreated samples, over time, so this option is double differencing, or “difference-in-differences,” because we difference over time (before-after treatment) and cross-sectionally (for the treated and nontreated groups). This double differencing amends the estimated treatment effect (13) to be

$$\hat{\alpha}^{\text{ATE}}(x) = \left[\bar{Y}_{\text{post-}t^*}^1 - \bar{Y}_{\text{pre-}t^*}^1 \right] - \left[\bar{Y}_{\text{post-}t^*}^0 - \bar{Y}_{\text{pre-}t^*}^0 \right], \quad (14)$$

which states that the average treatment effect is the difference in the conditional means of the treated group before (the pre- t^* period) and after (the post- t^* period) the treatment, relative to that difference for the nontreated group. The estimation method is the same as for first differences: we are differencing out the fixed effect η_i and then differencing out the effect θ_t , but here the second differencing occurs over treated and nontreated workers as well.

The basic advantage of double differencing compared to the first differencing is that we now have a control group, the nontreated group. Including the control group adds information in two ways. First, if we can assume that the time shocks θ_t are common between the two samples, then the nontreated control group lets us control for any time effects that altered productivity

22. Examples of this treatment can be found in Ichimowski et al. (1997), Lazear (2000), and Griffith and Neely (2009).

after t^* but are not due to the treatment. In contrast, first-difference models include no data on nontreated observations in the post- t^* period. Second, the control group gives us more information on which to estimate the underlying production function $g_t^0(x_i)$.²³

5.2.3. *Difference-in-Differences with Matching Estimator*

For this option, the analyst again uses a difference-in-differences estimator and has the same data as in Figure 1 for difference-in-differences, but the matching estimator is estimating the production function nonparametrically. Each treated outcome $g_t^1(x_i)$ is paired with a nontreated outcome $g_t^0(x_i)$, and the difference is the treatment effect. Given the extra data needed for nonparametric estimation, few insider econometric studies use this approach.

5.2.4. *Instrumental Variables or Semi-Parametric Methods*

If there are nonrandom (selection bias) differences between control and treatment—between the Type 1 and Type 2 panels in Figure 1—then the researcher must address these differences. If there is selection bias, then ϵ_{it} is correlated with D_{it} , and we need to add instrumental variable (or matching) estimator techniques that model the selection of the treatment. We do not review these methods here.

The type of treatment effect that is estimated depends on both the type of data available and the reason why the management practice was adopted. For example, some field experiments are now being done within firms.²⁴ In those experiments with random assignment of new management treatments, the estimator is an average treatment effect conditional on being in the firm (Imbens 2004). It is an average treatment effect, because assignment of the treatment is random, but it is also conditional, because it depends on the reasons the firm agreed to adopt the practice. The estimated average treatment effect would not apply to other firms.

When data are gathered across work groups or plants, where some are adopters and others are not, the estimator is a treatment of the treated effect. The estimated treatment effect applies to those who adopt the treatment, not a random group or firm (e.g., Ichniowski et al. 1997; Boning et al. 2007). In these studies, the researcher tries to provide evidence on the adoption equation (3). Increasingly, studies in developing countries are imposing management treatments randomly across a set of firms in the education or health sector.

Table 1 gives many more examples, classified according to the management practices being studied. The table also describes the type of data and thus implies the likely type of estimator

23. A disadvantage of difference-in-differences estimation is that if the treated and nontreated groups should in fact have different coefficients on the control variables, then the estimators from the difference-in-differences models will be biased relative to first differences.

24. Bloom et al. (2011b) are randomly imposing lean manufacturing practices on a random set of small manufacturing firms in India that had not been using those practices. Thus, they are estimating the average treatment effect of lean manufacturing but cannot study the reasons some firms adopt and others do not. Duflo et al. (2012) introduce incentive pay for teachers randomly across a set of teachers and a control group. Presumably, in studies using random assignment of a management practice across workers or plants, identifying observations that enjoy relatively large and small treatment effects could offer clues about where adoption makes more economic sense. See Levitt and List (2009) for a review of the new field experiment literature.

of the treatment effect. For example, Griffith and Neely (2009) have data on an incentive pay treatment for treated and control groups of retail stores, so they use a difference-in-differences estimator with a matching estimator for the TTE.

5.3. Estimating Heterogeneous Treatment Effects in Insider Studies

Central to insider studies is that researchers are modeling variations across workers in their responses to a new management policy; that is, (2) allows heterogeneity in the response to the treatment. Management policies never should have a single treatment effect; people differ and technologies differ. Therefore, researchers increasingly gather additional data aimed at capturing this heterogeneity in responses to the treatment. Examples illustrating this point include:

- Bandiera et al. (2005) gather data on friendships among the work crew members, showing that those with friends respond more to piece rate pay.
- Mas and Moretti (2009) gather data on the physical location of workers in the grocery store, showing that when a checkout clerk is watched by a productive co-worker, she works harder.
- Gant et al. (2002) collect detailed data on workers' communications networks in steel production lines, showing that production lines with denser social networks are more likely to have innovative management practices and higher levels of productivity.²⁵

6. Why Do Firms Adopt New Management Practices?

This question is crucial. To execute and interpret insider studies of the effects of management practices, we must know not only why the management practices were adopted by some establishments and not others but also why the adopters instituted the practices when they did. Economists believe that firms make optimal decisions about compensation plans, teamwork and related HRM practices, the scope and size of research projects, and whether to outsource certain work. So, why didn't Safelite adopt incentive pay for their windshield installers, or minimills put in problem solving teams, sooner than they did? Shouldn't these firms have always had these optimal practices? Fortunately, there are some clear reasons firms adopt new management policy treatments rather than having one set of optimal management practices from their inceptions.

There are several sources of time-series shocks to optimal management practices. First, there are shocks to the prices of capital inputs. If management practices are complements with capital inputs, then these practices change. Rapidly declining prices of new information technologies are an obvious recent shock. Several studies illustrate how, as information technology and

25. Of course, even great new datasets have their limits: we cannot extrapolate beyond the subgroups of workers who are employed by the firms. In econometric terms, we cannot extrapolate beyond the *common support*, which is the subspace of worker characteristics that are in the treated and nontreated samples.

processing become cheaper in firms, management practices also change.²⁶ New information technology in one industry also causes changes in management practices in related industries.²⁷ Furthermore, competitors in an industry are constantly changing, and new competitors can have modern management practices that force existing companies to change their practices.

There can also be technology shocks to management knowledge itself; best practices in management may improve over time. For example, the success of a distinctive set of management practices—including problem-solving teams, other innovative HRM practices, and lean manufacturing practices—among large Japanese manufacturers were slowly imported to other developed countries in the 1980s and 1990s.²⁸ Developing countries are still very slowly introducing these kinds of management practices to raise quality and productivity (see Bloom and Van Reenen 2007; Bloom et al. 2011b).

There are time series shocks to firms' external and internal labor markets. In a firm's internal labor market, stock options may become too diluted, or an aging workforce may need different incentive pay. External labor market shocks include immigration, which can increase the supply of workers with higher or lower levels of human capital than the existing workforce.

Cross-sectional within-industry shocks also exist. When firms enter an industry with new entrepreneurial ideas about the industry's products or processes, existing firms need to change product market strategies or processes. For example, as imports from Chinese firms enter U.S. markets, the U.S. firms move from the production of commodity-like products to customized products.²⁹ The production of customized products can change the demand for different types of workers, and as the skill or education levels of a workforce change, new management practices may be required.³⁰

7. A Practical Roadmap for Designing Insider Econometric Studies

The insider econometrician is, in many ways, designing an empirical experiment. Even though the insider econometrician does not often conduct an experiment that can assign the management treatment, the researcher in insider studies is choosing the right firm to study, the questions to ask, hypotheses to test, the type of data and the variables to collect, and then the specific econometric methods to test the hypotheses. We identify five key design factors for insider econometric research.

26. For evidence, see Bresnahan et al. (2002) and Lemieux et al. (2009). Oliner and Sichel (2000) present macro-level evidence that productivity has increased over time in industries that use computers.

27. When large retailers adopted information technologies that tracked product sales and sent those sales data directly to suppliers, the suppliers adopted new team-based HRM practices that allowed them to restock the retailer with smaller batches on shorter notice (Dunlop and Weil 2000).

28. For more on the notion of HRM technology shocks, see Lazear and Shaw (2007) and Bloom and Van Reenen (2007). For more on the transfer of Japanese HRM practices to U.S. firms and the effects of these practices on productivity among manufacturers in the two countries, see Ichniowski and Shaw (1999).

29. In India, Bloom et al. (2011a) offer empirical evidence that reduced trade barriers increased the adoption of new HRM practices.

30. Product market strategies that favor customized versus commodity products are shown to affect the choice of management practices in the minimill industry (Boning et al. 2007) and in the valve manufacturing industry (Bartel et al. 2007).

7.1. Five Key Research Design Decisions

In this section, we provide advice about how to answer some of the more specific methodological questions that naturally arise when designing and executing an insider econometric study. In Section 2, we offered a list of five features that characterize insider econometric studies. These features tell us that insider studies use micro-level data on individual workers or groups of workers to study the productivity effects of a new management practice and the reasons for the adoption of the practice. Still, many more decisions must be made about specific features of an insider study. What management practices should I study? What should be the structure of the dataset? What can I do to address the concern that the data are specific to only one particular production process? Here we describe the features of studies that will produce the most convincing insider econometric results.

7.1.1. Key Design Decision 1: Identify a Treatment and Measure It Accurately

In most studies, the researcher must first identify a treatment variable that changes. Most firms that have interesting management practices never change them, and thus there is no variation for the treatment to test its effects. The treatment must also address an interesting theory that would predict that the treatment affects performance. The researcher may have a theory in mind and have been searching for data to test it, or she may be offered access to interesting data and have explored possible hypotheses by talking to insiders. Discussions with insiders always spark ideas; insiders know much more than the researcher knows about why they adopted the practice and the expected effects of the new practice.

How does the researcher obtain the treatment data? Many datasets have information on the productivity of workers or work groups, but they do not contain information on management practices. However, as in most examples of insider studies considered in Table 1, new management practices are discrete events that change infrequently in firms. The researcher can interview insiders and build a dataset on the time path of management practices in or across firms.

The treatment needs to be specified accurately. First, insider studies have several advantages over traditional surveys, and one is that the researcher can use interviews to measure exactly what the management practices are. In contrast, respondents to a survey question that asks “do you have teamwork?” may interpret the meaning of the question in many different ways. Insiders’ insights help measure treatments accurately.

Second, the researcher needs to measure all dimensions of the management treatment. An important contribution of existing insider studies is that management treatments often involve the simultaneous adoption of a cluster of complementary management practices. The managers that researchers interview inside the firms will know that their new management initiative involved the adoption of multiple practices.³¹

31. MacDuffie (1995) finds that productivity is higher in auto plants that adopt several new HRM practices together with lean manufacturing methods and just-in-time inventory policies. Ichniowski et al. (1997) document improvements in productivity only when lines adopt entire systems of innovative HRM practices. Bartel et al. (2007) find that new computer-aided production equipment that raises productivity among customized valve manufacturers coincides with the adoption of complementary HRM practices. Azoulay (2004) identifies how the management decision to outsource drug trials always means the firm is putting the trial under a different compensation policy. See Milgrom and Roberts (1995) for discussions of complementarity.

Finally, the treatment need not always be a change in a formal management policy. Clever researchers are finding natural experiments in firms involving other kinds of treatments. For example, Mas and Moretti (2009) model the importance of peer effects on productivity. They identify the peer effects not from a change in management practices surrounding peer groups but instead from the movement of employees among different peer groups. That is, because workers are assigned randomly to different shifts, the authors can test whether working with different peers influences productivity. In another example, Lazear et al. (2011) model boss effects on workers' productivity. A good boss implements more effective training.

7.1.2. Key Design Decision 2: Test a Generalizable Principle by Modeling Economic Behavior

An important goal of insider econometric research is to test a more general economic principle that will enhance our understanding of the theory of the firm. In our review of eight insider studies in Section 4, we asked the question "why is this study interesting?" for each study. The answer was always that the results test a model of some fundamental economic principle. Even though only one firm or industry is studied, the testable hypothesis and results appear to be applicable to a wider set of workers or firms, because the paper models fundamental optimizing behavior.

Put differently, without insider datasets with rich details about the workers and production processes in a specific industry setting, convincing econometric tests of these fundamental models about worker and firm behavior would not be possible. The insider studies reveal factors that are routinely neglected in standard specifications of a firm's production function: friendship among co-workers, co-worker monitoring, complementarities among multiple HRM practices, interactions of HRM practices and product attributes, knowledge spillovers across workers and projects, and many more. Insider datasets that describe rich details about the context for a single production process are precisely the kind of data one needs to construct a convincing test of these novel hypotheses.³² Insider studies are helping to develop a much more accurate picture of the economics of real production functions.

7.1.3. Key Design Decision 3: Balance Homogeneity and Heterogeneity in the Sample

Prior to insider studies, production functions were estimated with aggregate industry-level, firm-level, or establishment-level data in broad cross-industry samples. Although these data might be appropriate for estimating the effects of such factors as capital-labor ratios on productivity, they will be less helpful for identifying the effects of management practices on productivity and for isolating why similar organizations or workers are covered by different practices (see the discussion in Syverson 2011). With more aggregate data, there is not one common production process that generates the data. Therefore, the number of variables that might be correlated with the management treatment variable is exceptionally large.³³

32. Consider the paper of Bandiera et al. (2005), in which friendships influence a worker's response to incentive pay (see Section 4.1.2). Their conclusion is not simply that friends influence people's behavior, but that when economists write a model of incentive pay, that model should include an externality—when maximizing utility in response to incentive pay, workers' responses internalize the externality of their friends' feelings. Economic theorists have introduced peer pressure and social norms into their theories of the firm (Kandel and Lazear 1992; Akerlof and Kranton 2000, 2005).

33. Differences in production equipment, worker and manager quality, occupational mix, and many other factors all could be correlated with differences in management practices and thus confound any attempts to use such industry-level data to generate a convincing estimate of a treatment effect due to any management practices. Of course, the methodological issues in generating a persuasive estimate of the effect of some management practice on

To mitigate the issues of unmeasured heterogeneity, insider studies seek data from production units—whether workers or work groups—that are very homogeneous. These workers all share one common production function that the researcher can model empirically—on-site car windshield installation, fruit picking in an orchard, finishing lines or rolling lines in steelmaking, and research projects or clinical testing processes in pharmaceuticals.

Although a homogeneous production function is important in insider studies, the insider dataset still needs heterogeneity to test hypotheses. Estimation of a treatment of the treated effect requires variance in the adoption of the management practice. Therefore, there must be subtle differences in the workers or organizations that lead to heterogeneity in the adoption of the treatment or in the response to a common treatment. The goal of sample design decisions in insider studies is to strike a purposeful balance between homogeneity in the production function and heterogeneity in either the adoption of the treatments or the magnitudes of the treatment effects.³⁴

7.1.4. Key Design Decision 4: Collect Information on Why the Treatment Was Adopted

Once the researcher identifies a management innovation that varies across observations, she must understand why the treatment was adopted. Because the management treatments are rarely natural experiments, the researcher needs to collect information about the determinants of the adoption of the management practice being studied. Although this point is perhaps obvious, unless it is fully appreciated prior to data collection efforts, the researcher may focus only on data related to the production function and management practices and may miss opportunities to obtain data on the factors that cause adoption of the practices. When there is no systematic data available on adoption, a description of the reasons for adoption from industry insiders can still provide important insights about differences between adopters and nonadopters.

Some insider studies have concluded that, even though the data come from firms choosing optimal management practices, the treatment appears to be exogenous to the productivity regression. For example, when data describe worker-level productivity outcomes in a single firm, the management innovation is likely to be exogenous with respect to productivity outcomes. In these cases, the new management treatment is imposed by the firm on all its workers or establishments.³⁵ The management innovation can also be exogenous with respect to productivity

productivity extend well beyond issues of unmeasured heterogeneity and omitted variables. Measurement error in the dependent variable does not have to introduce bias in the estimated treatment effect in a production function. But production functions estimated with more aggregate data typically must rely on value-added data for the dependent variable, even though value added contains product mix changes that are not part of production per se and thus can differ dramatically from the variable the researcher hopes to be measuring. See Syverson et al. (2008) for a discussion of this point.

34. List et al. (2010) make this point about the trade-off between homogeneity and heterogeneity when designing optimal field experiments.

35. In the Safelite (Lazear 2000) and fruit picker (Bandiera et al. 2005) studies, the productivity data are on workers, and adoption is clearly exogenous to the worker. This is true for other studies of retail stores in a single firm (Lafontaine and Sivadasan 2009; Griffith and Neely 2009) or for teams of workers in an apparel firm (Hamilton et al. 2003). At the same time, as described in Section 4, there are still potential sources of selectivity in the application of the exogenous management practice: workers can leave or join the firm (and enter or leave the sample) after the firm imposes the practice (as in Lazear 2000); or workers might be the ones who decide to opt in or out of the new practice (as in the study of work teams by Hamilton et al. 2003).

outcomes across plants. In their integrated steel mills study, Ichniowski et al. (1997) conclude that expected productivity gains for nonadopters would be the same as those observed for adopters, but nonadopters are not willing to pay the transition costs of management changes.³⁶

When the adoption is endogenous to productivity outcomes, researchers seek data to estimate the adoption regression. In minimills, mills adopting teamwork produce more complex products (Boning et al. 2007). In valve making, plants that adopt new information technologies produce more customized products (Bartel et al. 2007).

Researchers always want to know why firms do or do not adopt. Even in true experiments that impose new management practices randomly across firms, researchers ask: why don't firms adopt these practices on their own? For example, Bloom et al. (2011b) find that lean manufacturing practices raise productivity after these practices were randomly assigned in a sample of textile plants. A natural question to consider in light of these findings is why more of these plants do not use lean manufacturing and why the plants that were adopters in this study did not institute these practices on their own.

7.1.5. Key Design Decision 5: Collect Information on How Behavior Changes and Why the Treatment Was Successful

Even though insider econometric researchers use many different types of datasets and methodologies, all insider econometric studies document why the treatment was effective. In the broader treatment effects literature, this is typically not the case. When researchers study the effects of tax cuts on labor supply, researchers rarely collect data to explain why people increase their labor supply. However, in working with workers or establishments of firms, evidence on why the management practice is or is not effective is both available and essential. Models of the effects of management practices on productivity routinely model the reasons a practice is effective. Insiders can obtain the data to test these more detailed mechanisms and provide additional tests of the underlying model.

Consider some examples of the data researchers gather to test why management practices are effective. Bandiera et al. (2005) gather data on friendships among employees to show that a large gain in productivity after the firm switches from relative pay to piece rate pay is concentrated among employees who worked with friends and who were holding back their efforts under the old pay plan. Mas and Moretti (2009) gather data on where checkout clerks stand (relative to one another in the store) to document a large gain in the speed of grocery checkout clerks when a high-performing clerk joins a work shift. Gant et al. (2002) gather data on the communications social networks of all employees to show that interworker communication and problem-solving activities are much more pronounced among steel production lines with new HRM practices and higher productivity than they are in other lines. Many recent studies in behavioral economics are aimed precisely at showing how people behave in response to incentives or other HRM practices, and some of the most convincing evidence in insider econometric research describes the behavior of workers in treated and nontreated conditions.

36. With detailed insider data, it is possible to examine other reasons that could account for differences in the adoption of new practices. In the study of steel lines, for example, explanations related to differences in managerial quality, plant age, and prior productivity are tested and rejected, thus lending greater support to the conclusion that differences in transition costs explain nonadoption.

In sum, one advantage of doing insider research is that data are often available on why the treatment is effective, and these data allow the researcher to identify specific behavioral mechanisms that explain the connection between the management policy and the productivity outcomes. Insider studies are more convincing if they go beyond the estimation of a treatment effect. If additional data are collected about why the treatment is effective, the empirical work is more persuasive.

7.2. Detailed Steps to Take When Faced with Data

When faced with potential data from one or more firms, what should the researcher do? The following list offers some guidance:

1. Interview managers, workers, and others to learn about the mode of production and the management issues faced and addressed by the firm. Ask them to tell you what determines productivity. Learn the production process.
2. Identify a research question based on these interviews. Most researchers would not know the questions or potential hypotheses without the plant visits. Rule out some potential hypotheses.
3. Identify why this firm (or firms) has adopted these management practices and other firms have not.
4. Gather additional data needed for better tests of the hypotheses. Determine your econometric methods and how you will identify the appropriate treatment effect. If the data are on one new treatment in a single firm, can you collect data on factors that explain heterogeneity in observed treatment effects? If the data describe the adoption of the treatment across multiple firms or locations, can you collect data on the reasons for adoption versus nonadoption? Decide what is endogenous versus exogenous and where there might be measurement error or omitted variable bias.
5. Evaluate and interpret your results. Empirical researchers typically test the robustness of their models by introducing functional form changes. Insider econometric studies go a step further by asking the insider informants if the results make sense.
6. Collect additional data for more comprehensive and convincing tests. For example, though the primary model is a production function, it could be very persuasive to interview workers to gather other evidence to interpret or retest the results.

Insider studies identify factors that affect productivity, and they also identify what factors can be ruled out as determinants of productivity. Ruling out potential hypotheses can be as important as formulating new testable hypotheses. In cross-industry studies using firm-level data, the list of possible productivity determinants is endless. In insider studies, many possible reasons for productivity growth can be ruled out (or controlled for in the regressions) because of the narrow focus on a single production process, so the researcher can focus on testing the hypotheses that are most relevant to that firm, industry, or theoretical model.

Initial discussions with experienced insiders about how the production operations work can lead naturally to other steps. For example, the researcher may end up exploring managers' opinions about why some workers, work groups, or establishments are covered by the management treatment, whereas elsewhere the treatment is absent.

Ultimately, the researcher uses the real world experience of the industry insiders to inform their studies of the fundamental questions listed in Section 2. Why do some employees or organizations that appear to be competing in the same narrowly defined industry work under one set of managerial practices while others work under another set? When new practices are adopted, does productivity change, and do the changes in productivity vary across workers or establishments? Are there any changes in employee behavior that can help explain the changes in productivity?

8. Economic Lessons Learned from Insider Econometric Research

Many empirical findings across studies echo common themes. These broad economic themes emerging from insider studies can, we believe, provide guidance about the most promising avenues for developing richer theories of competing firms and their employees. In this section, we review several of these broad themes emerging from multiple insider studies.

1. Management matters. Effects of management practices on productivity can be big.

The fundamental conclusion emerging from insider econometric research reviewed in this chapter is that management matters, and that it matters in several ways. First, insider studies routinely document substantial productivity effects from the adoption of new management practices. As examples, the magnitudes of the overall productivity gains among windshield installers in Lazear (2000) or fruit harvesters in Bandiera et al. (2005) are substantial—44% and 58%, respectively. Studies in many other industry settings reviewed above also show dramatic productivity increases after adoption of other new practices.

Second, a wide array of management practices impact the productivity of workers, work groups, and plants in different industries. The two abovementioned examples focus on the productivity effects of incentive pay, but many other management practices are modeled in insider studies and are also shown to have big impacts (see Table 1).³⁷ Thus, managers must evaluate a very wide range of policy areas when deciding what practices would be optimal for their workers, their technologies, and their industries.

Third, the large productivity gains arising from new management practice vary across firms in a given industry. Insider studies routinely document heterogeneity in the magnitude of performance gains across workers and plants that use similar production pro-

37. Even in the area of compensation policies, there are many other types of compensation plans that we have not reviewed. For example, tournaments are readily modeled in laboratory experiments, so there is extensive experimental evidence showing that tournaments can motivate individuals better than other kinds of incentive pay can in some settings (see Bull et al. 1987). See the insider studies of Knoeber and Thurman (1994) for producers of broiler chickens; Drago and Garvey (1998) for Australian firms, and Ehrenberg and Bognanno (1990) for professional golfers. Different methods for determining CEO or other top executive pay would be yet another set of management practices that impact firm performance.

cesses. Managers need to understand subtle within-industry differences in production or product mix to decide whether a new management practice will increase profits for their specific operations.

2. The productivity of an individual worker is determined by her work group.

Several insider studies demonstrate that work groups matter. An individual's productivity is a function of her co-workers' productivity. Two work group effects stand out. First, productivity spillovers due to peer effects matter. When an employee is working next to a high performer, the employee works harder. We discussed this above regarding the Mas and Moretti (2009) paper showing that when a faster checkout clerk replaces a slower one on a shift, the shift becomes more productive not simply because the new clerk is faster than the old one, but because the other clerks also become faster.

Second, employees are complements in production when they work as teams, and teams can be much more productive than individuals. Teamwork implies that workers do not have identical skills and thus can complement one another. In a team-based production function, output is not the sum of individual outputs but instead is a function of the multiplicative interaction among employees. Several insider papers reviewed above delve into the details of what makes work teams productive.³⁸

Third, a good boss makes his work team more productive by training more (Lazear et al. 2011). The quality of managers matters for work team productivity.

3. Employees respond to management practices at both the extensive margin of whether to work for the firm and the intensive margin in deciding how hard to work at their jobs.

When firms introduce a new incentive pay plan, we expect workers to work harder and to target their efforts toward the output that is rewarded. This increase in effort operates on the worker's intensive margin (effort within the firm). Other management practices, such as teamwork or innovative job design, also aim to increase effort at the intensive margin. Management practices also have a big effect on workers at the extensive margin—on workers' decision to join the firm or the work group that offers the particular practice. Workers who do not like incentive pay avoid firms that pay for performance (Lazear 2000). In other cases, management can introduce teamwork into the firm but then leave it to the employees to join teams. There is selectivity in who joins which team (Hamilton et al. 2003). The key result is that when a firm chooses its management practice, it will cause worker sorting. Thus, the productivity gains that firms experience from management practices result from a combination of effort (the intensive margin) and optimal sorting (the extensive margin).

38. In steel finishing lines, problem-solving teams raise productivity because worker interactions become richer and more frequent. Problem solving requires interaction among co-workers (Gant et al. 2002). In apparel manufacturing, the productivity of work teams depends on the mix of skills and productivity levels of the team's members (Hamilton et al. 2003). In insider studies of orchards, the existence or absence of friendships among co-workers determines the extent to which efforts of the fruit pickers change after various kinds of incentive pay plans are adopted (Bandiera et al. 2005). In pharmaceuticals, the productivity of research on one project depends on knowledge spillovers from other related projects (Henderson and Cockburn 1996). Thus, in many settings, the true production function specifies not just an aggregate number of workers but also must capture the interactions among these individuals.

4. Firms compete using different product market strategies, and these different strategies require internal organizational structures to match the strategies.

Two general reasons exist for the adoption of management practices. First, there are innovations in the best practices of management: much like the technology innovations of computers, there are technology innovations in how firms are managed. New ways of improving productivity are discovered. For example, innovations in modern methods of lean manufacturing and total quality management were introduced by large Japanese firms in the 1960s and 1970s and spread to manufacturers in other parts of the developed world in the decades that followed. When there are innovations in best practices, and some new management practices would raise productivity in all plants in an industry, only differences in adjustment and adoption costs prevent such adoption. This is the message of Ichniowski et al. (1997) and Bloom et al. (2011b).

However, there is a second reason for the adoption of innovative practices: firms should adopt only the set of management practices that suits their strategy. Even though best practices are evolving over time, at any point in time, there are cross-sectional differences in the optimal adoption of practices. The business strategy literature has long recognized that firms in one industry compete in different product niches and therefore need different management practices. Low-cost mass producers coexist in industries alongside other businesses that serve customers who prefer higher cost specialty versions of the products. Several insider econometric studies document this link between product market strategy and internal management practices.³⁹ This link is an important result. It explains, in part, why some firms in an industry adopt certain management practices and other similar firms do not. It also explains why traditional output-per-person-hour productivity measures will be higher for some firms than others in the same industry.

5. Management innovations often require the adoption of multiple practices that are complements of one another.

Complementarities among management practices are pervasive. That is, the productivity gains from one management practice, such as problem-solving teams, interact with the gains from other practices, such as training, hiring, or compensation practices. Therefore, managers who are considering adopting one new management innovation cannot calculate the marginal gain from that practice independently of the set of other practices (Milgrom and Roberts 1990). There is extensive evidence from insider papers that choosing the right system of complementary practices increases productivity more than choosing individual practices in isolation.⁴⁰

39. Minimills that make complex steel products adopt problem-solving teams more often than do minimills making commodity products (Boning et al. 2007). Valve manufacturers making more customized valve products adopt more innovative information technologies, training, and teamwork (Bartel et al. 2007). Software companies operating in market segments that have big upside gains to innovative software development pay higher wages and offer more performance pay than do software companies operating in more traditional product market niches (Andersson et al. 2009). Southwest Airlines, targeting bargain-hunting airline customers, uses different hiring and training and pay plans than does Singapore Airlines, which targets quality-conscious customers.

40. Ichniowski et al. (1997) document this result in the steel industry. In auto assembly plants, innovative HRM systems are typically adopted along with lean manufacturing methods and just-in-time inventory procedures

This review of broader themes emerging from the empirical findings of insider econometric research highlights how diverse and complex the determinants of productivity really are. Managers who want to achieve high levels of productivity from their workforces must consider a wide array of factors. Which employees are working together? What are the skill differences among co-workers, and what are their personal relationships like? When I adopt a new policy, am I likely to attract the kind of employee I really want, or will the better performers leave my firm? Is the new practice I am considering consistent with others I have in place, or do I need to change multiple practices? If I change my competitive business strategy, will I need to reconfigure how I manage my workforce? Insider econometric research paints a picture of the manager's job as one that is extremely challenging. As the first theme discussed in this section states, management certainly matters.

9. Data Sources for Insider Econometric Studies

In the insider studies reviewed above, researchers worked with firms to obtain data. That is not always necessary. As described in this section, researchers can use publicly available data and augment it with that from other sources or from their own surveys. Datasets may contain information on productivity or on management practices, but not both: researchers must combine data from several sources to obtain both. Many insider studies are now being conducted in education and health care, and in firms in developing economies. As researchers obtain data in these or other sectors, new insider studies will be possible. In the following list of possible data sources, we include lengthy footnotes with references to papers that have used data from these kinds of sources. However, the authors of these papers have also been creative in their use of data that spans these categories:

1. *Insider data from within one firm.* The firm provides the data.⁴¹
2. *Insider data from multiple firms in the same industry.* Researchers obtain data from the firms (through visits) or conduct surveys of the firms to measure management practices.⁴² For surveys, the researchers use insider guidance to develop and administer their own

(MacDuffie 1995). In apparel manufacturing, new HRM systems are adopted when new information technologies that tie the manufacturer directly to large retailers are adopted (Appelbaum et al. 2000; Dunlop and Weil 2000). Decisions to adopt new information technologies are also linked with decisions to adopt a series of new HRM policies in valve manufacturing (Bartel et al. 2007) and in banking (Autor et al. 2002). Bresnahan et al. (2002) also find that HRM practices and new information technologies are complementary.

41. Studies in this category include Knoeber and Thurman (1994), Batt (1999), Lazear (2000), Autor et al. (2003), Hamilton et al. (2003), Bartel (2004), Gaynor et al. (2004), Bandiera et al. (2005, 2007, 2009), Bhattacharjee (2005), Freeman and Kleiner (2005), Encinosa et al. (2007), Kalmi and Kauhanen (2008), Griffith and Neely (2009), Jones and Kato (2011), and Lo et al. (2011).

42. Studies include Kruse (1993), Ichniowski and Shaw (1995, 2003), MacDuffie (1995), Berg et al. (1996), Huselid and Becker (1996), Oyer (1998), Dunlop and Weil (2000), Fernie and Metcalf (2003), Van Biesebroeck (2006), Bartel et al. (2007), Bloom and Van Reenen (2007), Boning et al. (2007), Kruse et al. (2008), and Bloom et al. (2011b, in press).

surveys, and the challenge is to obtain productivity data from the survey (or match it from a different dataset, e.g., census data).

3. *Insider analysis using data from public or regulated industries, such as education.*⁴³ The availability of data on teachers and students and keen interest in policy are resulting in much more insider work in education. Other regulated and government-funded industries—such as health care, trucking, and electricity generation—often have data available. The researcher may need to conduct surveys or visit firms to obtain information on HRM practices to link to the productivity data.
4. *Insider analysis using census data or datasets from consulting firms or industry associations.*⁴⁴ Some industries are followed by the U.S. Census Department, such as trucking, retail trade, and manufacturing industries. Some industries have consulting firms that follow the industry, as for venture capital. And some industries have industry associations or the desire to publicize their firm's attributes, as for franchising and law.
5. *Insider analysis using employer-employee matched datasets that are available for entire countries.* In Europe, the United States, and some developing countries, national census departments are matching data on individual workers to data from the firms where they work. These datasets span all workers in all industries. But it may be wise to take subsets of these datasets for certain industries or occupations and delve deeper into the production function. Though the datasets do not contain measures of management practices, researchers can use the wages and mobility of all workers in the firm to infer the sorts of HRM practices that firms are adopting.⁴⁵
6. *Insider analysis using data from developing countries.* There are increasing numbers of papers with randomized treatments of management practices on performance: Two papers were reviewed in Section 4.3 (see Duflo et al. 2009, 2011, 2012). Such studies that measure average treatment effects offer some unique opportunities to identify observations that enjoy relatively large or small productivity impacts, which in turn could help identify the causes for any observed heterogeneity in the treatment effects.

To obtain data on both productivity outcomes and management practices, the researcher will often need to merge several datasets. Helper (2000) discusses additional issues and ideas on working with firms and their data. When working with firms, it is important for researchers to show what they can do for the firm, while acknowledging the importance of the firm's generosity in these efforts aimed at furthering our knowledge of how businesses really operate.

43. For education, see Kreuger (1999), Eberts et al. (2000), Hoxby (2002), Lavy (2002, 2008), Jacob and Levitt (2003), Rivkin et al. (2005), and Duflo et al. (in press). For other sectors, see Asch (1990), Baker and Hubbard (2003), Dranove et al. (2003), Dee and Keys (2004), Rosenthal et al. (2004), Kalnins and Chung (2006), Garicano and Heaton (2010), Propper and Van Reenen (2010), and Imberman et al. (2012).

44. See Clark (1980), Landers et al. (1996), Lafontaine and Shaw (1999, 2005), Hubbard (2000), Black and Lynch (2001, 2004), Baker and Hubbard (2003), Oyer and Schaefer (2007), Autor and Scarborough (2008), and Garicano and Hubbard (2009).

45. See Andersson et al. (2009) for work using employer-employee matched data for the software industry. See Lazear and Shaw (2007) for examples of other papers and the range of possible datasets.

10. Conclusion

Insider econometric research has two goals. First, combine information from inside the firm with sound econometric methods to estimate the impact of management practices on productivity. Second, use these results to enrich our theories of the firm.

Insider econometric studies focus on three basic questions:

1. Does a new management practice raise productivity?
2. Why does the new management practice raise productivity?
3. Why is the new management practice adopted?

Ultimately, designing and executing a study that answers these questions is part art and part science. Decisions about which management practices to study and how to measure them, about how to balance homogeneity and heterogeneity in the design of the sample and dataset, and about the many aspects of modeling the determinants of performance require careful judgment. This chapter offers guidance on the many decisions involved in conducting insider studies.

In many ways, the insider econometrician must be an expert translator. The researcher must translate the real world experience of the industry insiders into a dataset and research design that persuasively models fundamental questions about worker and firm behavior. The research designs of insider econometric research rely on rich micro-level data on workers or work groups from a single industry and production process. Although the empirical tests pertain to one industry setting, it is precisely this kind of detailed information about new management practices, worker characteristics, the production process, product characteristics, and other aspects of the industry setting that allows the researcher to test new theories about what makes workers productive and firms productive and profitable.

Why do we need more insider econometric studies? These studies address three needs. First, the science of economics evolves, and we are improving and updating our models. Empirical work on real workers and work sites will give us further guidance on this path, providing new insights while testing and refining old models. Second, we wish to better understand the causes of economic growth, and the impacts of management practices on productivity growth is one component of this larger topic. Third, models that incorporate more of the realism of contemporary firms will improve the advice we offer managers.

Why do we expect there to be more insider econometric studies? Management practices are constantly being updated, markets are changing, and data about these changes are becoming more prevalent in firms. Firms are experimenting more. Firms will need more guidance from researchers who are trained in analyzing these newly available data as managers move toward data-driven management decisions. Therefore, more researchers will seek to understand why, when, and how much management practices matter.

Employment as an Economic and a Social Relationship

James N. Baron and David M. Kreps

1. Introduction

Because employment is simultaneously an economic and a social relationship, one cannot profitably study it as one or the other in isolation. To understand employment relationships requires taking into account both economic and social-psychological dimensions of their content and context and, especially, how economic and social forces interact. This is true of many economic exchanges, but particularly of employment: Fraught with the complexities of time, uncertainty, and ambiguity, employment contracts are often massively incomplete. “Market discipline” is likely to become less and less acute the longer an employment relationship endures. Although supply-equals-demand may be informative in the aggregate, at the level of the relationships between an organization and its employees—the level of greatest interest to practitioners and of increasing interest to scholars—more nuanced and, to some extent, quite different ways of thinking should be employed. In particular, insights from social psychology and sociology about what drives employee behavior—about what employees value, what they expect, and how they assess their situations—are essential to a full and useful understanding of employment relationships. Economics by itself is far from sufficient.

Economic reasoning should not be abandoned in favor of these other disciplines. Instead, economics should be blended with social psychology and sociology. We have found it particularly helpful to use an economic skeleton derived from the theory of relational contracting within the broader framework of transaction cost economics and then to flesh out the skeleton with ideas from the other disciplines.

Economists are customarily schooled in the crisp, concise tradition of supply-equals-demand, in which sparse hypotheses generate broad conclusions. Accordingly, economists may be troubled by the complex animals we construct. If the skeletal structure is simple, the variety of muscle and flesh—and their complex dependence on the broader social environment—leaves one with an incredibly rich menagerie of employment relationships. This is not to say that useful

predictions are impossible. But they are more nuanced than might emerge from a purely economic perspective. And, in at least some cases, social forces can turn predictions derived from economics alone on their head.

We begin by describing the skeleton. Readers versed in the theory of relational contracts will find this description to be very familiar territory. Then, more by examples than anything else, we show how concepts from social psychology and sociology flesh out the skeleton in ways that a mainstream economist might not anticipate.

2. Employment as a Relational Contract

The economic skeleton for employment relationships is a standard version of relational contracting within the framework of transaction cost economics, mixing bilateral, hierarchical, and, in some cases, trilateral governance, and with more than a nod toward more mathematical theories of repeated games and reputation. We expect that this story is well known to most readers of this chapter, so we outline it succinctly.

We focus for the moment on the relationship between employer and employee:

1. The relationship endures for some length of time. This is not a theory of spot labor transactions.
2. Because it is too costly (or, more likely, impossible) to specify all contingencies in advance, the contract between employer and employee is massively incomplete, both at the outset and as it evolves. Among the many terms of the exchange that are specified only as time passes are: the precise tasks to be performed by the employee and how to assess performance; training that might be provided; decisions about reassignment, promotion, and changes in compensation; and the identities of co-workers, subordinates, and immediate hierarchical superiors.
3. Market forces working on both employer and employee might be acute at the start of the relationship (although institutional factors, such as “company towns” and collective bargaining, may work against even this). As time passes, however, both parties build relation-specific assets, which relax the discipline of the market. Each side gains the ability to hold up the other, albeit their powers may grow quite asymmetrically.
4. The relationship, and how it evolves in the face of contingencies that arise, is often best characterized by its terms of governance: who makes which decisions.
5. The precise design of the contractual relationship will tend to optimize the net benefits of the relationship, net (in particular) of the transaction costs of forming, (re-)negotiating, adapting, and enforcing the contract. (But see, in particular, our discussion below of reputation concerns and effects.)

How should decision rights be assigned? Efficiency considerations point us in two directions: decision rights should vest (1) in the party with superior information and ability to make a particular decision; and (2) in the party in whom greater trust can be reposed that the decision rights will not be abused.

In his classic article on the subject, Simon (1951) proposes that employment is typically a hierarchical relationship, with the employer or hierarchical superior making the vast majority

of decisions. In Simon's model, the employee retains (only) the privilege of quitting, if the employer's demands become too onerous or distasteful. One can see both considerations at work here:

1. The employer, in many cases, acts to coordinate the activities of a number of employees. Being a specialist in coordinating the actions of others, the employer has greater access to information vital to decisions about what must be done when.
2. Trust is more naturally reposed in the party who has more at stake reputationally if the relationship is sundered. In employment, both employer and employee have assets at risk, because both have developed relation-specific assets. The employee expends time and energy acquiring knowledge and skills useful only for this employer, builds up a network of friends on the job, puts down roots in the community which she might lose if forced to seek employment elsewhere, and so on.¹ A list of the employer's assets at risk include: the employee, through time, learns on the job and through training provided by the employer, all of which must be repeated when turnover occurs; employees form networks within the employer's organization that are useful; and so forth. And each party has the substantial ability to diminish the value of the other party's assets. Absent slavery and indenture, the employee always retains the right to quit (although she may be bound to some extent by contractual non-compete clauses). The employer retains the ability to fire the employee, within the constraints that may be imposed by employment law and collective bargaining.

Because both parties have assets at risk, either can conceivably be trusted by the other, based on a threat by the other to destroy those assets. Indeed, measured as a percentage of the party's overall assets, the employee probably has more at risk in the employment relationship than the employer does with any individual employee. This observation might argue, on reputational grounds, for assigning decision rights to the employee who, having relatively more at stake, is potentially more trustworthy and at the same time, less likely to resist a hold-up. (Bargaining theory does not provide us with absolutely firm grounds for this conclusion, but still it seems reasonable.) The information advantage of the employer could be sufficient to overcome this trustworthiness advantage, but another general force works to increase the potential trustworthiness of the employer: Because employers typically deal with more than one employee, they develop reputations among all employees and prospective hires for how they behave as employers. In the usual virtuous-cycle fashion of reputation constructions, a reputation that—if credible—would elicit desirable behavior from trading partners can become self-enforcing. A desire to protect the value of reputation makes the reputation credible; this credibility enhances the value of the reputation, making it worthy of protection through adherence. Therefore, to the extent that an employer deals with multiple employees, *if* maltreatment of

1. Even in a pure transaction cost economics account, social forces are clearly at work here. Many of the job- or relation-specific assets an employee develops on the job are social in character, such as friendships made. The employer can influence the extent to which these assets develop—for instance, by promoting social exchange on the job, encouraging after-work fraternization, or (in the other direction) by a policy of frequently breaking up teams, moving people from one location to another, and so forth. In general, the more assets the employee has at risk, the stronger is the employer's bargaining position, and so actions that promote the formation of these social assets, at this level, are good for the employer. But as we discuss later, social comparison processes and group dynamics can present nontrivial trade-offs along this dimension.

a single employee would harm the employer's reputation with other employees, the reputational cost of such maltreatment increases enormously, which dramatically increases the employer's trustworthiness. This gives a further rationale for assigning to employers the bulk of the decision rights.

To be clear, specific decision rights are in many cases vested in employees. (More rarely, the two parties resort to trilateral governance, utilizing third-party arbitrators.) Employers probably have superior information about the coordination of activities among different employees; with highly interdependent jobs, they may also have an advantage in deciding what is done and how. But, to take a contrary example, academic deans may often have an advantage in scheduling when certain courses will be taught and even what general material should be covered; yet individual professors are nonetheless typically left with substantial—if not total—discretion about the specifics of how the material will be taught.

It is also worth noting that worker collectives—work councils, labor unions, and the like—can turn this picture on its side, if not its head. Worker collectives provide employees with representatives who can specialize in collecting and processing information valuable for coordinating activities, as well as a collective reputation stake in the relationship between employer(s) and the collectivized employees. Political considerations (e.g., American traditions of bread-and-butter unionism) aside, worker collectives can render it quite efficient to reassign decision rights to employees collectively or, at least, to require in the governance structure a measure of consensus before a decision is made.

3. Behavior: Beliefs and Tastes?

To flesh out this skeleton, we have to specify how the parties involved will behave in various situations in which they find themselves.

For a formal and mathematically inclined economist, behavior is purposeful, driven to achieve specific aims as encoded by the individual's unchanging and unchangeable utility function. That same economist views purposeful behavior as reflecting two distinct influences: *tastes* or *utility*, the primitives of value to the individual; and *beliefs*, predictions concerning how others will behave, particularly in response to one's own actions. But after acknowledging the importance of tastes and beliefs, economists do not have a lot more to say about either:

- Economists, by and large, forswear any competence in specifying tastes: *De gustibus non disputandum est* is perhaps economists' second favorite bit of Latin (after *ceteris paribus*). Having disavowed any competence to specify tastes, economists do so anyway, traditionally populating their models with individuals whose tastes are a function solely of their own consumption. Nothing in economic theory precludes *homo economicus* from having in her utility function a taste for justice, a competitive streak, a masochistic bent, or a desire to see her friends prosper and her rivals suffer. But one rarely finds these traits in economic models.²

2. For a recent attempt to infuse agency theory with more behavioral realism by invoking social and psychological forces, see Rebitzer and Taylor (2011).

- Beliefs are a more complex matter. In the repeated interaction and reputation stories that form the basic architecture of the skeleton we have proposed, equilibria are manifestly a matter of each party's beliefs. In more mathematical renditions of these stories, the Folk Theorem tells us that many equilibria are possible, depending on the equilibrium beliefs held by the parties. The importance of specific beliefs is clearly recognized, but little is said about where those beliefs come from, how they evolve, and so forth.

Our thesis is that social psychology and sociology provide substantial insight regarding individual tastes and beliefs in employment settings, especially the social nature of those tastes and beliefs. Accordingly, those disciplines may help illuminate which particular equilibria we might expect to see among the many possible options. But the insights provided by social psychology and organizational sociology generate a stronger challenge to the economists' way of thinking, sometimes blurring the line between beliefs and tastes and calling into question the economist's standard assumption that tastes are unchanging and unchangeable. A more accurate rendition of our thesis is that social psychology and sociology teach us much about individual behavior in employment settings, with special emphasis on social factors that affect behavior. In the next few sections, we provide some specific examples.

4. Agency and Consummate Effort

More attention in the economics literature on organizations is paid to problems of agency and incentives than perhaps to any other issue. Designing robust and well-functioning tangible incentives can be particularly difficult where (1) employees must tend to multiple tasks; (2) tasks are dynamic, interdependent among employees, and ambiguous (the links between employee inputs and observable outputs are noisy or, worse, subject to unforeseen contingencies); and (3) employees' levels of risk and effort aversion are not well known by employers.

Non-economics-based approaches sometimes "solve" the problem of agency in a manner that economists tend to regard as cheating; they appeal to social and psychological processes that lead employees to choose to act in the best interests of employers or some other constituency. Using the terminology of economics to express these social-psychological processes, they include:

- an appeal to motivation on the part of employees to do a good job because the task is inherently interesting, out of pride in the task itself, or because doing a good job is a general social norm;
- an appeal to the employee's sense of obligation (gift exchange); or
- an appeal to the employee internalizing (perhaps endogenously) the welfare of the employer or some other constituency.

All three of these work at the level of employee tastes; the idea is that, contrary to the assumptions of simple agency models, employees are not motivated solely by income received and the desire to avoid effort. Because one can incorporate these additional motivations in an employee's utility function, they are easily accommodated in the standard utility-maximization models of economists (but see the discussion in Section 4.4). Social psychology provides us with a number of interesting and even provocative hypotheses in this regard.

4.1. Explicit Extrinsic Rewards or Control Mechanisms Can Drive Out Intrinsic Motivation

When workers are intrinsically motivated to do a good job, emphasizing “supporting” explicit extrinsic rewards can dull or even reverse intrinsic motivation (see, e.g., Deci 1971, 1975; Lepper et al. 1973; Lepper and Greene 1975; Deci et al. 1999). Several psychological accounts are offered for this effect. Deci and colleagues associate intrinsic motivation with feelings of autonomy; imposing extrinsic rewards or external control mechanisms, such as surveillance, tends to increase the employee’s sense of being controlled, diminishing the level of intrinsic motivation. (Why are individual faculty members given autonomy over what they teach and how? A partial explanation may lie in this direction: The freedom enhances the intrinsic motivation of the faculty member, which is an essential piece of motivation for this complex task.) A different psychological account involves self-perception theory (Bem 1967): An employee who works hard at some task, without explicit extrinsic rewards, is insufficiently justified cognitively and will tend to rationalize to herself that her efforts at doing a good job must stem from her own pride in or love of the job itself. Having so rationalized her prior efforts, she subsequently acts in accordance with these values; her pride in doing a good job or intrinsic interest in the task rises. When extrinsic rewards or explicit controls are made salient, the individual may become over-sufficiently justified: Now she can attribute effort to a desire to earn the specific reward or avoid punishment. If she comes to believe that that is what motivates her, then she may do what is required, but only just what is required. She is less likely to attribute her effort to pride or love and, the story goes, is less likely to provide consummate effort subsequently.³

This is not to say that, by reducing the salary of an intrinsically motivated employee, an employer would perforce intensify that intrinsic motivation. These effects have more to do with the extent to which extrinsic rationales are made cognitively salient than with the provision of extrinsic rewards per se. Moreover, demotivation may ensue if compensation levels are not fair and equitable, especially based on social comparisons, or are inconsistent with status (see Section 5). The point is, instead, that highlighting explicit extrinsic incentives—emphasizing an explicit *quid pro quo*—can dull intrinsic motivation, which in turn may either lower performance or raise the cost to the employer of achieving the optimal level of performance.

This is also not to say that focusing on extrinsic incentives is always a bad idea. In some settings, intrinsic motivation to perform is scarce and of limited relevance to individual or organizational performance. But intrinsic motivation can be a very powerful and inexpensive control mechanism in a wide variety of settings: where work has social meaning, such as nursing; where it involves the use of a skill or craft acquired through a process involving strong normative socialization, such as a crafts union or professional school; where the individual employee is better equipped than the employer to make real-time judgments about what actions to take and in what sequence; where the difference between adequate and superlative performance is highly valuable to the enterprise; and where individuals work interdependently, so that spillovers in attitudes and outputs are possible among members of the employee group.

3. A somewhat different account of the self-fulfilling nature of extrinsic controls emphasizes the dynamics of performance sampling or what psychologists term “asymmetric disconfirmation.” Employers who underestimate the extent of employee opportunism will observe their errors and restructure jobs accordingly, producing a self-fulfilling cycle; in contrast, employers who overestimate the extent of employee opportunism are unlikely to structure jobs in such a way as to allow their priors to be disconfirmed (e.g., Denrell 2003; Larrick and Wu 2007).

4.2. Process (Language and Symbolism) Affects Gift Exchange

In a competitive labor market, profit-maximizing employers are meant to pay employees their market wages. Nonetheless, one sometimes observes employees being treated better—in terms of wages, benefits, or other perquisites—than their market alternatives. The typical economic explanation is that these are so-called “efficiency wages” (see, e.g., Campbell 1993): By paying above the market, the employer reduces the chances of the employee leaving the job for another opportunity or for personal concerns (e.g., one’s spouse has found a better job elsewhere). This, the story goes, economizes on turnover, supervision, and training costs. Moreover, above-market compensation induces employees to take particular care not to be fired. To protect their privileged job (in an environment where they might be terminated unexpectedly), employees reciprocate with above-market diligence, they forbear from dysfunctional rent seeking, and so forth. These considerations suggest that efficiency wages are expected when it is difficult or costly to exercise direct managerial oversight; tasks are interdependent among employees; turnover, monitoring, and training are costly; and hold-up problems are intensified by virtue of scale, technology, worker organization, or skill monopolies among star employees with external opportunities. And empirical evidence is at least partially supportive; in particular, premium wages are often associated in a given labor market with larger firms, which complement premium wages with premium benefits.

An alternative and somewhat noneconomic view is that above-market wages and benefits actuate a reciprocal pattern of gift exchange. The employer is providing gifts to employees; employees are then motivated to reciprocate with gifts of consummate effort. Employees do not precisely calculate the monetary value of the gifts they are given or what it would cost them monetarily to lose the gifts by losing the job. Instead, employees feel a more basic social obligation to reciprocate gift for gift. In this story, the character of the gift from employer to employee can powerfully affect how the employee responds. Gifts are more likely to engender reciprocation the more personal the gift is, the more it seems to have been personally costly to the gift giver, and the more it seems to be a gift and not simply extra compensation. To reduce this idea to something of a caricature, a gift basket of books or music CDs at the holidays, particularly if the composition of the basket reflects the individual tastes of the recipient, is more effective than is the equivalent amount of cash, especially if the cash amount is determined by a specific formula that depends objectively on the employee’s base salary. (Compare with the standard economic point of view: Except for their tax-favored status or economies due to large-scale purchases or the solution of adverse selection problems, specific benefits are less valuable to employees than is the equivalent amount of cash.)

A gift is more clearly and obviously a gift—and therefore more likely to trigger reciprocal gifts—the more clearly it is “unnecessary.” Efficiency wage stories imply that employers should utilize efficiency wage regimes to mollify employees having the highest expectations, the most abundant external opportunities, and the greatest ability to impose costs on the employer. Yet these may well be the employees among whom it is most difficult to cultivate feelings of obligation by providing treatment that exceeds what is customary in a given occupation, industry, or locale. The relative affluence and clout of these employees makes it more likely that they will frame the above-market compensation simply as their due. In contrast, above-market rewards paid to those lower in the employment pecking order are, for that reason

alone, more likely to be framed as gifts. It may be employees with lower expectations regarding compensation and treatment who are affected most profoundly by receiving a gift of a specific value.⁴

This insight has been leveraged to great effect by George Zimmer, founder of Men's Wearhouse, a retailer selling low-priced menswear in conveniently located establishments that minimize the travel and shopping time men must spend when purchasing clothing. In an industry characterized by astronomical turnover rates, low wages, minimal benefits, and reliance on technological surveillance and controls to deter employee misconduct, Zimmer has adopted a contrarian approach. He invests heavily in employee training and development, in providing short- and long-term benefits, and in making the workplace fun (O'Reilly and Pfeffer 2000). Many individuals he hires are passed over by competitors who do not see in the resume the indicia of trustworthiness and business acumen. For Zimmer, a lack of experience or a string of past travails creates opportunities to engender more intense feelings of obligation and gratitude. Zimmer offers these disadvantaged individuals not simply a job and a paycheck but also a chance for self-esteem and a new life.

There is evidence in support of the economic benefits realized through this regime. According to the 2005 *National Retail Security Survey* (NRSS) of 156 retail chains (Hollinger and Langton 2006), shrinkage in retail averaged 1.59% of total annual sales in 2005, slightly higher (1.62%) in the men's and women's apparel sector.⁵ A Stanford Business School case on Men's Wearhouse reports a shrink rate of "roughly 0.5%" (Pfeffer 1997). At the time of the NRSS survey (2005), the company reported revenues of \$1.725 billion. If its shrinkage rate was $1.62\% - 0.50\% = 1.12\%$ lower than its competitors, this represents a savings of about \$19.3 million. According to the 2005 NRSS, on average 5% of theft was due to vendors, 15% to administrative and paperwork errors, 33% reflected shoplifting, and 47% was due to employee theft. Even if one assumes that Men's Wearhouse human resource (HR) practices only affect shrinkage from employee theft and shoplifting (80% of the total), the savings still add up to about \$15.5 million for the year or about \$1,120 per employee. And these rough estimates may well understate the savings from reduced shrinkage: the NRSS reports considerably higher shrinkage rates in retail establishments with high turnover and heavy reliance on part-time personnel (Hollinger and Langton 2006: figures 25 and 26), and Men's Wearhouse is far below the industry average on both dimensions.

On the expenditure side, it is difficult to calculate the magnitude of the efficiency wages being paid, but the Stanford case reports that training expenses (which include many social activities having team-building effects) average roughly 2% of payroll. In FY2005, selling, general, and administrative expenses for the entire company totaled \$531.8 million, so an upper bound on the entire training tab is 2% of that amount or \$10,637,000, which works out to \$771 per employee. In short, the goodwill Zimmer creates by investing in a workforce whom others have shunned pays for itself handsomely simply due to reduced employee theft and increased employee attention to customer theft. This estimate ignores any benefits obtained through greater sales productivity, less turnover, or lower administrative overhead.

4. For some field-based and experimental evidence consistent with this speculation, see Baron (2011).

5. More recent annual versions of the NRSS yield very fairly similar estimates but warrant less confidence due to much lower response rates among firms in men's apparel.

Figure 1. Proposed Thanksgiving gifts for employees of the I. M. Spice Corporation.

Interestingly, Zimmer apparently resists appeals from his management team to quantify the return on investment for expenditures such as the annual companywide retreat at the beach in Pajaro Dunes, California, to which all employees are invited. In a videotaped conversation with a class of Stanford students about the company, Zimmer says that this is “the best money we spend” and that the expenses will only be curtailed “over my dead body, even if it is hard to quantify from a cost-benefit point of view” (Pfeffer, personal communication, 1998). Given the apparent magnitude of the return and Zimmer’s shrewdness, one cannot help but wonder whether this posture is intended to preserve the gift-exchange properties of the company’s training investments by not emphasizing any calculative logic involved in having made them.

Conversely, opportunities to leverage gift exchange can be squandered through words or actions that emphasize the calculative underpinnings of employers’ actions. For an (admittedly fowl) example, imagine employees of the fictional I. M. Spice Company discovering the spreadsheet shown in Figure 1 on their boss’s desk just before Thanksgiving. It is hard to imagine Spice’s employees responding to their proposed Thanksgiving perk with unbridled displays of loyalty and corporate citizenship.

Cultural and social factors largely outside the firm’s control can also affect if and how employer largesse triggers reciprocity, by affecting how the recipients frame the gift. These cultural and social factors may pertain to the recipients. For instance, it is not a great overstatement to

suggest that the educational experiences at elite business schools reduce mightily opportunities for engendering feelings of reciprocity and obligation among newly minted MBAs vis-à-vis the organizations that employ them. Throughout the business school experience, students are described and treated as the “best and brightest” and indoctrinated with the principles of neo-classical economics, a cocktail that encourages many students to presume (if not assert boldly) that they are worth whatever they are able to extract in the labor market. This, in turn, suggests that MBAs, especially those from elite programs, might be relatively more sought after by organizations that eschew gift-exchange processes in favor of greater reliance on extrinsic incentives.

Cultural and social factors may also relate to the gift itself. For instance, a gift that runs counter to the dominant local culture may be dysfunctional: Think of a very early provider of health benefits for same-sex domestic partners. This offering was more likely to have the desired effect in, say, San Francisco, than it might have in, say, Utah or the deep South. Moreover, the power of this gift was probably strongest in San Francisco for the early adopters: Whereas a gift that is utterly unusual or unprecedented may be misunderstood or misperceived, one that is utterly commonplace or has become an industry norm provides relatively little luster. The impact of a given HR system is likely to depend on the distribution of alternative systems being utilized within the relevant sphere(s) to which employees attend. Zimmer would presumably derive considerably less benefit if his approach to employment relationships were the norm in apparel retailing.

Evidence of similar effects is found in the high-tech sector. The Stanford Project on Emerging Companies examined how founders’ early blueprints or mental maps regarding employment relations affected the evolution and performance of a large sample of Silicon Valley start-ups. The researchers found that companies founded with high-commitment HR systems displayed higher rates of survival and success from 1994 to 2001 than did most otherwise-comparable companies, even those founded with “star” models of the sort generally thought to promote technological excellence (see Baron and Hannan 2002). This was true in a locale (Silicon Valley) and time period (the Internet boom) in which “commitment” was generally regarded by the mid-1990s as an outmoded construct that impaired organizations from being flexible and fast. The point here is that if the significance of an employer’s offer to employees depends on the benchmark in terms of which it is assessed, then the returns to building a high-commitment culture may be greatest precisely when such cultures are uncommon and somewhat suspect: the significance of investing in employees and committing to their long-term development is greater when few rivals are doing so and when it is relatively more constraining or costly for employers to do so.

4.3. Internalizing the Welfare of Others

Sections 4.1 and 4.2 considered situations in which one party, the employee, takes actions that benefit a second party, the employer, without any apparent extrinsic incentive to do so and, presumably, at some personal cost in time or effort. By the principle of revealed preference, the observation of such behavior is explained by supposing that this behavior is, on net, utility enhancing: The benefits to the first party exceed the cost of the time or effort required. One possible explanation—what we mean to suggest in Section 4.1—is that the party finds the act

inherently enjoyable, takes pride in the act itself, or feels that the action per se is compelled by norms of proper behavior. We could test this idea by seeing whether the first party would take a similar action that benefits no one in particular or that benefits only unknown third parties. A second explanation—suggested by the language of gift exchange—is that the first party is discharging some perceived obligation to the second party; the action would not be taken for anonymous third parties, nor would it be taken on behalf of the specific second party once the original gift was adequately reciprocated. (This behavior can be rationalized as conformance to the norm of reciprocity, but it is reciprocation that is normative and not the specific behavior itself.) A third possibility, where the action would be taken for a specific second party (and not for an anonymous third party), is that the first party has (positively) internalized the welfare of the second party; roughly put, the first party's utility depends positively on the welfare of the second party.

It is probably difficult to separate the second and third explanations of this pattern of behavior empirically, especially where the two parties interact repeatedly: Unrequited love notwithstanding, any persistence in my internalizing your welfare is likely to require that you demonstrably reciprocate. One might simply view a sequence of back-and-forth gift exchanges as a device, especially on the employer's part, for increasing how much the employee internalizes the employer's welfare, thereby efficiently solving agency problems. However, in the spirit of escalating commitment (Staw 1981), which psychologists have examined primarily in the context of ill-fated decisions, we suggest that virtuous cycles of internalization can occur. The two parties might begin by exchanging small and inexpensive gifts, but as time passes and the relationship matures, if it matures positively, the extent to which each side internalizes the other's welfare will escalate.

Psychologists and others have documented a number of mechanisms by which this internalization occurs, aside from a generalized social norm of reciprocity. Studies of commitment in a variety of contexts (corporations, unions, voluntary associations, and long-term relationships) have documented that the time and effort associated with investment in a relationship itself tends to foster and deepen internalization of the other's welfare (e.g., Sheldon 1971). Moreover, the diminution of alternatives that often accompanies investment in building long-term alliances can strengthen the tendency for each party to internalize the welfare of its other exchange partners. And numerous studies of escalating commitment to ill-fated courses of action have highlighted the role of self-justification in sustaining prior commitments, lest the decision-maker appear unwise in the eyes of others (Brockner 1992). Similar processes of self-justification, self-perception (Bem 1967), or cognitive consistency (Festinger 1957) are presumably activated by taking actions that benefit another individual or entity without sufficient extrinsic rationale. In Section 4.1, we imagine an employee who exerts herself without the prospect of a contingent, extrinsic reward as rationalizing this effort, *ex post*, with "since I worked so hard on it, it must be because it was fun," or "because it is important to me personally to do a good job." In the right social environment—such as in an organizational culture that emphasizes cooperation and loyalty—she might justify her efforts with "I did it because I want my co-worker [or team, boss, department, organization] to succeed" and, having so justified her past efforts, might adopt this attitude when choosing her subsequent levels of effort.

Such justifications are not merely attempts to rationalize or justify one's actions to oneself or others. Behavioral scientists have documented an important moral dimension of commitment,

which seems distinct from other facets of commitment. For instance, studies of marital commitment and duration have identified personal, moral, and structural dimensions of commitment, corresponding (respectively) to a person's responses when asked how much he or she wants to stay married, should stay married, and has to stay married due to irretrievable investments, limited alternatives, or social approval (Johnson 1991; Johnson et al. 1999). Moreover, research in a variety of contexts suggests that the persistence of all sorts of relationships depends on the individual internalizing the welfare of specific parties. For instance, commitment to one's spouse as a person, and changes in that commitment, predict the level of self-reported love and marital discord experienced in Norwegian marriages (Swensen and Trauhaug 1985).

In sum, prior investments, structural constraints, social and moral prescriptions, cognitive consistency and self-justification motives, and the familiarity that develops over time can all drive individuals to internalize the welfare of those with whom they transact, in ways that go far beyond straightforward self-interest. The rub, however, is that researchers have found this blissful state of affairs to be very difficult to sustain over long periods of time. Consider, for example, how the authors of the just-mentioned Norwegian marriage study summarized their research findings:

Those [who developed] increased commitment to the spouse as a person over the course of marriage expressed significantly more love to their spouses and had significantly fewer marriage problems. *However, commitment to the spouse as a person declined for most couples over the course of marriage.* [Swensen and Trauhaug 1985: 939, emphasis added]

In a similar vein, Sheldon (1971) documented that the commitment of PhD scientists to their employer (a private laboratory) increased with their investments, captured by measures of age, length of service, and position level in the enterprise. But commitment to their profession also increased powerfully with work experience, beginning to undercut commitment to the organization after a moderate length of service. Sheldon found that social involvements—a high degree of involvement and identification with co-workers, on and off the job—mitigated the negative effects of professional commitment on organizational commitment. Put differently, as the scientists' commitments to the firm per se began to wane relative to their identification with the broader professional community, personal involvement and identification with their colleagues, on and off the job, became the focal mechanism for binding the scientists to the laboratory.⁶

In Section 4.1, we cited work that showed how (over)emphasizing extrinsic incentives can diminish intrinsic incentives. One explanation for this phenomenon is that emphasizing extrinsic rewards provides another rationale for the effort provided; an individual who is over-sufficiently justified (to use the language of social psychologists) need not resort to ex post rationalizations of how interesting the tasks are, or how important it was to her to do a good job. The same process, presumably, would dull the development of positive internalization; if I can rationalize help that I give you as being driven by extrinsic rewards, I am less likely to adopt the position that I do it because I care for you.

6. One cannot help but note an analogous pattern that sometimes occurs in long-term marriages, in which commitment to the spouse as a person wanes as a basis of marital attachment and is overtaken by a more vibrant commitment to the shared products of the marriage: the kids.

It is worth noting in this context that in all but the simplest of work technologies, employees must interact repeatedly with parties other than the “employer” (put in scare quotes because the employer is rarely a single individual but rather a conglomerate of hierarchical superiors, managers, etc.). In some work technologies, it is crucial that employees help one another. In some instances, strong and cooperative relationships between employees and clients are crucial to success. Our point is that internalizing others’ welfare—which would induce helping efforts or strong and cooperative relationships with clients—is a possibility in virtually any long-term relationship. Moreover, employers have levers with which to control the extent and nature of this internalization, such as job rotation policies, workplace architecture, workforce demographics, and job titles. Of course, before an employer can employ these levers, she must first analyze where internalization is desirable and where it might work against her own interests. An appreciation of this social psychological process, of both its impact on economic outcomes and on the ways and means of controlling it, can be very informative in the study of particular job designs.

4.4. These Phenomena in the Economics Literature—and the Issue of Changing Tastes

A few economists have written papers concerning the psychological phenomena described above, although this work is not always cast in the employment context. Three important streams in the literature are:

- Frey (see, e.g., 2008) stresses the sorts of explanations given by Deci; i.e., the importance of autonomy to intrinsic motivation.
- Fehr and his associates present a series of experimental papers that put particular emphasis on the norm of reciprocity and the role of gift exchange. A survey of this work is provided in Fehr and Falk (2002).
- Gneezy and Rustichini (2000) provide some field data that they interpret as an example of extrinsic incentives driving out intrinsic motivation in the context of picking up children at the end of the day from daycare.

In addition, two papers by Bénabou and Tirole (2003, 2007) concern these phenomena and, in particular, an important methodological issue. At the start of Section 4, we said that accommodating these phenomena was “simply” a matter of introducing into the utility function of employees such arguments as the enjoyment of a specific task (i.e., performing the task raises utility directly); a primitive desire to do a good job or to conform to a particular norm; a propensity to reciprocate, especially to reciprocate a gift; or the welfare of another party. But, in fact, things are a bit more complex than simply putting those arguments into the utility function, because the phenomena we have described involve interactions between those arguments and things like the degree and salience of extrinsic, contingent rewards; the degree to which the individual perceives herself to be autonomous; and the degree to which a reward is perceived to be a gift. To develop formal models of the phenomena described, one requires either a utility function with complex interactions among its many arguments or—more simply, but more controversially—a model of endogenously changing tastes, where what the employee wants today concerning her efforts tomorrow is not what she will want tomorrow concerning those efforts. Behavioral models along these lines, particularly models of economic behavior

with changing tastes, have become increasingly fashionable. But such forays into behavioral economics are still regarded with considerable suspicion by many mainstream economists.

Bénabou and Tirole, then, seek to explain the phenomena within a standard model, in which the economic actors have the standard sort of preferences. In Bénabou and Tirole (2003), a principal has private information about how onerous a particular task is for the agent. When and if the principal puts in place extrinsic rewards for good results, the agent (correctly) infers that the principal knows this task to be onerous, and she (the agent) is less intrinsically motivated to perform. In Bénabou and Tirole (2007), the agent has private information about how intrinsically motivated she is in general. Even if she is not intrinsically motivated, it is good for her to pretend to be, because of the treatment she will then receive from this principal or in other engagements, and she will therefore act as if she were intrinsically motivated, as long as doing so sends the “right” signal. But when and if the principal puts in place extrinsic rewards, consummate performance by the agent is no longer as powerful a signal; the agent might be responding (only) to the extrinsic incentives. The signal she wanted to send is jammed, and she acts as if she were less intrinsically motivated (closer to her true preferences) as a consequence.

These are very clever models, and Bénabou and Tirole argue that they fit well with specific phenomena observed in the field. Nonetheless, they involve a degree of calculativeness (each involves a complex signaling equilibrium) that we find somewhat implausible, especially in light of some of the experimental evidence, and they are not in accord with the psychological accounts of what is happening. So we continue to hold that understanding the psychological and sociological underpinnings of behavior is crucial to understanding incentives and motivation in employment, even at the cost of models in which utility functions sport arguments with which economists are largely unfamiliar and in which those utility functions—viewed as they should be, as modeling artifacts of revealed preference—may change according to the individual’s experiences and environment.

5. “How Am I Doing?”: Social Comparison, Procedural and Distributive Justice, and Status Consistency

In an ongoing employment relationship, participants continually must answer the question, Am I being treated appropriately? In a game-theoretic equilibrium, an objective, absolute standard must be met, but in real life, matters are not so simple. A host of social, psychological, and sociological factors play a pivotal role here.

For one thing, employees mix absolute standards with relative ones: They ask how they are being treated relative to others in the organization. These social comparisons can be with hierarchical subordinates or superiors, but perhaps most often they involve peers who are socially and/or demographically similar. Moreover, the social comparisons that are made are manipulable. Cognitive and social psychologists have demonstrated convincingly that the nature and extent of social comparisons can be influenced by such factors as formal categorical distinctions (e.g., job titles and subunit distinctions), physical propinquity, frequency and intensity of contact among group members, group demography (how similar members are), and the purpose or motive being served. Organizations have control over all these factors, in some cases at little or no incremental cost.

Theories of procedural and distributive justice offer a somewhat more specific formulation of how comparisons and equity judgments are made and assessed. Having identified a referent that (by virtue of functional role, social standing, or demographic traits) is viewed as comparable, person A compares the perceived ratio between rewards and output or performance for himself to the equivalent ratio for the referent.⁷ Experimental and field research in a host of organizational settings has demonstrated that the process by which rewards are determined and distributed is also highly influential (Lind and Tyler 1988; Tyler 2010). One should not put too much weight on the prescriptions of simple agency theory, but it is easy to construct toy agency-theoretic models offering prescriptions that are utterly contraindicated by these social psychological considerations. Imagine, for instance, an agency problem in which persons A and B must each independently take an action. Independent outcomes for A and B are observed. If X is the desired action, agency theory says to reward A most highly when the observed outcome has a relatively high likelihood if X is taken, relative to the likelihood of X under other actions.⁸ If B operates independently, and the connection between B's actions and outcomes are independent of those of A, then B faces similar incentives. And, without the appropriate monotone likelihood ratio properties (and more), this could result in a situation where A receives a greater reward, even if B's outcome is "better" for the firm. This result is fine if A and B don't engage in social comparisons or look for distributive justice. But, in real life, they often do, which complicates the agency problems facing the employer or, in some cases, even turns them on their head.

Status consistency can also play a role in these judgments. The idea underlying the notion of status consistency is quite simple: when an individual occupies multiple positions that differ markedly in their typical expectations and entitlements, he or she experiences a set of psychological stresses associated with this inconsistency. Some research (e.g., Jackson 1962; Hornung 1977; Bacharach et al. 1993) has documented emotional, psychosocial, and even physical strains associated with occupying multiple roles that vary markedly in their status or prestige (e.g., the CEO who is 20 years younger than everyone else on her leadership team or the London cabbie who received his doctorate in Classics from Oxford). However, the empirical results are far from conclusive or consistent, and this simple idea has proved astoundingly difficult to pin down theoretically or empirically. It raises all sorts of niggling questions about the referent against which to compare those in inconsistent situations; how to disentangle "inconsistency" effects from the main effects of the respective statuses; how to deal with change over the life course (if a person experiences upward mobility on one dimension but not on the others, does that have the same effect as experiencing "cross-sectional" inconsistency?); and so on.⁹

Notwithstanding these difficulties and ambiguities, there is considerable intuitive appeal to the notion that the utility employees derive from a particular allocative regime at work may depend on their relative standing in status hierarchies outside the workplace. For example, numerous quantitative and ethnographic accounts of the feminization of occupations document

7. The literature has identified a multiplicity of ways in which individuals respond to perceived equity, such as altering perceptions of rewards or performance for themselves or for the referent, altering their choice of referent, seeking to transform the allocative regime, or disinvesting psychologically in the activity or role at issue.

8. We are being very rough here, but readers versed in agency theory will know what this statement means.

9. For a trenchant overview, see Smith (1996).

the resentment and anger men often display, stemming from a perceived loss of status as their roles become “women’s work.” Conventional measures of males’ satisfaction and organizational commitment decline as occupations become more gender integrated (Wharton and Baron 1987). Interestingly, however, there is some evidence that males working in integrated work settings are not particularly dissatisfied if they have a nonworking wife at home (Kessler and McRae 1982; Wharton and Baron 1987: 583–584). This finding suggests that among men working in previously male-dominated settings, those who retain the traditional role of sole breadwinner within their households are least troubled by the devaluation that occurs when the workplace becomes more gender integrated. Most economic models of employment and labor markets assume, explicitly or implicitly, that employers and employees compare the gains to trade against either their next-best alternative in the market or a no-trade state of affairs. But if employees are keenly attuned to their social standing relative to others and relative to how they rank in other social roles and settings, then two employees with observationally equivalent “next-best alternatives” might react very differently to identical offers or treatment from the same employer.

6. History Matters

In judgments made to answer the question “how am I doing?” and in the answers given by employees (and their employers) to such questions, history matters. There is now a massive literature documenting how anchoring and expectations mold judgments and decisionmaking, suggesting that early experiences are particularly important in determining what referents workers employ and what norms they invoke in responding to their workplace experiences. Some recent empirical studies corroborate this point. For instance, analyses based on the Stanford Project on Emerging Companies have documented a menu of five basic HR blueprints from which most entrepreneurial founders seemed to choose (commitment, star, engineering, bureaucracy, and autocracy), with the initial choice having profound and enduring consequences for the enterprises they created. Attempts to alter the initial employment model or blueprint generally had deleterious consequences for organizational survival and performance and heightened employee turnover, especially when the firm sought to change from one of these five relatively “pure” or clearly understood blueprints to one that was less coherent or internally consistent (Baron et al. 2001).

Social psychologists have also documented a widespread preference for increasing consumption and reward levels over time, even when other sequences (such as declining wages coupled with savings) would produce superior returns over time (Loewenstein and Prelec 1991, 1992). In the employment context, such a preference is consistent with the notion that initial treatment of employees establishes anchors and expectations that govern how subsequent allocations are assessed (also see Baron 2011).

History can matter in other ways. Sørensen (2000) has demonstrated that employees’ turnover propensities are affected not simply by current organizational demography—which presumably captures patterns of communication, cohesion, and the like—but also by the entire demographic history individuals have experienced while employed at their current place of work. In other words, it is not simply how well one fits in demographically with one’s co-workers

today that determines “fit” or what economists might be inclined to call “match quality”: It is the entire demographic history an individual has experienced in the work setting that influences present-day propensities to stay or remain. One cannot think of a career simply as a succession of job titles, responsibilities, and assignments. It also involves a series of relationships and interpersonal experiences at work, which may have persistent effects long after the relationships themselves have withered.

7. Reputation

For organizations scholars whose background is game theoretic, the concept of reputation is often enlisted as a magic bullet when it comes to employer credibility. For instance, an employer can credibly promise to reward employees later for something done today because, if she fails to carry out her promise, she will damage her reputation for doing so, and employees in the future will disbelieve her promises. If the ongoing value of keeping her promises so that employees trust her exceeds what the employer could earn (in present-value terms) from defaulting once on her promise, it is an equilibrium for her to make and keep the promises, and for the promises to be believed.

The magic in this magic bullet comes from the Folk Theorem (and similar results). Many things are equilibria, in theory, and the model builder gets to pick the equilibrium and corresponding reputation that best suits the point to be made. More specifically:

1. The employer seemingly selects whichever equilibrium makes her best off.
2. Having selected her preferred reputation and/or equilibrium, it is in fact attained.

It is a nice story. It even makes some sense within the confines of the typical model, where actions are simple and discrete and neither the population of employees nor the set of contingencies to be met varies much. Reputations are for things like “don’t abuse employees” in a context where in each round the employer chooses between “abuse” and “don’t abuse.” In such a simple context, it makes sense that prospective employees will conclude that this is a valuable reputation for the employer, so she has instant credibility upon adopting it.

But this story does not match the complexities of the real world. Actions are not always discrete, and when they are, more than two or three options are usually available. Employees vary in their tastes and personal circumstances, and the employer must deal with a host of employees who vary along demographic, educational, and cultural lines, to say nothing of the types of work they do. The contingencies that must be met in specific situations vary enormously.

In real-world applications of this idea, reputations must be acquired, not announced. Assuming that the reputation inheres in the employer, it must be comprehensible to present and prospective employees. This is not simply a matter of learning what the reputation is. The core of a reputation construction is that the parties whose actions the reputation influences must be able, *ex post*, to verify that the reputation bearer acted in conformance with her reputation. Otherwise, the reputation exerts no constraint on the actions of the reputation bearer *ex ante* and has no particular value (as far as endowing credibility is concerned). So comprehensibility here entails a measure of *ex post* verifiability.

All these considerations point to several conclusions that bring us into the domain of sociological and psychological concerns:

1. Reputations must be relatively easily understood, communicated, and verified. They should reflect relatively few clear, simple precepts that are psychologically powerful and inexpensive to communicate.
2. To aid in understanding, it is helpful if reputations (bearing on workplace relations) mimic or are consistent with norms and roles routinely encountered elsewhere in the society. “They treat you like family at that firm” or “that’s entirely a ‘best athlete’ culture” or “it’s ‘dog eat dog’ when you work there” are the sorts of themes we have in mind. The Stanford Project on Emerging Companies research mentioned earlier found that there was not one efficient design or blueprint for the HR management policies of a high-tech Silicon Valley start-up; rather, there were five, each reflecting a relative clear and consistent pattern that could be communicated parsimoniously (e.g., “autocracy” versus “star” culture). Moreover, altering the HR blueprint resulted in dislocation and diminished organizational performance, as employees struggled to understand the new pattern of expectations. But the disruptions were less severe when firms shifted from an aberrant or incoherent blueprint (i.e., one not fitting into any of the five basic types) to one of the more prevalent and consistent types.¹⁰
3. Efficiency is enhanced by hiring individuals who commence employment with a superior understanding of the firm’s informal practices and culture and whose background enhances their prospects for understanding those practices and internalizing the culture. For instance, notwithstanding its pernicious aspects, hiring through alumni networks or on the basis of internal referrals not only enables employers to get more and richer information on applicants, it also increases the likelihood that those hired will have expectations that are closely aligned with those of their superiors. Firms that mimic the military in management practices are inclined to hire from the military, and so forth.

7.1. Consistency of Practice in an Organization

Reputation comprehensibility and credibility require that “similar” employees in an organization must be treated with sufficient uniformity that a coherent picture of how the organization does business emerges. This requirement can limit the activities of the firm or specific subunits in the firm. For instance, a firm claiming to “treat employees like family” might expect to confront more difficulty and cost in outsourcing some of its activities, unless those outsourced activities involve employees who are conspicuously different socially from core employees. And, in such cases, it helps to minimize contact between the outsourced labor and the core employees—the

10. The exception to this pattern involved shifts to pure bureaucracy or pure autocracy. These invariably were destabilizing (inducing high turnover), irrespective of the initial HR blueprint being supplanted. Bureaucratic and autocratic cultures are universally reviled among scientific, technical, and engineering talent in Silicon Valley; hence, even when companies replaced an incoherent employment blueprint with a coherent bureaucratic or autocratic one, employees responded negatively. Put somewhat differently, when diners hate the dish, calling attention to it, making it easier to recognize, or serving larger portions only makes things worse.

archetypal example here is the custodial crew, which (only) comes in at night after core employees have left. But this family-culture firm is likely to find outsourcing menial tasks superior to insourcing them, if the employees performing these tasks are going to be treated menially.

To be sure, developing a consistent reputation does not require that all employees be treated the same in all respects. Almost every enterprise of any scale and complexity is vexed by the issue of how much uniformity to impose across subunits and localities in rewards, organizational structures and practices, and workplace cultures. It is self-evident that uniformity will be most problematic when the tasks involved are highly disparate among subunits or localities and when the labor markets in which tasks are carried out vary markedly. But we can offer some other conjectures and guidance by drawing on relevant psychological and sociological scholarship. Intra-organizational variation in HR practices across subunits and locales is likely to be most problematic when it is imposed

- on organizational units or locales whose employees share strong social connections,
- in organizations whose business strategy necessitates significant cooperative effort across units or locales,
- across geographical locales with similar regional or national cultures (Hofstede 2001), and
- across units or locales whose employees are in frequent contact and/or share abundant information.

Because of what might be thought of as psychological and sociological complementarities, differentiation among units or locales is also likely to be most contentious for organizations that knowingly or unknowingly foster uniformity among their employees in other ways. Examples might include extensive reliance on companywide jargon and centrally issued corporate communications, mandated stints at corporate headquarters by field personnel to soak up “HQ culture,” or frequently rotating personnel geographically. Organizations may also foster uniformity of thought and behavior among employees by virtue of their linkages with particular sources of personnel, such as hiring heavily from the military, American schools worldwide, or religious schools, all institutions that themselves foster a certain degree of uniformity. And uniformity is likely to emerge when Organization X faces the same key supplier(s) or customer(s) across its divisions or locales, and those partner organizations themselves have very distinctive and uniform cultures and practices. The exigencies of collaborating with such partners will mandate a degree of cultural and behavioral uniformity across X’s different divisions or locales, which complicates efforts to diversify local compensation systems, organizational practices, or cultural edicts.

7.2. Dynamics: Acquisition and Change

To maintain a reputation for behaving in some manner, it is manifestly important to behave in that manner. But to *acquire* a specific reputation, one must convince the intended audience that one *will* behave in that way. In some situations, the opportunity to demonstrate the desired behavior occurs naturally. For instance, a party seeking to dissuade others from challenging it—in the fashion of the chain-store paradox—fights when challenged and, it is hoped, slowly dissuades challenges. In cases where the reputation is specific behavior that elicits trust from

others, bootstrapping the reputation is harder to imagine. In the simple situations of game-theoretic models, no one will trust someone who lacks a reputation for being trustworthy, and if no one trusts that party, the party never gets the opportunity to verify its trustworthiness. Either a leap of faith is made at the outset or, seemingly, it is not.

Bootstrapping this sort of reputation and equilibrium may be informed by social-psychological considerations. One might induce one party to make the necessary leap of faith and then, by treating that party well, slowly convince others to do likewise. One might begin with members of one's family or social acquaintances, individuals with a predisposition to trust. Trustworthiness might be "borrowed"—for example, by forging an alliance with a central, highly respected member of the local union or professional association, convincing that individual of your good intentions, and enlisting that individual to recruit others. Or a reputation for trustworthiness might be built in small steps: a party induces others to trust her in little things, again perhaps relying on related social exchanges, and then moves to bigger, and then even bigger, items. Whatever the means, it is clear how important founding circumstances and conditions are when it comes to establishing a reputation. Initial impressions are powerful anchors for subsequent expectations; stories about "the early days" can be used as vivid tools of acculturation, and changing a reputation, once it is established, can be a very difficult endeavor.

There is clear evidence that this sort of change in premises and expectations—and reputation in general—is regarded by managers as being of the utmost importance. For example, a study of 765 CEOs by IBM Global Business Services (2006) found that chief executives across diverse firms, industries, and nations were increasingly seeking innovation by transforming their organizations' underlying business model, rather than focusing simply on changes in operations or products and markets. The most frequent focus of such change initiatives was organizational structure, mentioned by roughly two-thirds of CEOs who were seeking to transform the business model for their enterprises. And when asked to identify the main obstacles to innovation they confront, "unsupportive culture and climate" topped the list, with "workforce issues" also represented among the most frequent responses.¹¹ A survey of leaders in 365 companies in Europe, Asia, and North America by Bain & Company highlights the difficulty of transforming organizational cultures: 68% of leaders responded that culture provides the greatest source of competitive advantage; 81% stated that an organization lacking a "high-performance culture" is doomed to mediocrity; 75% said that culture can be changed; and 65% admitted that cultural change was necessary in their own organization (Rogers et al. 2006). Yet, according to the study, fewer than 10% of firms actually succeed at achieving this cultural transformation.

The fact that cultures and HR systems are difficult to change should come as no surprise. Organizational cultures, reward systems, and control structures would have little value were they not difficult and costly to change. Or, to put it more in the language of competitive strategy, they would confer little competitive advantage if the currently most efficient system were easily imitated. But why is this so? If one accepts the game-theoretic constructions of reputation, it

11. Among internal obstacles, roughly 35% of CEOs mentioned unsupportive culture; 34% cited "limited funding for investment," and about 27% cited workforce issues. Only one external obstacle was cited by more than a fifth of the CEOs: "government and other legal restrictions," cited by about 31% of chief executives.

ought to be possible, when a superior alternative comes along, to tear up the old (implicit) agreements and initiate the new ones.¹²

We believe that an important sociological and psychological effect is at work here, having to do with the almost unconscious legitimacy of a given system in the minds of the employees and employer. To give a (psychological) analogy, people have internalized norms about interpersonal distance and turn-taking in conversations, which vary in rather subtle ways across contexts. We do not pay conscious attention to these norms unless or until we happen to observe them being substantially violated (e.g., you “can’t get a word in edgewise” or someone is literally “in your face”). And the lack of conscious attention can promote efficient interpersonal interactions. Of course, individuals do pay some conscious attention to these things—for instance, by asking whether they themselves are talking too much.¹³ But it is in the most relaxed and “natural” social settings that the least conscious attention is paid to them.

Similarly, we believe that much of the force and value of organizational control systems stems from their tacit and taken-for-granted character. Making controls explicit and salient generally entails costs—not only the costs of formulating and implementing explicit rules and controls, but also the costs of monitoring adherence to them. As we have argued, intense, formal, and explicit controls can also undermine intrinsic motivation and commitment processes, which often can provide more powerful and less expensive means for aligning employees’ perceived interests with those of the enterprise. And, as Baker et al. (1994) have noted with regard to subjective performance criteria, tacit rules and controls may be more difficult for employees to circumvent; they also have the potential to broaden and generalize, subsuming a wide variety of contingencies for which no explicit provisions have been made.

It should be clear how all these considerations relate to changing a firm’s reputation or organizational culture: Attempts to make changes will raise the level of salience of matters that have heretofore been tacit and implicit. This calls into question longstanding norms and expectations, often altering the categorizations and social comparisons to which employees have become accustomed and acclimated. And by opening up one set of issues, it raises the possibility that everything should be put on the table. Having started this chapter by recounting standard transaction cost economics, we cannot resist the opportunity to cast our argument in those terms: Attempts to change a piece of a firm’s reputation will raise enormously the costs of adaptation and renegotiation, because it potentially takes a very efficient adaptation or renegotiation mechanism that resides somewhere beneath the full calculative consciousness

12. Mathematical economic and game-theoretic analyses are at a disadvantage on this point, because their agents are never so surprised by evolving circumstances that it makes sense to abrogate an old implicit contract and initiate a new one. In all but a handful of formal analyses, the economic actors anticipate the possibility of the specific contingency arising that would call for the new implicit arrangement, and the original arrangement includes an understanding of what will happen when and if the contingency arises. Formal and explicit contracts may be renegotiated, and old formal contracts may be important points of departure for the new agreements that are reached. But at the outset, everyone understands that if the specific contingency arises, this is what will happen next. So essentially, the old equilibrium, in the full sense of the term, is never modified. In that sense, the question being asked here is entirely outside the realm of economics or, at least, of standard economics.

13. Though it is seldom those who are talking too much who ask the question.

of employees and replaces it with some very conscious calculations about the overall legitimacy of the firm's employment transactions.

7.3. The Economizing Principle

These considerations bring us full circle to one of the basic premises of transaction cost economics, at least as presented by Williamson (1985). Williamson argues that the basic unit of analysis should be the individual transaction and, further, that one should expect that transaction to adopt whatever form of governance maximizes benefits from the transaction, net of transaction costs. The social and psychological effects we have discussed in this chapter suggest that his argument should be amended to some extent. First, individual transactions are important, but transactions are embedded in a social environment that cannot be disregarded. Furthermore, transactions are linked together—how firm A transacts with employee X powerfully constrains and is powerfully constrained by firm A's dealings with employees Y and Z. The individual transaction is, of course, important. But, especially in the intense social environment of employment, the constellation of transactions firm A has with all its (diverse) employees, situated within the particular society in which those transactions take place, may be the more appropriate unit of analysis.

And although a firm's constellation of transactions may tend toward the structures that maximize efficiency net of transaction costs, history—particularly the history of a firm's past management practices and relations with its employees—makes this only a tendency, not an indomitable economizing force. When confronted with secular changes in market conditions, we should expect to see firms, especially larger and more established ones, trapped in employment practices that no longer appear as fit as they once did. If employment were only an economic relationship, this might not be so. But employment's social character means that any economizing has to take into account the costs arising from the social and psychological processes we have discussed, as well as the economics of the situation.

8. Conclusion

In after-dinner remarks celebrating Oliver Williamson and his book *Markets and Hierarchies*, Jim March developed the simile that economists were well-regulated and orderly Methodists, who crave order and simplicity and know very well to stay away from what March termed "the saloons of sociology." Economists reading this chapter may be forgiven for thinking they have been touring one such saloon. Thinking of employment relationships as both economic and social relationships and, in particular, culling useful insights from social psychology and sociology, is not especially edifying if one craves the order and simplicity of Debreu's (1959) *Theory of Value*. For at least one of the two authors (Kreps), who masquerades as an economist and who has those cravings, writing this chapter was a frustrating exercise in trying to impose neat and tidy order on a messy collection of important ideas.

Yet when it comes to employment—and probably other forms of long-term economic exchange—that is the nature of the beast. It may not be pretty, at least to an economist's aesthetic sense, but incorporating psychological and sociological influences into economic models of employment relationships is useful for scholarship and managerial practice. And although

these influences may not be as neat and tidy as economists like, they present important specific and generalizable insights:

- Knowledge about the psychological and sociological factors that foster commitment, promote organizational citizenship behaviors, build and maintain cohesive groups, and sustain adherence to norms (especially the norm of reciprocity) can be marshaled to identify where and when solutions inspired by agency theory are inefficient and even dysfunctional. The need for incentives or controls diminishes when employees are intrinsically motivated, can be motivated to reciprocate what they perceive as gifts, or internalize the welfare of co-workers and the firm generally. Especially when explicit incentives and controls are most difficult to get right—when employees must work innovatively, autonomously, and interdependently, and when they must deal with ambiguous and unanticipated contingencies without explicit control or oversight—high-powered incentives and controls may not only be less efficient; they may become dysfunctional, if they dull the more efficient motivations employees already have to “do the right thing.”
- The processes by which individuals perceive and judge their own situations are rarely as straightforward and objective as is assumed in economic models. Anchoring and recency effects, social comparisons, and status consistency all play their roles, and perceptions and judgments can be profoundly influenced by what (to many economists) seem to be irrelevant facets of the social environment beyond the workplace.
- History powerfully shapes the behavior of individuals and organizations; to understand current patterns, one does well to study the course of past experiences. Reputation concerns can powerfully shape what a firm can and cannot do with its employment practices. Indeed, they can lead firms to decide not to alter their cultures or HR policies, even in the face of powerful environmental pressures.¹⁴
- Attending to differences in the psychological and sociological resonance of different incentive and control systems is also likely to prompt a reranking of various alternatives for rewards and organizational designs, relative to an ordering based solely on the direct and transactional costs and benefits associated with the production process. Approaches

14. An example that comes to mind concerns AES Corporation, a global power company founded in 1980 by two former government energy officials with strong moral and religious convictions, convinced that an energy company free from the bureaucratic constraints, functional specialization, and disempowering practices commonplace in the industry could produce extraordinary results. They built their culture around four core values: integrity, fairness, social responsibility, and having fun. In mid-June 1992, nine technicians at a new AES plant in Oklahoma conspired to falsify water test data required by state and federal regulators. Following these revelations, the firm's share price dropped by nearly 40%. The plant management, under intense pressure from lawyers, abandoned most of the company's distinctive HR practices. According to one of the firm's founders:

I mean, they just went for a total control kind of mentality, because they were scared to death . . . They basically fired me. They said “Please do not come back to the plant.” . . . [It] was a real test of whether we were going backwards toward centralization . . . And we went along with it. I wouldn't go there for a whole year, and they finally called back and said, “We'd like you to come back again, we'd like to rejoin the company.” . . . [It] illustrated a couple of things. One was that we did mean it when we were talking about decentralization and autonomy. And second, it proved . . . [that] support for AES principles was surprisingly strong.” [Pfeffer 2004: 15–16; also see Bakke 2005]

that mimic or leverage values, attitudes, and behaviors that employees embrace frequently and fervently outside the workplace are likely to be easier and less costly to implement and sustain. This is true as well for approaches that leverage personal bonds and reputational concerns among employees outside the workplace, which is why firms and labor unions have sometimes embraced nepotistic practices. It is also one reason firms often take steps to get their employees deeply engaged in activities and institutions in their local communities.

Stated simply, what traditional models of economic exchange miss in the employment context is that many of the tasks for which employees are being compensated involve interaction with other human beings, inside and outside the organization. Those interactions occur in a social and cultural context from which employees cannot escape, and they manifest cognitive and social psychological processes that employees cannot put on hold (at least entirely) simply because the exchange is work related.

Having preached this message to incredulous economists over the years, we know that there will be objections. A standard rejoinder is that behavior is not as complex as we have claimed. And those making this rejoinder will point to organizations run according to a basic design right out of an agency theory primer, in which employees act just as agency theory predicts they will.

We do not doubt that such organizations can be found; they are part of the organizational menagerie. But they are only part, and their existence is entirely consistent with our view of things. One of our messages, after all, is that the style of on-the-job interactions can have a profound impact on their content. For the principals of agency theory to be able to carry out their prescribed role effectively would seem to require considerable detachment from the agents, lest a clever and cohesive band of agents manage to co-opt a vulnerable principal and play him or her against the remaining principals. (There are strict rules in prisons limiting fraternization between inmates and the guards whose job is to control them.) Yet a firm in which owners and managers adopt such a stance toward employees is a very different kind of firm simply by virtue of that stance, particularly in the employment context, where the inmates often have some role in determining who becomes their guard. Certainly, an HR blueprint will tend to attract and retain employees who are comfortable in enterprises run in that fashion. But the blueprint chosen for the firm will influence much more than that: the kinds of productive activities at which the firm's employees are likely to have an advantage; the intensity of social bonds that are likely to form among the labor force; and, perhaps most importantly, how both agents and principals come to think about their own and one another's roles. This endogeneity can produce among employees precisely the attitudes and orientations that the principals initially believed justified the incentives and controls put in place (e.g., effort aversion, lack of trustworthiness, lack of loyalty), creating a self-fulfilling prophecy.

Let us put it this way. Economists are sometimes demonized for creating their own (demonic, self-interested) reality. Much has been made of the fact that in a variety of experimental situations, economists and economics majors pursue more self-interested strategies than their counterparts in other professions or academic majors. They also contribute less to charities and public television than equally wealthy individuals in other occupations. And longitudinal studies indicate that these propensities increase with exposure to microeconomic theory (see Frank et al. 1993). Regardless of how one feels about economists' self-interest, it is precisely this sort

of effect that we assert will take place in the context of employment. Different approaches to pay and control systems foster different ways of thinking, believing, and acting, which in turn shape the way that principals and agents think about the roles of each.

Economic models of employment should be tested not simply by asking, “do employees at firms that are run the way economic orthodoxy says firms should be run behave the way orthodoxy would expect them to?” One should also ask, “do employees at firms run on wholly different principles and blueprints behave in different ways? And when it comes to performance (the measurement of which is likely to become the next point of contention), is one way of managing human resources superior?”

Our answer is clear. Looking at a broad spectrum of employment situations, blending social insights into economics will increase the R^2 in analyses of organizational designs and incentive systems. But we believe it will do much more than that. It will illuminate the diversity of management regimes that can flourish in a given setting. It will clarify the complexity and fragility of those regimes and the challenges of trying to optimize employment relationships dynamically. And, in the process, it will produce insights that not only invigorate the scholarly study of organizational economics but also prove managerially useful.

Authority in Organizations

A Survey

Patrick Bolton and Mathias Dewatripont

1. Introduction

Much of the theory of the firm has been concerned with what determines the boundaries of firms. When does a firm reach its efficient size? When does a merger between two separate entities improve efficiency of production? Which core activities should a firm focus on, and which should it outsource? A central achievement of the property rights theory of the firm (Grossman-Hart-Moore) is that these questions can all be framed in terms of an allocation problem of control rights or property rights over productive assets. That is, all questions relating to the boundaries of the firm can be phrased in terms of who should own which productive asset.

As powerful as this framework is for analyzing the boundaries of firms, it has little to say about what actually goes on inside firms and how firms should be organized internally. When it comes to understanding what managers do it is not very helpful to reduce firms to just a collection of productive assets and a set of owners. One needs to step back from this extreme abstraction and introduce elements from Coase (1937), Simon (1951), and Williamson's (1975, 1979, 1985) transactions-cost theory of the firm. In his foundational article Coase (1937) envisions firms with internal transactions processes that are different from market processes. He describes firms as relying on authority procedures in completing production and distribution of goods rather than on negotiation and exchange as in a market: "the operation of a market costs something and by forming an organisation and allowing some authority (an 'entrepreneur') to direct the resources, certain marketing costs are saved" (Coase 1937: 392).

Thus, what is special about internal transactions in firms is that they are based on a different mechanism, which we shall refer to in general terms as *authority*. This mechanism is a central and integral part of the process of production and distribution of goods. The exercise of authority broadly defined is what managers do. As we detail in the definition below, managers' day-to-day job is to execute the broad mandate that is handed to their teams by their superiors, to coordinate the execution of this mandate by their subordinates, and to keep tabs on what their subordinates

are doing. Although the notion of authority is quite broad and complex, it is interesting to observe that almost all of its multiple facets are relevant to firms, how they are organized, and how they are run. Following Fama and Jensen (1983), let us define four main different aspects of authority:

1. Authority is a supervisor's power to initiate projects and direct subordinates to take certain actions.
2. Authority also involves the concomitant power to exact obedience. For if the supervisor was unable to get his subordinates to execute the directed actions and had to coax a negotiated agreement from the subordinate each time an action is required, there would not be much point in granting a manager the power to direct subordinates.
3. Authority is the power to ratify and approve actions in a predetermined area of competency. Formal authority in a firm rests with the firm's owners, who have the ultimate right to make decisions and to delegate authority to managers. In owner-managed firms there is full centralization of decisionmaking authority with the owner(s). In larger firms authority is delegated to a board of directors, and in turn to a professional management team and managerial hierarchy. However, this delegation of authority only stands if managers' power to ratify and approve action has been previously delineated.
4. Finally, authority also involves the manager's duty to monitor subordinates and her ability to reward them for good performance.

A central question for the theory of the internal organization of firms is the allocation of authority among its members. How to define lines of authority? How to circumscribe the authority, of any given agent? How to credibly delegate authority, and how to ensure that the exercise of authority is respected? A fundamental theme uniting all contributions surveyed in this chapter is that the role of authority and its separation from ownership rights arises from the presence of information processing and communication costs. The firm owner's inability to attend to all decisions involving the operation of the firm, his inability to master all relevant information to make decisions, and his limited capacity to communicate with all employees are the main reasons authority is separated from ownership. The same reasons are also the source of Coase's marketing costs, which authority procedures inside firms seek to economize.

In this chapter we survey the recent economics literature on the internal organization of firms that deals with authority inside firms. The literature surveyed in this chapter builds on the foundational works of Max Weber, Herbert Simon, Alfred Chandler, Anthony Downs, and Oliver Williamson, among others, but seeks to frame some of the core ideas of this literature in the language and formalism of modern contract theory. In the process, this literature offers new perspectives and sharper intuitions on the delegation of authority in organizations. Our goal in this survey is to provide a unified presentation of this contracting literature. A central question this literature is concerned with is how the ultimate holders of formal authority, the owners of the firm, are able to credibly delegate authority to managers further down the organization. A related question is how authority is optimally allocated inside the firm. To address these questions, it is helpful to begin with a taxonomy of contract-theoretic models, which will allow us to discuss the outline of this survey.

2. A Taxonomy of Contract Models

As a way of organizing the literature, it is helpful to distinguish between three different categories of contract models that differ in the degree of enforceability of contractual agreements. The first, classical, category assumes that essentially every transaction, service, or trade that is observable is enforceable. In particular, in the classical contract theory paradigm it is assumed that agreements on both *ex ante* and *ex post* action choices are enforceable. Under these broad enforceability assumptions the contracting parties are able to write an optimal comprehensive contract that fully determines how the game between the parties is played. There is then no role for an authority mode, as—so to speak—the contracting parties are then simply executing the prescribed actions by the mechanism designer under the optimal contract.

A second category of contract models allows for weaker enforceability assumptions, whereby some *ex ante* agreements on future action choices are not enforceable. *Ex post* agreements on *ex post* action choices, however, continue to be enforceable. The justification for these assumptions that is commonly given is that although agreements on action choices are easy to describe *ex post*, they are impossible to describe *ex ante*. The incomplete contracts literature following Grossman and Hart (1986) and Hart and Moore (1990) is the prime example of this category of models. It involves only partial contracting—to use the terminology of Aghion et al. (2002)—in the sense that the contracts that are superimposed on the underlying game between the contracting parties do not fully determine how the game is played. Some actions typically remain to be determined *ex post*. This category of contract models introduces the notion of ownership as residual rights of control, by defining a right of the owner to determine *ex post* all actions left unspecified in the *ex ante* contract. This is an important advance toward a formalization of authority, but as we shall argue, the assumptions about contractual enforcement must still be further weakened to be able to fully formalize the notion of authority. This framework (where only agreements on future action choices are not enforceable) opens the way for a theory of the optimal allocation of *ex post* bargaining power. However, it does not lead to a theory of authority over actions.

To be able to model the concept of authority, the assumptions about contractual enforcement must be weakened still further to allow for the nonenforceability of both *ex ante* and *ex post* agreements on action choice. This third category of contract models can be subdivided further into two subcategories: models where allocations of control are enforceable even though agreements over action choice are not, and models where neither agreements over action choice nor allocations of control rights are enforceable.

The category of models assuming contractible control focuses on the decision rights facets of authority (parts 1 and 3 in our definition) and allows for the formalization of three different notions of authority, which we refer to as *horizontal*, *vertical*, and *contingent authority*. Section 3 addresses horizontal authority, which deals with issues relating to the delineation and assignment of tasks or missions to individual agents; Section 4 focuses on vertical authority, which is concerned with the definition of lines of authority, precedence, and responsibility; and Section 5 deals with contingent authority, which addresses the rationale for and merits of temporary assignments of authority over specific issues or projects.

After reviewing these contractible control models, we turn in Section 6 to models with noncontractible control, which focus on the interpersonal facets of authority (parts 2 and 4 in our definition). In these models the agent has effective control over actions (because of the

principal's limited attention) but the principal will still want to align the agent's objectives through some incentive scheme. He may still attempt to "get his way" by incentivizing agents to do what he wants (as in classical moral hazard models), by partially monitoring agent's actions (as in efficiency wage models), and through relational contracts, or persuasion. We follow Van den Steen's (2007, 2010) terminology and refer to these models as models of interpersonal authority.

Finally, Section 7 offers concluding comments and suggestions for future research.

3. Horizontal Allocation of Authority: Multitask Perspectives

While the early contracts literature on the economics of organization based on the principal-agent framework by and large simplified the agency problem by assuming that agents are only responsible for a single task ("hidden effort"), contributions of the past decade have recognized the need for a broader perspective. Managers, workers, and bureaucrats not only need to be motivated to work but also must be incentivized to optimally allocate their attention among several different activities they are responsible for. Their allocation of attention to the different tasks is determined both by the relative (intrinsic or financial) benefits they derive from the various tasks and by the technological complementarity or substitutability across tasks. This section discusses how the multitask principal-agent framework can shed light on the organizational problem of horizontal allocation of authority.¹

3.1. A Framework

Consider the following multitask incentive problem, where π_i denotes the level of output on task $i = 1, \dots, m$. The distribution of output can be altered through the agent's allocation of effort (or attention) across tasks. The principal has access to a population of identical agents who can exert effort on the various tasks. The principal is interested in maximizing the expectation of an output function ψ , which depends on the vector of statistics π minus the wage costs of the agents he hires. A special case that we shall refer to for most of the discussion below is the functional form $\psi(\pi) = \sum_{i=1}^n \pi_i$. In reduced form, we can define $\Psi(a) = E[\psi(\pi) | a]$, where a is the constellation of the agents' effort vectors. For an individual agent, an effort vector $a = (a_1, a_2, \dots, a_n)$ has utility cost $c(a)$. An individual agent's objective function is a (linear or concave) separable function U of her wage w minus her effort cost $c(a)$.

The first-best efficient outcome is achieved if effort a is directly contractible. It is obtained by maximizing the principal's gross payoff $\Psi(a)$ minus the agents' wage bill, which is just sufficient to induce them to accept the employment contract of the principal (participation constraint). The first-best cost of obtaining effort a from an agent is given by the function $U^{-1}(U^* + c(a))$, where U^* is the agents' reservation payoff. Whether it is optimal to rely on one or several agents depends on the shape of this function, which is affected by the level of the reservation utility and the curvature and economies of scale and scope of the cost of effort function $c(\cdot)$.

Noncontractibility of effort, however, means adding to the maximization problem of the principal an incentive constraint on top of the participation constraint. This incentive

1. See Dewatripont et al. (2000) for additional details.

constraint takes into account the impact of agents' efforts on the level of the contractible variables and on wage levels. What can be contracted on is only the outcome $F(\pi_1, \pi_2, \dots, \pi_m)$, which can be a scalar or a vector. In general, the dimensionality of the contracting problem an organization faces depends on both the number of tasks m and the number of outputs m . The traditional single-task principal-agent problem with output as the only performance measure involves $n = 1$ and $F(\pi_1) = \pi_1$. In this section we survey a number of approaches on horizontal allocation of authority for the multitask case ($m > 1$). The constrained optimization problem for the multitask case then takes the following form:

$$\max_{a, w(F(\pi_1, \pi_2, \dots, \pi_m))} \Psi(a) - E(w(F(\pi_1, \pi_2, \dots, \pi_m)) | a)$$

subject to

$$E(U(w(F(\pi_1, \pi_2, \dots, \pi_m))) | a) - c(a) \geq U^*$$

and

$$a \in \arg \max_{\tilde{a}} E(U(w(F(\pi_1, \pi_2, \dots, \pi_m))) | \tilde{a}) - c(\tilde{a}).$$

3.2. Multiple Tasks and Effort Substitution

Focusing on the two-task case for simplicity, the mainstream multitask problem is based on the observation that encouraging effort on one task may crowd out effort on the other task when the cross-partial derivative of the effort cost function is strictly positive ($\partial^2 c / \partial a_1 \partial a_2 > 0$). A major theme from this literature is that when a single agent has authority over multiple tasks, then the incentive scheme must be designed to balance incentives across tasks. In a moral hazard context, if, for example, the performance on task 1 were measured more precisely than that on task 2 ($\pi_1 = a_1 + \varepsilon_1$ and $\pi_2 = a_2 + \varepsilon_2$, where ε_2 is noisier than ε_1), it would seem natural that the incentives be more high-powered on the first task (i.e., $dw/d\pi_1 > dw/d\pi_2$), for which the agent is exposed to low compensation risk. Yet if $c(a_1, a_2) = c(a_1 + a_2)$, for example, the incentive powers on the two tasks cannot differ without the agent neglecting completely the less-rewarded task.²

The cost of balancing incentives across tasks is thus that overall, the agent is given low-powered incentives even on tasks with well-measured outputs (Holmström and Milgrom 1991).³ This will lead the organization to either (1) go for a job design that gives authority to agents for tasks that are equally easy or hard to measure (with high-powered incentive schemes given only when a precise measurement is possible) or (2) assign authority over the two tasks to two different agents. Indeed, just as a profit-maximizing multiproduct firm must take into account possible cannibalizing effects of a reduction in price of one product on the sales of other

2. That is, $dw/d\pi_1 > dw/d\pi_2$ will imply $a_2 = 0$.

3. Holmström and Milgrom (1991) also discuss incentive pay for teachers: since only a subset of the skills taught to pupils can be measured (e.g., standardized math or language scores), a cost from introducing explicit incentive pay for teachers is that it can lead them to neglect general education to train pupils exclusively for the purpose of doing well on tests.

products, a principal must factor in the fact that offering stronger performance incentives along some dimension, while inducing the agent to spend more time on the corresponding task, may also divert attention from the other tasks.⁴

3.3. Conflicts between Tasks

The optimality of task separation is even clearer in the presence of direct conflicts between tasks. Conflicts between two tasks arise, for example, when $F(\pi_1, \pi_2)$ is single dimensional and depends positively on π_1 but negatively on π_2 . In this case, it is clearly hard to induce the agent to increase both π_1 and π_2 simply by providing wage incentives on the basis of $F(\pi_1, \pi_2)$. This situation arises in the following circumstances:

- Assume (e.g., Dewatripont and Tirole 1999) that π_1 and π_2 represent the amount of verifiable evidence obtained, respectively, on the pros and cons of a given decision. Efforts spent looking for pros and cons increase, respectively, π_1 and π_2 . The decision $F(\pi_1, \pi_2)$ will then depend positively on π_1 and negatively on π_2 , while ex ante the principal cares about obtaining the best possible evidence on both sides, so $\Psi(a_1, a_2)$ is increasing. Such an adversarial setup is to be expected in any situation where the firm faces a major decision that is not clear cut, such as a merger with another firm or the launch of a new product, and where the decision is improved if it is based on the best available information for or against the decision. As Dewatripont and Tirole (1999) have shown, the principal may then benefit by deliberating with two managers, each with an opposing stake in the decision.
- Managers who have to perform both ex ante and ex post monitoring of agents in the organization will face a dilemma: uncovering shirking or a faulty product only ex post reveals that the manager has failed to spot the problem ex ante. The manager may then be conflicted ex post in revealing the problem. Separation of ex ante and ex post monitoring can then help avoid cover ups (see, e.g., Boot et al. 1993; Dewatripont and Tirole 1994).⁵ Interestingly, such a separation has been implemented in the area of banking regulation in the United States: the Office of the Comptroller of the Currency (OCC) is in charge of the ex-ante monitoring of banks, while the Federal Deposit Insurance Corporation (FDIC) is in charge of ex post intervention in case the bank is in trouble.

4. Other interesting implications of this framework in terms of job design include the following topics:

1. *Helping coworkers in organizations* (Itoh 1991; Auriol et al. 2002): Managers facing high-powered incentives on their own performance will probably spend less time helping their fellow managers. In academia, individual research incentives may lead to reduced effort in teaching and/or interaction with students and colleagues.
2. *Multiple principals and exclusivity* (see, e.g., Martimort 1996): Effort substitution induces principals to compete for the agent's attention. This leads to incentive schemes that are too high powered and may justify exclusivity (the agent being forced to deal with a single principal).

5. Of course, separation of tasks also involves duplication of effort and moral hazard in teams à la Holmström (1982a).

3.4. Implicit Incentives and Missions

Multitask problems giving rise to a horizontal authority allocation problem are also present when there are no (or not only) explicit incentives in place to motivate managers, such as when managers are mainly motivated by career concerns or their reputations, as in Holmström (1982b). In the standard career concerns model the managerial labor market tries to infer a manager's talent from his past performance. The manager's incentives to expend effort on one task then depend on how the market infers the manager's talent based on his performance on that task. Such career concerns can be captured in our framework by assuming that $F(\pi_1, \pi_2, \dots, \pi_m) = (\pi_1, \pi_2, \dots, \pi_m)$, and that the strength of the reward connecting $F(\pi_1, \pi_2, \dots, \pi_m)$ to wages for an agent is not contractually chosen but is determined by the labor market. The agent's effort level in a rational-expectation equilibrium is then determined by

$$a \in \arg \max_{\tilde{a}} E(U(w_0 + w(F(\pi_1, \pi_2, \dots, \pi_m), a^*)) | \tilde{a}) - c(\tilde{a})) \quad \text{and} \quad a = a^*.$$

In the simplest version of this problem, π_i depends positively on the agent's effort a_i on task i , her talent θ (which neither the agent nor the market knows a priori), and noise. On observing the vector of performances $(\pi_1, \pi_2, \dots, \pi_m)$, the market tries to infer the talent parameter θ given the expectation of effort a^* , which is assumed to be correct in equilibrium. In a later period, the agent is then rewarded (through promotion, new job offers, etc.) according to her perceived talent, which is embodied in the formulation $w(F(\pi_1, \pi_2, \dots, \pi_m), a^*)$. Note that the agent's incentive to work here is driven solely by her desire to influence the market's perception of her talent, and her current-period wage w_0 is, by assumption, constant. In equilibrium, she does not succeed in fooling the market; however, she is still driven to perform to avoid disappointing the market: she expends effort *ex post* because the market expects it. Whether she *ex ante* benefits from this incentive depends on whether the initial wage w_0 reflects the market's expectations about equilibrium effort.

Dewatripont et al. (1999) study how equilibrium effort depends on the number of tasks the agent has authority over. For example, they establish conditions under which reducing the number of tasks n the agent has authority over increases her total effort ($a_1 + a_2 + \dots + a_n$) and the principal's total profit. The reduction in tasks tends to increase overall performance when the link between performance and perceived talent is enhanced with fewer tasks, due to less-noisy performance measures (higher signal-to-noise ratio). Note that lowering n has more drastic consequences here than in the standard multitask problem with explicit incentives: it is not a matter of less effort substitution but of an increase in total effort!

This benefit from focus is consistent with Wilson's (1989) celebrated study of bureaucracy, where he argues that successful government agencies are the ones that manage to concentrate on reasonably focused missions. Focus means that accountability improves, because performance is easier to evaluate. The agency in the end benefits from this situation if better accountability translates into enhanced autonomy.

Wilson's book is replete with examples of processes by which bureaucracies have transformed their grand-but-vague objectives into more specific and more operational missions. For example, the Department of Agriculture's mission of feeding the nation has been transformed into mainly

helping farmers, and the Department of Transportation's mission of improving the safety of transportation has traditionally been confined to improving car safety.

The three approaches detailed above all point to the cost of multiple tasks and the advantage of splitting them among several agents. They also imply predictions concerning optimal task clustering when each agent has to be allocated several tasks. First, the traditional multitask approach suggests that agents have to be given authority over tasks that have similar degrees of measurability. Agents allocated easily measurable tasks can be given more powerful financial incentives, while others must find less powerful incentives. Second, the conflicting-task approach argues for avoiding conflicts of interest in job design. This will lead to specialization of management in pursuing narrow goals and reliance on competition among specialized managers to ensure overall balance. Finally, the focused-mission approach pleads for functional specialization. That is, it calls for specializing agents in tasks that require similar talents, so as to keep the inference process between overall performance and talent strong.

4. Vertical Allocation of Authority

As Alfred Chandler (1962) has emphasized, most large firms are run by professional managers, and shareholders—the ultimate owners of the firm—have relatively little say in firms' day-to-day operations or strategic decisions. In other words, in most larger firms the owners delegate authority to the CEO and the management team. The CEO in turn delegates authority further down the hierarchy to divisional managers, product managers, and so on. A central question for the theory of organizations is: How can owners credibly delegate authority to managers? How can owners transfer residual rights of control to nonowners? Can they formally transfer authority without transferring ownership rights?

One basic difficulty for owners in delegating authority to managers is that it is very hard to formally describe the manager's area of competency and duties to shareholders. Thus, it is tricky for owners to commit to delegating discretion to the CEO over some decisions, such as the firm's marketing strategy, outsourcing policy, or product design. A dominant owner who has board representation can always meddle in the managerial decision process, and it is difficult for the CEO to ignore such a shareholder if she has the power to fire the manager. Thus, for example, when there is a transfer of ownership of a newspaper or a television channel, to what extent can the new owner credibly delegate editorial policy to the managing editor? This question is always critical when there is a change in ownership of a media company.

One answer to this question is that the transfer of authority can be made more credible if there are higher costs for the owner of firing the manager. There is then a trade-off for the principal between more effective (or credible) delegation of authority and better incentives for the agent. One extreme way of delegating authority—as in academia or in the judiciary—is to grant tenure to the agent. Although there are undoubtedly incentive reasons for the tenure system, as Carmichael (1988), Waldman (1990), and Friebe and Raith (2004) have notably argued, another important reason for the system is surely to be able to credibly delegate hiring decisions to departments and to guarantee academic freedom or the independence of the judiciary.

Another answer, which has received more attention in the literature, is that the credibility of delegated authority rests on the superior knowledge or information of the agent. In other words,

if shareholders of large firms do not have the skills or knowledge to run a firm efficiently—which is likely to be the case when ownership is dispersed and no single owner has a strong incentive to become more knowledgeable about the firm’s business—then the delegation of authority to a team of professional managers is credible.

In this section we first review and discuss the fundamental contribution of Aghion and Tirole (1997), which has spawned a large literature. This article directly addresses the question of how a principal can use an agent’s informational advantage to credibly commit to an arm’s-length incentive scheme or credibly delegate authority to an agent. As we detail in Section 4.1, Aghion and Tirole show how real decisionmaking depends on individual costs of information acquisition, the degree of congruence of the parties involved in the relationship, and the allocation of formal authority. We also discuss the credibility of the allocation of formal authority, with special emphasis on the case of academic contracts.

Aghion and Tirole explain how, in some cases, parties not endowed with formal authority can, when they enjoy an informational advantage, “have their way” by communicating to the other party what to do. In settings more general than theirs, this leads to the question of strategic information transmission as in Crawford and Sobel (1982). The desirability of delegation in such a context has been studied by Dessein (2002), and we discuss this work in Section 4.2 as well as extensions of it in Section 4.3, which focuses on the interplay between delegation and adaptation to an uncertain environment.

4.1. Formal and Real Authority

4.1.1. *The Aghion-Tirole Model*

Aghion and Tirole (1997) focus on a noncontractible action, which in their setup amounts to choosing one project that the agent has to work on. There are initially $N \geq 3$ potential projects. Project $k \in \{1, 2, \dots, N\}$ gives the principal a private benefit B_k and the agent a private benefit b_k . Initially, these various projects are indistinguishable from one another. At least one of them is sufficiently bad that choosing one project at random is worse for both parties than undertaking no project (with associated payoff normalized to zero in this case). In contrast, the parties know in advance that the best project for the principal gives him $B > 0$, while it gives the agent $\beta b > 0$, and that the best project for the agent gives her $b > 0$, while it gives the principal $\alpha B > 0$. Call α and β the “congruence parameters,” and assume that they are positive but smaller than one. The higher these parameters are, the more congruent the preferences of the two parties will be. Note that partial congruence is built into the setup in any case, because one has assumed that (1) the two parties agree that choosing a project at random is worse than undertaking no project and (2) they each prefer to allow the other party to choose his/her favorite project rather than undertaking no project (since α and β are assumed to be positive).

These assumptions about congruence are crucial given the information acquisition technology: although both parties are initially uninformed about the private benefits associated with individual projects, they can each exert effort to improve their information. Specifically, the principal can at cost $\psi_P(E)$ (increasing and convex in E) become fully informed with probability E about project benefits, while he remains fully uninformed with probability $1 - E$. Similarly, the agent can at cost $\psi_A(e)$ (increasing and convex in e) become fully informed with probability e about project benefits, while she remains fully uninformed with probability $1 - e$.

The timing of the game is as follows. In stage 1, the parties contract; in stage 2, they exert effort to acquire information about individual project payoffs; finally, in stage 3, a decision can be taken on which project to undertake, if any. Assuming that efforts are privately chosen and that parties only care about their private benefits,⁶ the contract only consists of an allocation of authority for stage 3. As Aghion and Tirole (1997) stress, what can be contractually allocated is solely formal authority, that is, who has the right to make the decision. This differs from real authority, that is, who actually makes the decision. Indeed, given the partial congruence built into the model, a party endowed with formal authority chooses to undertake a project only if she is informed about project benefits; otherwise, she transfers authority to the other party (or equivalently, asks the other party for a recommendation and follows it). In turn, this other party chooses a project/makes a recommendation only if he is informed about project benefits. Otherwise no project is undertaken.

Given this continuation equilibrium in stage 3, if the contract allocates formal authority to the principal, the payoffs for the principal and the agent (U_P and u_A , respectively) upon choosing their effort levels are

$$U_P = EB + (1 - E)e\alpha B - \psi_P(E)$$

$$u_A = E\beta b + (1 - E)eb - \psi_A(e).$$

These conditions reflect the fact that the principal chooses his favorite action whenever he is informed about individual project payoffs, while the agent's information matters only when the principal is uninformed. In stage 2, simultaneous effort choice leads to the following first-order conditions:

$$(1 - \alpha e)B = \psi'_P(E)$$

$$(1 - E)b = \psi'_A(e).$$

As indicated by the second first-order condition, higher effort E by the principal crowds out effort e by the agent, who understands that her effort matters with a lower probability. There may therefore be a gain for the principal to commit to exerting lower effort, for example, by choosing an agent who is more congruent with him (that is, an agent with a higher α).⁷ In this case, indeed, the principal exerts less effort, as indicated by the first first-order condition. He is less worried about being uninformed, because the project chosen by the agent when she is the only one informed leads to a lower relative loss for the principal.

Another way for the principal to induce the agent to work harder is to delegate her formal authority on project choice. In this case, given the continuation equilibrium in stage 3, the payoffs for the principal and the agent upon choosing their effort levels are

$$U_P = e\alpha B + (1 - e)EB - \psi_P(E)$$

$$u_A = eb + (1 - e)E\beta b - \psi_A(e).$$

6. This is assumed for the sake of presentation and can be generalized (see Aghion and Tirole 1997).

7. Aghion and Tirole (1997) also look at increases in the span of control of the principal as a way for him to commit to spend less effort per agent, because he then has more projects to acquire information about.

The agent now chooses her preferred action whenever she is informed, while the principal's information matters only when the agent is uninformed. Simultaneous effort choice now leads to the following first-order conditions:

$$(1 - e)B = \psi'_P(E)$$

$$(1 - \beta E)b = \psi'_A(e).$$

A comparison of these first-order conditions with those in which the principal has formal authority indicates that the agent exerts more effort and the principal exerts less effort under delegation. Indeed, the two effort levels are strategic substitutes, which reinforces the fact that the individual endowed with formal authority has more incentives to exert effort, *ceteris paribus*, since he can have the first go at choosing the action.

Using a very simple model, Aghion and Tirole are able to generate interesting predictions about the allocation of authority in organizations (e.g., as Burkart et al. 1997 argue, that shareholder dispersion acts as a commitment device to empower management). These predictions are in line with some prominent cases of internal organization described by Roberts (2004), such as BP's (or Johnson & Johnson's and ABB's) organizational strategy to empower front-line managers by lightly staffing its corporate headquarters. Using a similar model, Rotemberg and Saloner (1993) have also been able to generate simple predictions on what traits a CEO should have to be an effective leader in motivating agents under her authority. They show that a more empathic CEO (i.e., a CEO who puts more weight on maximizing her subordinate's utility) may be able to induce greater incentives for subordinates to exert effort to come up with new ideas, even if this comes at the cost of implementing too many bad ideas *ex post*. In general, Rotemberg and Saloner show that a somewhat empathic CEO is optimal for the firm: she provides the agent with some incentive to exert effort but also rejects the worst ideas he proposes.

4.1.2. *Credible Delegation?*

Although the key innovation behind the Aghion-Tirole model concerns the concept of real authority, it has also generated debate about formal authority. At some level, one can interpret delegating formal authority simply as the equivalent, in the Grossman-Hart-Moore approach, of selling the underlying asset necessary to get the project going. This interpretation is straightforward, but it is not that interesting if one focuses on authority within organizations. In such a case, delegation of formal authority is problematic because, at least in the United States, the business judgment rule typically leads courts not to enforce contracts written between parties within a single firm. It thus seems that, as far as authority within organizations is concerned (e.g., between the firm and one of its divisions), one can choose the allocation of real authority but not of formal authority. In the end there is no credible way for the boss to commit not to take back formal authority when it is in his interest to do so. This can be circumvented in a repeated-game setting, where allocation of formal authority does matter for efficiency, as has been analyzed by Baker et al. (1999; see also Section 6.2), but these arguments do not work in a one-shot setting.

Note, however, that there are exceptions to this business judgment rule. First of all, it does not apply to financial investors: as has been discussed in the financial contracting field, there are

enforceable allocations of formal authority among the various investors who have put money in the firm. Another exception, already mentioned in the introduction of this section, concerns some employment contracts: as academics, we are well aware of contracts that grant us not only tenure but also academic freedom. Aghion et al. (2008) have built on this observation to discuss the relative merits of academia and the private sector in the innovation process. In fact, as a modeling strategy, they keep at a minimum the differences between academia and private sector profit-maximizing firms, focusing solely on the allocation of formal authority between the researcher and the organization.

They consider an economically viable product (e.g., a new drug), which starts with an idea I_0 , that can be built on by researchers, leading to idea I_1 , I_2 , . . . , until idea I_k , which generates economic value V . Assume that, for each of the k stages, one researcher can work on the idea (this can be generalized to more than one researcher). In academia, the researcher is free to pursue his own strategy. He can therefore choose the practical strategy, which yields a probability p of being successful, that is, of moving to the next stage. However, he can also choose the alternative strategy, which yields a probability 0 of moving to the next stage.

Why would the researcher go for the alternative strategy? There are several reasons. First, (and this makes it hard for academia to emerge as an efficient organization) one assumes that financial incentives are not possible, and only fixed wages are possible. Second, although the alternative strategy involves zero disutility for the researcher, the same is not true for the practical strategy: with probability α , it does generate zero disutility, but with probability $1 - \alpha$, the researcher will have a disutility z from the practical strategy. Moreover, at the time of being hired, the researcher does not know what his preferences will be.

Consequently, when the researcher is protected by academic freedom, that is, can choose his research strategy, he will only pursue the practical strategy with probability α (this also makes it hard for academia to emerge as an efficient organization: in reality, the alternative strategy will not have zero value). Instead, in the private sector, the researcher's boss can direct her research, that is, impose the practical strategy. This raises the probability of success, from αp to p , which is the benefit of private research. However, there is also a cost. Having a boss imposes an ex ante disutility of $(1 - \alpha)z$ on researchers, and if researchers have an outside option whose value is R , equilibrium academic wages will be R and private-research wages will be $R + (1 - \alpha)z$. This is in fact consistent with evidence presented by Stern (2004) on academic versus private sector wage offers given to the same individuals.

The cost and benefit of academia are intuitive, but they generate an interesting prediction in the context of a sequential innovation process. Indeed, in the last stage of research, that is, when one already has idea I_{k-1} , the private sector is the more efficient way of organizing research if and only if

$$\pi(k) = pV - R - (1 - \alpha)z > \alpha pV - R.$$

Assume this first condition is satisfied. Then, in the next-to-last stage, the private sector is the more efficient way of organizing research if and only if

$$p\pi(k) - R - (1 - \alpha)z > \alpha p\pi(k) - R.$$

Interestingly, because $\pi(k) < V$, this second condition is harder to satisfy than the first one. Intuitively, the idea is that, if as assumed, the wage difference between academia and the private sector is (roughly) constant across stages, then academia looks worse and worse when one moves downstream in the innovation process, because the cost of a lower probability of moving to the next stage represents a bigger and bigger financial stake. As the two conditions above indicate, in the last stage the stake is V , but in the next-to-last stage, the stake is only $\pi(k)$, the value of moving to the last stage. Indeed, the main result is that the efficient sequence will have academia perform the earlier stages and the private sector the later stages of the innovation process. And the efficient transition from academia to the private sector occurs earlier the lower the level of α or z is and the higher that of V is. The model therefore generates academia as an endogenously efficient institution, even if the assumptions make academic freedom costly, by not allowing (explicit or implicit) incentive schemes and by assuming away any value for the alternative strategy except in terms of the researcher's disutility.

As shown by Aghion et al. (2008), real authority can also be brought into the picture: if to exert her authority, the boss of a private firm needs to expend effort to be informed about the specifics of the practical strategy, it is easy to see that the return to such effort, and therefore its intensity, will grow as research progresses. The model therefore generates the prediction that the private firm becomes "bossier," and pays higher wages, the closer one gets to the final product.

4.2. Strategic Information Transmission and Delegation

The Aghion-Tirole model stresses the importance of information as the source of real authority and casts the problem of optimal allocation of formal authority in terms of an incentive problem to obtain information. An extension of this model by Dessein (2005) shows that relinquishing formal authority may be a way for the principal to signal congruence with the agent and therefore to increase his real authority. This can make sense in the setting considered by Dessein, where there is a probability that the principal, even when keeping formal authority and being informed about his favorite project, cannot "get his way," because his control over the agent is imperfect. In such a case, the agent's behavior when uninformed will depend on her belief about the congruence between the two parties. Relinquishing formal authority can then be a credible way for the principal to signal such congruence, because it is less costly for him to do so if the parties are actually more congruent. Dessein argues that this setting can help explain how venture-capital contracts are structured and how formal authority is allocated between the venture capitalist and entrepreneur. In a somewhat similar vein, Aghion et al. (2004) discuss a model where a principal also faces an agent over which he has only partial control, and may initially want to relinquish partial (formal) authority to learn about her type—in this case, her degree of trustworthiness.

A key assumption of the Aghion-Tirole model is that communication between the parties takes an extreme form: when uninformed, a principal with formal authority blindly follows the instructions of the agent. In general, one would expect that the principal would, in such cases, try to elicit information from the agent and then make the best decision from his point of view, as in the "cheap-talk" model of Crawford and Sobel (1982). Of course, the informed agent may then respond by attempting to manipulate the principal. As shown by Crawford and Sobel,

equilibrium communication will then inevitably be noisy communication, with a higher level of noise when the principal's and agent's objectives are less congruent. Dessein (2002) builds on the Crawford-Sobel model by adding the possibility for the principal to delegate the decision altogether to the agent (and giving up on communication). In Dessein's expanded problem, the principal has to decide between informed-but-biased decisions (under delegation) and noisy-but-unbiased decisions (under no delegation).

For the sake of brevity, let us focus here only on a very simple example, where one project $k \in \{1, 2, 3, 4, \dots\}$ has to be chosen, and where the loss function of the principal is $(s - k)^2$, while the loss function of the agent is $(s + b - k)^2$. The variable s is the value of the profit-maximizing project. It can take values 1, 2, or 3, with respective probabilities p_i , $i = 1, 2, 3$. The agent has a bias $b > 0$ in favor of bigger projects. This would be the case, for example, if the agent were an empire builder.

Dessein compares two organization structures: delegation and no delegation. Under delegation, of course, the higher the bias b is, the worse the outcome for the principal becomes. For $b < 1/2$, the agent always chooses the project the principal prefers, leading to a loss of 0 for him; for $1/2 < b < 3/2$, the agent always chooses a project one unit higher than what the principal prefers, leading to a loss of 1 for him; for $3/2 < b < 5/2$, the agent always chooses a project two units higher than what the principal prefers, leading to a loss of 4 for him; and so on.

Without delegation, we are in the Crawford-Sobel setting, where communication involves the agent sending (costless) messages to the principal about s . Without loss of generality, given rational expectations, we can assume that these messages are truthful (with noise), but obviously the amount of information they reveal will depend on parameter values. Just as with delegation, the principal will be worse off when the bias rises, because communication will become less revealing. But here, since the principal can always choose the best outcome from his point of view (conditional on the information he has), the loss is bounded. At worst, he can disregard any information sent by the agent and choose the loss-minimizing project, that is, choose the k which minimizes $\sum_k p_i (s - k)^2$. For example, if the principal chooses $k = 2$, his loss is limited to $p_1 + p_3$, which is less than 1. Clearly, delegation is therefore dominated in this example when $b > 1/2$.

The next question is: how well can the principal do without delegation?

1. For $b > 3/2$, he can do no better than disregard information sent by the agent. Because the agent knows that the principal will never choose any project greater than 3, the principal cannot hope to receive information leading him to choose a project lower than 3. Indeed, in this case, even if $s = 1$, the agent prefers the principal to choose $k = 3$, so that the only equilibrium involves full pooling (i.e., no meaningful communication).
2. The principal can hope to obtain some information for lower levels of the bias b . In fact, for $b < 1/2$, full revelation is possible, because the agent prefers the principal to choose $k = s$ rather than a higher k . Here we have equivalence between delegation and no delegation (zero loss for the principal) even if, in the absence of delegation, less than full communication is also an equilibrium. As is well known, cheap-talk games also admit "babbling equilibria" with coordination failures; namely, the agent sends an uninformative message because she expects the principal not to pay attention, and this expectation is self-fulfilling.

3. Finally, for $1/2 \leq b \leq 3/2$, the possibility of partial communication depends on parameter values. Because the principal will never choose $k > 3$, the principal cannot hope to distinguish between $s = 2$ and $s = 3$. Similarly, if $p_2 > p_3$, it will be impossible for the principal to distinguish between $s = 1$ and $s > 1$: indeed, the latter case would imply $k = 2$, which is then attractive for the agent if she knows $s = 1$. In this case, we are back to no information revelation. In contrast, if $p_2 < p_3$, it becomes possible for the principal to distinguish between $s = 1$ and $s > 1$: indeed, the latter case would now imply $k = 3$, which is unattractive for the agent if she knows $s = 1$, because she prefers $k = 1$ to $k = 3$. In this case, the loss for the principal is only p_2 , and he does strictly better than under delegation.

This example delivers a number of general lessons. First, it illustrates the general trade-off for the principal between informed-but-biased decisions and noisy-but-unbiased decisions. Second, it shows that an increase in the bias hurts the principal both under delegation (because the decision becomes more and more biased) and under no delegation (because it becomes noisier and noisier). Third, it shows that delegation becomes worse when the bias is high enough, because without delegation the loss for the principal is bounded.

One dimension for which the answer delivered by the example is special concerns the potential optimality of delegation when the bias b is low (so much so that communication is possible under no delegation). In the original Crawford-Sobel example (which allows for continuous values for k and s and assumes a uniform distribution for s on a bounded interval), Dessein shows that delegation dominates no delegation for all parameter values for which communication becomes possible under no delegation, which is quite a striking result. Dessein shows, moreover, that his result does depend on the uniform-distribution assumption. And indeed, here, there exists an equilibrium where no delegation strictly dominates delegation while involving communication when $1/2 \leq b \leq 3/2$ and $p_2 < p_3$. However (and in keeping with the Crawford-Sobel setting), when $p_2 > p_3$, delegation does as well as no delegation when communication is possible under no delegation, and one can argue that it is safer to delegate in this case, because this guarantees that a babbling equilibrium is avoided.

4.3. Coordination, Adaptation, Costly Communication, and Decentralization

We now turn to another rationale for delegation or decentralization inside an organization: economizing on the costly communication, red tape, and costly bureaucracy that coordination of multiple agents' actions entails under a centralized command. We discuss this theme in the context of the Dessein and Santos (2006) model of an organization, where the benefit of multiple agents working together in an organization arises from individual agents' abilities to increase their productivity through specialization.⁸ To reap the benefits of specialization, however, requires coordination. In particular, in a changing environment the organization must be able to

8. The notion that gains from specialization are the source of value added of an organization is, of course, not new to Dessein and Santos (2006). This idea can be traced back at least to Adam Smith and also underlies recent models of optimal team organization following Radner (1993). See, for example, Garicano and Van Zandt (this volume).

adapt to new circumstances, which means that individual agents' tasks must be continuously redefined and coordinated to achieve maximum productivity. This coordination may involve more-or-less high communication costs, depending on how centralized the organization is. Dessein and Santos assume away incentive problems in their model for simplicity (in this respect following the team theory literature), whereas we continue our discussion by exploring how incentives may be introduced in their setting and the implications for delegation that follow from such an extension, using an approach developed by Dewatripont (2006) (itself based on Dewatripont and Tirole 2005).

4.3.1. The Dessein-Santos Model

In their model, Dessein and Santos (2006; hereafter DS) endogenize the degrees of centralization and adaptiveness of an organization with an arbitrary number N of agents as well as the quality of its internal communication. For consistency and simplicity, we shall only consider a simplified version of their model, with only two agents and two actions: a primary action a and a complementary action b . Action a should ideally be as close as possible to local information θ , a random variable with mean θ_0 and variance σ_θ^2 . One can interpret θ_0 as the status quo and the realized θ as the change in the organization's environment. Also, action b should ideally be as close as possible to action a (think of b as an input that must fit with a). The expected misadaptation and miscoordination cost to the organization is given by $E [\phi(a - \theta)^2 + \beta(b - a)^2]$, where ϕ is the weight given to misadaptation and β the weight given to miscoordination. With two agents there can only be two possible organizational forms: decentralization (or delegation), where each agent is assigned decision rights over one action, and centralization, where a single agent (the boss) has authority to command both actions (and the other agent simply executes what he is told to do). Under delegation each agent is more specialized and therefore more productive, but the organization faces greater coordination and adaptation problems. Centralization allows better coordination and adaptation, but there are lower returns to specialization.

4.3.1.1. Decentralized Organization. Decentralization means that two individuals are hired and each controls one and only one action. We assume that the individual who chooses a is able to first observe θ but that the individual who chooses b observes neither θ nor a . Let the individual who chooses a be called the "sender" (S , "she"), because she must send a message about a to the other individual, called the "receiver" (R , "he"). Communication is assumed to be imperfect: S 's message is received by R only with probability p , while R learns nothing with probability $1 - p$.

The timing of the game is assumed to be as follows. In stage 1, S observes θ , chooses a , and communicates it to R ; in stage 2, R receives S 's message with probability p and sets b . Given that we take a team-theoretic perspective, both parties want to minimize miscoordination and misadaptation costs $E [\phi(a - \theta)^2 + \beta(b - a)^2]$, and so R sets $b = a$ when he learns the value of a and sets $b = \theta_0$ otherwise. Consequently, S chooses a to minimize $\phi(a - \theta)^2 + \beta(1 - p)(\theta_0 - a)^2$ for each realization of θ :

$$a = \theta_0 + \frac{\phi}{\phi + \beta(1 - p)}(\theta - \theta_0).$$

The ratio $\phi / [\phi + \beta(1 - p)]$ can be interpreted as the degree of adaptiveness of the organization and also as the level of discretion enjoyed by S . It grows with ϕ and p and goes down with β . Substituting for the value of the optimal action a into $E[\phi(a - \theta)^2 + \beta(b - a)^2]$ yields the equilibrium expected cost for the decentralized organization:

$$\frac{\phi\beta(1 - p)}{\phi + \beta(1 - p)}\sigma_\theta^2.$$

As is intuitive, equilibrium costs are increasing with the variance σ_θ^2 (the change in the environment), the importance of misadaptation measured by ϕ , and the importance of miscoordination measured by β ; and they are decreasing with the quality of communication measured by p . If the quality of communication can be improved at a cost (i.e., if the firm can invest in better internal communication), DS ask what determines the optimal choice of p . They allow for a continuous p and a continuous convex cost function, but here, for simplicity, we shall only allow for two levels: $p_L = 0$ and $p_M > 0$, where p_M is obtained at a cost F to the organization. With an endogenous p , the expected cost to the organization under decentralization is then

$$EDC = \min \left\{ \frac{\phi\beta}{\phi + \beta}\sigma_\theta^2, \frac{\phi\beta(1 - p_M)}{\phi + \beta(1 - p_M)}\sigma_\theta^2 + F \right\}.$$

4.3.1.2. Centralized Organization. Miscoordination costs can be reduced under centralization, as a single individual commands which actions all agents in the organization must take. However, centralization comes at the cost of more costly communication, red tape, and less individual discretion (or initiative), which lowers the beneficial scope of specialization. In our simple two-agent version of the DS model, we can only crudely represent centralization and the benefits and costs it entails.

We shall assume that centralization is essentially a more extreme form of decentralization, with higher quality and costs of communication. That is, under centralization the quality of communication p_H and cost K is such that $1 \geq p_H > p_M$ and $K > F$. Moreover, under centralization a single individual commands both actions a and b when communication is effective (with probability p_H). When communication is ineffective, the second agent does not receive her order from the boss and makes a best effort to coordinate by choosing $b = \theta_0$. Under centralization, the expected cost of the organization is then

$$ECC = \frac{\phi\beta(1 - p_H)}{\phi + \beta(1 - p_H)}\sigma_\theta^2 + K.$$

The choice of centralization or decentralization for the firm then reduces to a comparison of EDC with ECC . When is decentralization likely to be better than centralization?

4.3.1.3. Results. The comparison of ECC and EDC illustrates the following results derived in a more general setting by DS:

- Higher uncertainty σ_θ^2 or higher misadaptation costs ϕ raise the benefits of adaptiveness, which in turn raises the benefits of communication and centralization. Thus, in highly volatile environments it is best not to decentralize. A decentralized organization would either incur high costs of miscoordination or high costs of misadaptation, as the agent who observes the realization of θ would choose to be less responsive to improve coordination. The DS model thus captures in a simple way why disaster relief is best done by highly centralized organizations.⁹
- Higher miscoordination costs β have ambiguous effects: for β close to 0 or ∞ , decentralization with $p = 0$ is optimal, but for intermediate values of β this is not necessarily the case. Indeed, a rise in β from a very low level raises the value of communication to keep achieving ex post coordination. But when β is very large, the best solution is to have $a \rightarrow \theta_0$ and thus avoid miscoordination costs. In this case the organization relies on ex ante coordination, with very little communication and responsiveness to local information. Decentralization is then optimal to reap the smithian returns from specialization.
- Lower communication costs F under decentralization may result in (1) a move away from centralization (with a move from p_H to p_M) and therefore lead to decreased adaptiveness or (2) a rise in adaptiveness (with a move from $p_L = 0$ to p_M) while the organization remains decentralized. In a symmetric multitask setting DS also show that lower communication costs—by raising the attractiveness of adaptiveness—may at times imply more (partial) centralization with more task bundling and less specialization.

The DS model offers a rich setting, which our two-agent illustration cannot fully do justice to. It sheds light on the recent moves toward higher adaptiveness as well as increased communication and task bundling in organizations. In particular, their analysis helps explain the empirical findings of the simultaneous shift toward more communication and more decentralization in organizations of Caroli (2001), Caroli and Van Reenen (2001), and Bresnahan et al. (2002).

The DS model (at least in our two-agent formulation) is also a good starting point to introduce incentive considerations. Assuming away internal incentive problems is a useful first step in the study of organization design, but it is only a first step. To better capture the internal organization design problems firms face in practice, it is important to also allow for the incentive problems associated with hidden information and/or hidden actions. As far as communication is concerned, incentive problems can hinder efficient communication in two main respects. First, a lack of congruence of objectives can arise between the sender and the receiver with respect to the decision to be taken. Second, the problem of moral hazard in communication can arise. This is really a form of moral hazard in teams problem, because (1) the sender must spend time, attention, and other resources to communicate her knowledge effectively; and (2) the receiver must spend time by paying attention, decoding, understanding, and rehearsing the acquired knowledge. In a nutshell, when it comes to communication, it takes two to tango.

9. A related but somewhat orthogonal explanation by Bolton and Farrell (1990) is that a centralized organization can respond more quickly to a change in the environment (there is no delay) and can achieve better coordination (there is no duplication of actions). However, this comes at the cost of worse adaptation (decentralization is better at using local information).

4.3.2. Cheap Talk versus Costly Communication

Imperfect communication with incentives is largely an unexplored topic.¹⁰ One exception is Dewatripont and Tirole (2005; hereafter DT), who discuss a model that considers both imperfect congruence and moral hazard in teams. It distinguishes in particular between costless but soft communication—cheap talk, where the receiver must decide whether to trust the sender's message or not—and hard-but-costly communication—which the receiver knows he can trust but which entails a cost for both parties.

To introduce communication incentives in the DS framework, suppose first that achieving hard-but-costly communication (with probability p_M) requires the principal and agent to expend one unit of effort at cost $F/2$. That is, any single effort is wasted if the other party does not also expend effort. Second, to make the problem interesting, suppose also that the two parties have different objectives. Indeed, if they had the same objective then there is no role for costly communication, because soft communication about the value of a can occur at no cost.

Specifically, assume that (as in DS) S has payoff $U_S \equiv -sE(\phi(a - \theta)^2 + \beta(b - a)^2)$, but that R has payoff $U_R \equiv -r(\alpha E|b - a| + (1 - \alpha)E|b - \theta_0|)$. With probability α it is then in R 's interest to align his action with that of S by picking $b = a$, and with probability $(1 - \alpha)$ it is in R 's interest to instead stay with the status quo ($b = \theta_0$). Thus, α is a measure of the degree of congruence between the two parties. Assume, finally, that neither S nor R know the realization of R 's objective function, but that α is common knowledge.

The timing of the game is then as follows. In stage 0, each party privately decides whether to expend one unit of effort, at an individual cost of $F/2$. In stage 1, S observes θ , chooses a , and—if she has expended effort—can at no further cost try to engage in hard-but-costly communication. In stage 2, if both parties have expended effort, then R learns the outcome of hard-but-costly communication. Cheap talk is also always possible, independently of communication efforts. Finally, in stage 3, R sets b .

What is the difference between cheap talk and hard-but-costly communication in this setting? We assume that hard-but-costly communication enables R to learn his objective function. In contrast, under cheap talk, R has to trust S about a and cannot learn his objective function (which S does not know and therefore cannot convey).¹¹ For simplicity, we further assume that cheap talk conveys the value of a to R with probability 1.

Under these assumptions, it is easy to see that one of two outcomes will obtain:

- Under high congruence (which occurs when $\alpha > 1/2$), S has real authority in the sense of Aghion and Tirole (1997): she can pick $a = \theta$ and announce it to R using cheap talk while not expending effort on costly communication, because faced with the impossibility of learning about his objective function, R cannot do better than choosing $b = a$.
- Under low congruence (which occurs when $\alpha < 1/2$), R will not select $b = a$ unless he becomes convinced that his objective function is $-rE|b - a|$. In this case, cheap talk is useless and the only way to induce R not to pick $b = \theta_0$ is to have successful

10. There is a literature on costly state verification (starting with Townsend 1979), which considers costly audits. This literature concerns unilateral information acquisition and thus differs from the model presented here, where communication is costly for both parties.

11. Note, however, that S has an incentive to tell the truth about a .

costly communication.¹² For a given α , an equilibrium of costly communication (with probability p_M) exists when the cost of communication F is low enough and when both parties' stakes in the relation are high enough (i.e., when $\min \{s, r\}$ is sufficiently high).

An increase in the congruence parameter α between S and R therefore leads at some point to the breakdown of costly communication when S can start counting on R to rubber-stamp her (costless) recommendation. This breakdown leads to an upward (respectively, downward) jump in S 's (respectively, R 's) expected payoff. When this point is reached, centralization is of course not attractive for the sender. In contrast, centralization might be attractive for $\alpha < 1/2$, provided its cost is not too high.

While the DT model allows for costly communication as an alternative to cheap talk, Kartik et al. (2007) and Kartik (2009) have more recently generalized the Crawford-Sobel cheap-talk paradigm (Crawford and Sobel 1982) to allow for endogenously costly soft information communication by introducing intrinsic lying costs for the sender. Kartik et al. (2007) show that even with low costs of lying, it is possible for the sender to truthfully communicate her information (without noise) in a separating (signaling) equilibrium when the sender's type space is unbounded. In a more general model with convex lying costs Kartik (2009) also shows that signaling equilibria involve language inflation in the sense that equilibrium messages overstate the truth in the direction of the sender's bias. Moreover, when lying costs decrease, the equilibria with language inflation involve more inflation and become less informative. A natural question worth exploring in such a model is when delegation of authority from the receiver to the sender is a superior outcome to centralization with inflated and distorted (costly) communication.

5. Contingent Allocation of Authority

Another common form of authority allocation in organizations is a temporary contingent allocation in response to major changes in the environment, unexpected events, or the advent of special problems. There may be several reasons control needs to be shifted in this way.

A first reason may be the limited attention of the party in control. When major new changes occur the controlling party may not have the time to deal with these new problems or opportunities. As is often the case in government, one response is to delegate decisionmaking authority over these new tasks to a new agent or committee. Even if the original party retains formal control rights, the committee gains real authority, because it is able to make better informed decisions, as Aghion and Tirole (1997) have stressed.

A second reason control needs to be allocated to a new party (typically appointed from outside the organization) is that the existing holder of authority may no longer be best placed to deal with the new situation. Thus, a common practice in many corporations is to replace managers of underperforming units and to temporarily appoint so called "turnaround managers," who are specialized in restructuring failing businesses. These managerial services are often provided by major consulting firms, or by buy-out firms, who then also acquire the unit and run it until it is turned around and resold. In addition, large distressed corporations

12. Even then R picks $b = a$ only with probability α .

entering chapter 11 often appoint a specialized crisis manager referred to as “chief restructuring officer” to provide expertise in reorganizing the firm while it operates under bankruptcy protection.

A third reason control is removed from the agent in charge when there is significant underperformance is to protect other agents in the organization against decisions that may go against the interests of the organization. The manager in charge of the failing unit may, for example, be tempted to gamble for resurrection by taking excessively risky actions that could restore her reputation and further her career in the event of a good outcome.

Although the contracting literature has not analyzed the turnaround management problem *per se*, there are at least two closely related literatures that can shed light on this problem. One is the literature on referrals in hierarchies initiated by Garicano (2000), and the other is the literature on state-contingent allocations of control following Aghion and Bolton (1992). We shall discuss the main themes of these two strands of literature in turn and explain how they shed light on the turnaround management problem.

Taking the referral, or management-by-exception, perspective of Garicano (2000), the management turnaround intervention can be seen as an optimal institutional arrangement designed to address unusual problems requiring extraordinary skills. Thus, according to Garicano, it would be too costly to train all managers to be able to rectify the operations of their divisions when they seriously underperform, because in normal circumstances divisions are expected to perform properly and turnaround of operations requires more involved and costly training. In an effort to minimize managerial training costs it may be more desirable to let a few talented managers specialize in turnaround skills (the management consultants and private equity shops) and let them take over control of a division or the entire firm in the event of major underperformance. It is worth noting that this is an efficient organizational arrangement even in situations considered by Garicano, where all managers’ objectives are aligned.

In contrast, when managers’ objectives cannot be perfectly aligned with the firm’s overall objectives, the choice between an internal or external turnaround manager may no longer be a matter of indifference. When the divisional manager has private information on when it is optimal to allocate authority to a turnaround manager, he may choose to delay the reporting of damaging information to hold off the change in control. In such situations it may be optimal to give the divisional manager either a stake in the success of the turnaround or some alternative job protection or career path. Although these incentives have the negative effect of dulling the divisional manager’s incentives to run the divisions’ day-to-day operations, they have the advantage of avoiding the worst underperformance and of permitting more timely interventions. However, as suggested by Garicano and Santos (2004) in their analysis of optimal referrals under asymmetric information, to make way for such incentive adjustments, a more inconspicuous internal turnaround procedure may be desirable than the very visible outsourcing to an external turnaround expert.

Related to the Garicano (2000) analysis of ad hoc efficient interventions is the analysis of *ex ante* contingent allocation of authority or control in Aghion and Bolton (1992) and the subsequent literature on financial contracting. However, unlike in the literature on hierarchies and referrals, the basic reason a change of management may be desirable in response to underperformance is not so much to appoint a turnaround manager with special skills as to ensure that divisional managers’ objectives are best aligned with the firm’s objectives.

To see why an *ex ante* commitment to replace a divisional manager in only some contingencies helps align managerial and firm objectives, consider the following stylized example of a division in a firm. The division's lifecycle can be divided into three key dates: date 1, when the division's investment of I is undertaken; date 2, when a new event or state of nature occurs, which calls for new actions on how to run the division (e.g., whether to let it continue or close down its poorly performing operations); and date 3, when the final returns from the division's operations are realized. In our simple example we normalize the returns to 0 in the event of failure of the division's investment and 1 in the event of success. We shall also take it that the probability of success or failure of the investment depends both on the (verifiable) realization at date 2 of a state of nature θ and on a managerial decision to be taken following the realization of the state. There are only three equally likely states of nature in our example, denoted by θ_1 , θ_2 , and θ_3 .

As in the previous sections, the role for managerial authority arises from a basic limitation of contract enforceability: the inability to specify a complete state-contingent enforceable action plan to be carried out by the divisional manager. All the contract with the manager can specify is that he is in charge of running a division and that he is ultimately responsible for its performance. The contract can also specify an incentive scheme that is based on the division's final performance and, if the division is a wholly owned subsidiary, in what states of nature θ the holding company can remove the divisional manager.

We shall also simplify the managerial decision problem to the extreme and assume that in each state of nature the divisional manager only needs to decide whether to restructure the division or to continue operating as usual. In our example, expected payoffs in each state and for each action choice are then given as follows:

1. Returns. In any given state θ the probability of success of the investment is π_R when the manager chooses to restructure. In contrast, when the manager chooses to continue operations as usual, the probability of success is π_i in state θ_i , with $\pi_1 < \pi_2 < \pi_3$.
2. Payoffs. Company headquarters' objectives for the division are to obtain the highest possible financial return. The divisional manager, however, also derives on-the-job, private, benefits (in the form of perquisites, prestige, reputation, power, etc.) as long as the division is not restructured. We denote these benefits by $B > 0$. These payoffs capture the idea that divisional managers often don't like to rock the boat or are reluctant to fire their employees in a restructuring out of loyalty to them.
3. Optimal decision. Assume restructuring is desirable in a first-best world only in state θ_1 , that is, $\pi_1 + B < \pi_R < \min\{\pi_2, \pi_3\} + B$. But from the point of view of company headquarters alone, we assume it would be best to restructure in both states θ_1 and θ_2 , because $\pi_2 < \pi_R < \pi_3$.
4. Participation constraint. The new investment is worth undertaking as long as the division is restructured in at least state θ_1 , because we assume that $(\pi_R + \pi_2 + \pi_3)/3 > I$. However, the new investment is unprofitable if the divisional manager has to be compensated for the loss of private benefits in state θ_1 , that is, $((\pi_R - B) + \pi_2 + \pi_3)/3 < I$.

In this example the first-best outcome can be achieved if headquarters can commit to only leaving the divisional manager in charge in states θ_2 and θ_3 . If the divisional manager could not

be dismissed in any state without cause, he would only agree to restructure the division in state θ_1 if he is fully compensated for the loss of private benefits B . But then the divisional manager would be too entrenched and would make the division unprofitable.

Unfortunately, letting headquarters decide on management changes and on appointments of turnaround managers *ex post* would also be inefficient. Indeed, because $\pi_2 < \pi_R < \pi_3$, headquarters would choose to appoint a turnaround manager in both states θ_1 and θ_2 , thus rendering the divisional manager's job too precarious. This is why there is generally a benefit of committing *ex ante* to precise and objective conditions that can lead to a managerial turnover or a change in control.

In mature and stable organizations, it may be possible to achieve such a credible *ex ante* commitment informally by developing a reputation for predictable human resource management policies. However, for younger and smaller firms the choice is often only between full entrenchment of divisional management or complete discretion of headquarters. An intermediate solution is to set up the division as a wholly owned subsidiary and to write an enforceable management contract, with contingent control change clauses, between the subsidiary and the holding company.

6. Interpersonal Authority

In this section we review models of organizations where contractual enforcement is extremely limited. *Ex ante* agreements on action choices between a principal and an agent are not enforceable, and formal agreements on transfers of authority (absent transfers of ownership titles) are also not enforceable. The key question these models are concerned with is how the principal—who does not have formal control rights or who has to rely on the agent taking a desired action—can nevertheless exercise authority. When can she rely on her superior knowledge—her intellectual authority—to induce the agent to implement her recommendations? When does she need to give a more formal order, how can she get the agent to follow her orders, and, finally, what is the role of financial incentives in helping induce the agent to do what the principal wants?

The first model we discuss builds on the Aghion and Tirole 1997 model (AT). Unlike in their model, the principal cannot formally appropriate authority from the agent. The principal may, however, rely on her intellectual authority to get the agent to do what she wants. She has intellectual authority over the agent when she is informed but the agent is not. In that case a simple recommendation will be sufficient to induce the agent to do what she wants. The principal may also exercise her authority by giving the agent an order. This is a more effective way of getting things done, as the agent then has to do what he is told, even when he prefers some other action. However, to make sure that the agent executes the order, the principal then has to rely on a costly enforcement technology.

6.1. A Simple Model of Hard and Soft Authority

The model outlined in this section is concerned with the question of how to best exercise authority. Three main modes of authority are considered and compared. First, hard authority takes the form of the principal ordering the agent to take a specific action. Second, the strong

form of soft authority involves the principal making recommendations rather than issuing orders. Third, discretion (or the weak form of soft authority) consists of the principal giving discretion to the agent to decide what to do.

As the focus of the analysis is on the relative benefits of soft and hard authority, we simplify the model by assuming that the principal is always well-informed about project returns. As in AT, we reduce the authority problem to a one-shot relation, where the principal cannot take the action himself and has to rely on the agent to get things done. The principal's options are:

- **Hard authority.** The principal can at some cost K make his orders *verifiable*, and thus force the agent to follow them.
- **Soft authority.** The principal makes a recommendation or gives advice at some cost $k \in (0, K)$, but ultimately the agent is free to ignore the advice and to take whatever action she prefers.
- **Discretion.** The principal gives the agent *carte blanche* and lets her decide what the best action is.

More formally, as in AT, assume the two parties face $N > 3$ mutually exclusive (ex ante identical) actions (or projects). Ex post, all but two of these projects produce losses for both parties. Of the two remaining projects, one gives the principal a private benefit $B > 0$ and the agent a private benefit βb (with $1 > \beta > 0$). The other project gives the principal a lower private benefit of αB (with $1 > \alpha > 0$) and the agent a higher private benefit of $b > 0$. Finally, inaction is also an option and gives both parties a payoff of zero.

Although the principal always knows the true payoffs of all the projects, the agent only obtains this information with probability $p \in (0, 1)$. Ex ante expected payoffs are then as follows under the different modes of authority:

- **Hard authority.** The principal is sure to be able to enforce her preferred action and obtains $B - K$, while the agent obtains βb .
- **Soft authority.** When the principal makes a recommendation it will be followed by the agent if and only if he is uninformed. Thus, the principal can expect to get $(1 - p)B + p\alpha B - k$, while the agent expects $(1 - p)\beta b + pb$.
- **Discretion.** The agent chooses his preferred action when informed and otherwise chooses inaction. Thus, the principal expects to get $p\beta B$ and the agent pb .

Although this is a highly stylized model of interpersonal authority it still produces some striking insights. First, if p is small enough, the principal does not need to rely on hard authority, where the agent is required to follow specific orders: all she needs to do is recommend an action (provided k is small enough), and the agent will follow the recommendation with high probability. Second, if p is high, the principal may want to rely on hard authority (provided K is not too large), as otherwise the agent will, with high probability, not follow her recommendations. In other words, the principal may be worse off hiring an agent who knows too much or is overqualified (the principal's payoff is not monotonic in p). This may be one simple explanation for the observed difficulty highly qualified unemployed workers have of finding employment in jobs requiring lesser skills or experience. Third, when principal and agent objectives are highly

congruent (α and β are close to one) then the principal may prefer to give full discretion to agents with a high p .

The insights gained from this simple model can be applied to two important aspects of job design. First, if the amount of discretion granted to the agent can be contracted on, how much discretion should the agent be given? Second, if the principal can give financial incentives to the agent, to what extent should the agent's compensation be based on output performance?

6.1.1. *Partial Contracting over Authority*

Suppose that the probability p that the agent learns the true payoffs of all the projects is a function of some prior effort of the agent. That is, the agent could choose to learn more, gain more skills, and thus be able to raise p . As we have seen, to the extent that a higher value of p may force the principal to switch from a soft to a hard authority mode, the principal could be made worse off by such an increase in p . In such a situation, the principal could benefit from contractually limiting the agent's discretion, either by reducing the number of actions in her action set, or by committing to a hard authority mode. By only granting partial control to the agent, the principal could discourage the agent from learning too much and thus make the agent more compliant.

As an illustration, suppose that a contract can be written giving the agent only partial authority over projects $j = \xi, \dots, N$, where $\xi \geq 1$. Suppose in addition that if the agent puts in effort e , she becomes informed with probability $p(e) = e$, and that her effort cost is $\psi_A(e) = \frac{1}{2}e^2$. Then, given that projects are ex ante identical, under a mode of soft authority, the agent chooses e to maximize her expected payoff:

$$\frac{N - \xi + 1}{N}eb + (1 - e)\beta b - \frac{1}{2}e^2.$$

The probability $p(e^*) = e^*$ that the agent becomes informed is then given by $e^* = ((N - \xi + 1)/N - \beta)b$, so that the agent can be induced to become more and more compliant by limiting her authority by means of increasing ξ .

6.1.2. *Authority and Financial Incentives*

Except for the very top managers in a firm, it is rare to see other employees' compensation be based mainly on firm performance.¹³ As Van den Steen (2007) argues, one reason may be that, although high-powered output-based incentives boost employees' effort incentives, they may also exacerbate differences of opinion and conflicts over the optimal choice of projects. He argues that output-based incentive schemes may therefore be dominated by input-based incentive schemes.

To illustrate this point in our simple model, suppose that the monetary payoff of any project q_j can take two possible values $q_j \in \{0, X\}$, where $X > 0$. The principal and agent's "private benefits," B and b , respectively, now stand for the principal's and agent's respective beliefs of success: $B = \Pr_P(q_j = X) \in [0, 1]$ and $b = \Pr_A(q_j = X) \in [0, 1]$. Each project costs $\kappa > 0$ to undertake, and as always, we assume that only two actions generate positive net payoffs, given the

13. Two notable exceptions, in which output-based incentive schemes are more common, are high-technology start-ups and investment banking.

principal's and agent's respective beliefs: $\alpha BX - \kappa > 0$ and $\beta bX - \kappa > 0$ (where, as before, $\alpha \in (0, 1]$ and $\beta \in (0, 1]$). In addition, when uninformed, all projects look alike to the principal and the agent and have a negative net expected value: $E_0[q_j] - \kappa < 0$.

Suppose that the principal learns the payoffs associated with each project with fixed probability $E \in (0, 1)$. The principal could offer the agent an output-based incentive scheme to induce her to invest in knowledge and discover the payoffs associated with each project. The benefit to the principal is that a positive net present-value project is then more likely to be selected. Let $\theta \in (0, 1)$ denote the share of profits the agent receives under an output-based incentive scheme, and suppose that θ maps into a probability $e = v\theta$ of the agent learning the payoffs of each project, where $v \in (0, 1)$ is a parameter measuring the incentive efficiency of the performance-based compensation contract.

The agent's knowledge about projects is only valuable in states of nature where the principal is uninformed. In those states the net benefit to the principal is $\alpha B(1 - \theta)X - \kappa$, because (1) the agent chooses her preferred project and thus generates an expected payoff αB given the principal's beliefs, and (2) the principal only receives a share $(1 - \theta)$ of the financial returns and pays the setup cost κ . From an ex ante perspective, the expected value to the principal of giving the agent a performance-based incentive contract θ under a soft authority mode is then

$$E([(1 - v\theta)B + v\theta\alpha B](1 - \theta)X - \kappa - k) + (1 - E)v\theta(\alpha B(1 - \theta)X - \kappa - k),$$

where, recall, $k \in (0, K)$ is the cost to the principal of making a recommendation. Indeed, when the agent is informed, she ignores the principal's recommendation and just picks her favorite action. Therefore, with probability $v\theta$ the principal only obtains $\alpha B(1 - \theta)X$. The marginal benefit of raising θ is then

$$(1 - E)v(\alpha BX(1 - 2\theta) - \kappa - k),$$

and the marginal cost is

$$EBX(1 + v(1 - \alpha)(1 - 2\theta)).$$

Therefore, when

$$EBX(1 + v(1 - \alpha)) > (1 - E)v(BX\alpha - \kappa - k),$$

it is optimal for the principal not to put the agent under a high-powered output-based incentive scheme. Note, in particular, that this condition is more likely to hold the lower is α . In other words, the more the principal and agent's beliefs differ, the less the principal will want to reward the agent based on output performance:¹⁴ he would rather protect his real authority over the agent.

14. Similarly, the less effective is the incentive scheme (the lower v), the more likely it is that this condition will hold.

6.1.3. Abuse of Authority

So far we have only considered situations where both the principal and agent benefit from an action choice. Moreover, we have assumed that the congruence of the principal's and agent's objectives is commonly known to both parties. As a result, an uninformed agent is happy to follow the principal's recommendation, as she knows that she would also benefit from taking the recommended course of action.

But suppose now that the principal's recommended actions do not always benefit the agent, and that the principal may have better information than the agent on the two parties' objectives. Specifically, suppose that the degree of congruence can be either (α_H, β_H) or (α_L, β_L) , where $1 > \alpha_H > \alpha_L > 0$ and $1 > \beta_H > 0 > \beta_L$. And assume that the principal knows the true value of α and β , but the agent's prior beliefs put equal probability weight on high and low congruence. Under these parameter values, the principal may want to take an action under low congruence, even though the agent is made worse off by that action choice. Thus, the agent now worries that with a 50% probability, the principal's favorite project is worse than doing no project at all.

Under these circumstances the preferred mode of authority may vary, depending on the realization of (α, β) , so that the principal's chosen mode of authority may itself be a signal of congruence. For example, the principal may choose soft authority when congruence is high and hard authority when it is low. This is the case when the following conditions hold:

$$p\alpha_L B + (1 - p)B - k \leq B - K - \beta_L b$$

$$p\alpha_H B + (1 - p)B - k \geq B - K.$$

This simple example illustrates the effect first highlighted in Dessein (2005) and mentioned at the beginning of Section 4.2: when congruence is high but unknown to the agent, the principal may prefer to give her more discretion. The principal's recommendation then carries more weight, as the agent always chooses to follow the principal's recommendation when she is uninformed herself.

The example above illustrates a situation of benign potential abuse of authority, which can be overcome through an appropriate choice of mode of authority. In the next section, however, we explore a situation with more severe abuse of authority, which cannot be overcome in a simple one-shot interaction between the principal and agent. In this situation the principal always has an informational advantage over the agent ($p = 0$) and may prefer actions that make the agent strictly worse off. For example, the principal may have an action in his choice set with payoffs $(\theta B, \lambda b)$, where $\theta > 1$ and $\lambda < 0$, but where $\theta B + \lambda b < B + \beta b$. Clearly, in a one-shot contracting relation the agent will not be able to stop the principal from recommending the abusive or exploitative action. But as we illustrate in the next section, in a repeated long-term employment relation similar to relational contracting situations studied in Bull (1987), MacLeod and Malcomson (1989), Baker et al. (1999), and Levin (2003), among others, it is possible for the principal to gain authority over the agent by developing a reputation for treating employees fairly.

6.2. Authority as an Optimal Relational Contract

This final section also discusses a form of authority that has to do with issuing orders that are expected to be followed by subordinates because of an informational advantage of the principal, and that is sustained by an ongoing relation built on trust, as Bolton and Rajan (2001) have argued (see also Bolton and Dewatripont 2005: 585–594). The central questions concerning this form of authority are why it exists in the first place, and why this mode of transaction is preferred over a spot-contracting mode.

Bolton and Rajan (2001) assume that giving orders requires in the first place superior information by the principal (the issuer of orders). The principal must have superior information on which action by the agent is best for the agent. Second, an ongoing authority relationship based on trust is fundamentally more flexible than a spot-market negotiation-based transaction. However, such a relation is not always sustainable if the agent suspects that the principal will exploit the agent in the authority relation.

As in Simon (1951), Bolton and Rajan compare two modes of transacting, a *negotiation/contracting mode* in anonymous markets and an *authority mode* built on long-term personal relations. In the contracting mode, the services or goods to be provided by an agent (the seller) as well as the terms of trade are spelled out in detail in a spot contract. In the authority mode, the principal (the buyer) writes a long-term employment contract with the agent (seller), specifying only the terms of employment, leaving the details of which service to provide in any given period unspecified. In this mode, the buyer gives orders or directs the seller to perform a specific service in each period. The seller only has the choice of executing the order or quitting. There are no ongoing negotiations about which service to provide or at what terms.

As the authority mode is based on a long-term contract and an ongoing relationship, the timing of the seller's payments can be made more flexible. The principal can now compensate the agent with a bonus after the latter has carried out a particularly costly service. The principal's incentive to voluntarily pay such a bonus, which is purely discretionary, is supported by the agent's threat to dissolve the relationship should the principal not compensate him adequately. When the principal is expected to always fully cover the agent's costs *ex post*, the agent is also willing to execute the order. Moreover, since the principal always ends up paying the true cost of services ordered under the authority relation, she has an incentive to always demand the value-maximizing services. In other words, the principal chooses the first-best action in the authority mode and thus generates an efficiency gain, which will be lost should the agent (employee) decide to quit. It is the prospect of losing this efficiency rent that preserves the principal's incentives to adequately compensate the employee's costs and induce him to stay. Thus, as long as the principal and agent transact sufficiently frequently and do not discount the future too much, they will be better off in a long-term employment relationship than by trading anonymously in a spot market.

A related analysis of authority as an optimal relational contract has been proposed by Wernfelt (1997). He considers an employment relationship as an efficient relational contract to economize on explicit contract negotiation costs. The main benefit of the employment relation in his model is that fewer contractual terms have to be bargained over before trade can take place.

7. Conclusion

As the literature discussed in this chapter highlights, approaching the analysis of the internal organization of firms from the perspective of allocation of authority to managers is a fruitful avenue of research. This approach emphasizes the dilemmas managers face in exercising authority and thereby sheds new light on the importance of (formal and informal) internal communication protocols, as well as institutional commitments to preserve managerial discretion. The rational contracting perspective of most articles reviewed in this chapter, however, paints an excessively hopeful picture of the efficiency of firms' internal organizations. In reality, the sheer complexity of the problem of dynamic organizational design is likely to overwhelm even the most persistent efforts at rationalizing the firm's internal hierarchy. What is more, power struggles and office politics, forces this chapter has entirely ignored, substantially complicate the implementation of a rational internal order.

Decisions in Organizations

Robert Gibbons, Niko Matouschek, and John Roberts

1. Introduction

Organizations exist largely to get things done. Determining what should be done, by whom, how, when, and where (and then actually getting it done) requires decisions, and making good decisions depends on the decisionmaker's having the relevant information. However, as emphasized by Hayek (1945), the relevant information is typically dispersed (and may need to be developed). Thus, communication is necessary if decisionmakers are to become informed. If those communicating the information recognize how what they transmit will affect decisions, then they may be led to communicate strategically, withholding information or misrepresenting it. Then the decisionmaker will need to take account of this behavior when making decisions. This chapter investigates these issues and how the negative consequences of strategic behavior can be limited and the quality of decisionmaking improved through design of the decision process and the reward structure of the organization.

Jacob Marschak initiated the formal study of the value of information in decision problems under uncertainty during the 1950s, culminating in Marschak (1971). In parallel, Hurwicz (1960) began exploring the problem of designing communication and decision systems to achieve allocative and informational efficiency. Especially notable in this vein of research is the Marschak and Radner (1972) theory of teams, which analyzed systematically the problems of information acquisition, communication, and decisionmaking in organizations. Notably, this work and the large literature that follows from it assume that all parties share a common objective, such as maximizing the firm's profit. There is thus no shirking, free riding, lying, lobbying, collusion, or politics in these models.¹

We are very grateful for help from Ricardo Alonso, Dan Barron, Nancy Beaulieu, Leshui He, Anton Kolotilin, Hongyi Li, Meg Meyer, Mike Powell, Michael Raith, Heikki Rantakari, Eric Van den Steen, Tommy Wang, Julie Wulf, Luis Zermeno, and seminar participants at Oxford. We also gratefully acknowledge research support from the Massachusetts Institute of Technology Sloan School's Program on Innovation in Markets and Organizations.

1. See Garicano and Van Zandt (this volume) for a thorough treatment of common-interests models of organizations.

The formal analysis of such incentive issues in decision and allocation mechanisms began with Hurwicz (1972, 1973), who introduced explicit game-theoretic treatments of strategic communication and first investigated the possibility of designing mechanisms to minimize the effects of strategic behavior induced by the mechanism. Essentially all the literature we discuss in this chapter builds on the foundations that Hurwicz laid.²

The other key element in developing the literature we examine here is contractual incompleteness.³ The parties not only cannot bind themselves to be fully honest in their reports, they also cannot necessarily commit to particular decision rules or future reward schemes. This moves the analysis from the domain of “mechanism design” that has flourished in the wake of Hurwicz’s initial contributions to one where shirking, free riding, lying, lobbying, collusion, or politics are central.

Informal arguments that conflicting interests in organizations are widespread and important for the design and functioning of the organization go back a long way in economics. For example, Knight (1921/1964: 254) observed that the “internal problems of the corporation, the protection of its various types of members and adherents against each other’s predatory propensities, are quite as vital as the external problem of safeguarding the public interests against exploitation by the corporation as a unit.”

Consistent with the importance of these issues, outside economics, the political approach to organizational behavior also has a long pedigree. For example, March (1962/1988: 110–112) described “the business firm as a political coalition” in which “the executive . . . is a political broker” who cannot “solve the problem of conflict by simple payments to the participants and agreement on a superordinate goal.” In a similar spirit, Zald and Berger (1978) described organizational conflict and change in terms of social movements, finding inside corporations analogues of coups d’état, bureaucratic insurgencies, and mass movements.

As Gibbons (2010: 347) suggests, some of this early work outside economics is close in spirit to current economic modeling. For example, Cyert and March (1963: 30, 32) constructed strategic accounts of organizational behaviors in terms of individuals’ decisionmaking, beginning from the assertions that “people (i.e., individuals) have goals; collectivities of people do not” and “the existence of unresolved conflict is a conspicuous feature of organizations.” More specifically, Cyert and March (1963: 79) anticipated the application of information economics to the study of organizations, arguing first that “where different parts of the organization have responsibility for different pieces of information relevant to a decision, we would expect . . . attempts to manipulate information as a device for manipulating the decision.” They also saw that such strategic behavior would generate attempts by the decisionmaker to undo the attempted manipulation: “We cannot reasonably introduce the concept of communication bias without introducing its obvious corollary—‘interpretive adjustment’” (Cyert and March 1963: 85). In short, compared to the traditional description of an organization in terms of an organization

2. See Maskin (1977/1999) and Myerson (1981) for seminal contributions to mechanism design; see Mookherjee (this volume) for applications of these ideas to organizational issues.

3. Williamson (1975) was a leader in insisting on the importance of contractual incompleteness in organizational problems, although, for example, Simon (1951) also depends on incomplete contracting. Grossman and Hart (1986) introduced formal models of incomplete contracts.

chart, Cyert and March (1963: 202) suggested that “the kinds of models presented in this book describe the organization as a decision-making process”—and a strategic one, at that.

This chapter surveys the theoretical literature in organizational economics on decisions in organizations, focusing on models where parties’ interests are imperfectly aligned. This literature is mostly recent but is growing quickly. Our overarching perspective is that this literature is very much in the spirit of the approach initiated by March (1962/1988) and Cyert and March (1963).

More specifically, we break our discussion into two parts. In the first half of the chapter (Sections 2 and 3), we study game-theoretic models of communication and decisionmaking under fixed decision processes (e.g., fixed specifications of who controls which decisions). These models categorize various ways in which strategic considerations with respect to information transmission can impose costs on organizations. In the second half (Sections 4 and 5), we then endogenize the decision process (e.g., we ask what allocation of decision rights the parties should choose). More generally, in these sections we explore the tools that organizations have to mitigate the costs identified in Sections 2 and 3.

2. Fixed Decision Processes

This section is the first of two on decisionmaking under fixed decision processes. Here we describe and analyze a basic model that is on one hand quite simple but on the other surprisingly flexible, in that it encompasses a wide range of models from the literature. We use this basic model mostly to introduce ideas. Section 3 then discusses richer analyses.

One of the motivations for our basic model comes from Milgrom and Roberts (1988), who discussed the incentives for people in organizations to distort information collection and transmission to influence decisions to their advantage. They recognized a variety of possible costs of such “influence activity,” including the opportunity costs of time and other resources spent on trying to affect the distribution of costs and benefits without improving efficiency, the possibility of decisions being distorted by the influence, and the costs of altering the organizational design and decision processes to limit influence.

Another motivation comes from Mintzberg (1979), who described a decision process as moving from information to advice to choice to execution, as shown in Figure 1.⁴ We begin by defining our basic model based upon what we see as the influence link in Mintzberg’s schema, from advice to choice. While a surprising array of models can be captured this way, in Section 3 we discuss both a reinterpretation of our basic model as being from choice to execution and an enrichment of the model to being from information to advice to choice.

After describing the basic model in Section 2.1, in Sections 2.2–2.6 we analyze five illustrations of the basic model, motivated by the cheap-talk model in Crawford and Sobel (1982), the signal-jamming models in Holmström (1982/1999) and Gibbons (2005), the signaling models in Austen-Smith and Banks (2000) and Kartik (2007), the verifiable-information models in Grossman (1981) and Milgrom (1981), and the strategic management of public information

4. Fama and Jensen (1983) proposed a related process running from initiation to ratification to implementation to monitoring. This process does not so directly involve communication, so we favor Mintzberg’s for present purposes.

Figure 1. The decision process, adapted from Mintzberg (1979).

models in Rayo and Segal (2010) and Kamenica and Gentzkow (2011).⁵ These five illustrations show how even this basic model, although simple, also can generate quite rich examples of strategic political behavior in communication and decisionmaking. We illustrate how different environments for communication and decisionmaking produce different strategic behaviors that impose different costs on the organization.

In Sections 2.2–2.6 we present just the core results that arise from these five illustrations of the basic model. In Section 2.7 we compare, contrast, and interpret these five models and relate their results to prominent claims and observations in the noneconomic literature.

2.1. A Basic Model

Our basic model has only two players, each of whom moves once in the following simple sequence:

1. The state of the world $s \in S$ is drawn from the distribution $f(s)$.
2. Player 1 privately observes the signal θ drawn from the distribution $g(\theta|s)$.
3. Player 1 chooses an *influence action* $a \in A$.
4. Player 2 privately observes the signal σ drawn from the distribution $h(\sigma|s, a)$.
5. Player 2 chooses a *decision* $d \in D$.
6. The players receive payoffs $U_i(s, a, d)$ for $i = 1, 2$.

Note that we assume that payoffs $U_i(s, a, d)$ are independent of the signals θ and σ , capturing the idea that it is really the state $s \in S$ and the players' choices that matter.

For simplicity (and, to some extent, for realism regarding the environments we attempt to capture), we assume that nothing in this model is contractible. For example, player 1's influence action $a \in A$ is not contractible, nor is player 2's decision $d \in D$, nor are the players' payoffs $U_i(s, a, d)$. Thus, there cannot be bargaining over either player's move, nor can there be mechanisms designed to elicit either player's private signal, nor can there be outcome-contingent incentive contracting.

5. Although the terms “signaling,” “cheap talk,” and perhaps “signal jamming” are well established, the models in Sections 2.5 and 2.6 go by various names, some of which apply to most or all models in this section, such as “persuasion” or “information disclosure.” We have therefore chosen names for the models in these two sections that illustrate their core assumption or interpretation: “verifiable information” and “strategic management of public information,” respectively.

For definiteness, we take player 1 to be male and player 2 female. As appropriate below, we also refer to the players as “sender” and “receiver,” “employee” and “owner,” or “leader” and “follower,” respectively.⁶

2.2. Cheap Talk

Perhaps the most direct application of our basic model is the seminal theory of “cheap talk” by Crawford and Sobel (1982), in which messages are costless (so talk is not just cheap but actually free). In particular, player 1 learns the state of the world (i.e., $\theta = s$), player 1’s action is to send a message to player 2 (i.e., $\sigma = a$), and this message is payoff irrelevant (i.e., payoffs are $U_i(s, d)$). The major result in such models is that the misalignment of preferences typically prevents full revelation of information.

As an informal example of a cheap-talk sender-receiver game, consider a biased local manager advising a CEO about capital allocation to the manager. The manager can say anything he wants to the CEO, at no cost. The CEO wants to gear her decision to the local information that only the manager has, but the manager is known to want the decision to differ systematically from what the CEO would want in any particular state, for instance because of empire building or career concerns. Although the manager is biased, suppose he also has an interest in the CEO’s decision being geared to the environment. Then the manager’s interest in the CEO’s decision being geared to the environment may limit, but not eliminate, his incentive to misrepresent his information. Put differently, in a cheap-talk setting, the CEO cannot accept at face value any claim the manager makes (lest the manager make an inflated claim that would then cause the CEO to take the decision the manager wants), nor can the manager tell the CEO the full truth (lest the CEO then ignore the manager’s preferences and impose the decision she prefers). In equilibrium, however, if the manager is not too biased, then partial communication can occur, as follows.

Suppose that the state s is uniformly distributed on $[0, 1]$ and the parties have quadratic payoffs $U_2(s, a, d) = -(d - s)^2$ and $U_1(s, a, d) = -(d - [s + b])^2$, where the imperfect alignment of the parties’ interests is captured by the parameter b , which we take to be positive for definiteness. In this setting, the sender’s message rule $a(s)$ cannot perfectly reveal the state. Loosely, if the sender’s message did reveal the state, then the receiver would choose the decision $d = s$, so the sender would want to send a message that induced the receiver to choose $d = s + b$.

Instead of full revelation of the sender’s information, what does happen is that all perfect Bayesian equilibria are economically equivalent to partition equilibria: the state space is partitioned into N intervals $0 = s_0 \leq s_1 \leq \dots \leq s_{N-1} \leq s_N = 1$ and the sender’s message reveals which interval $[s_{i-1}, s_i)$ contains the state. For any value of b , there is an uninformative equilibrium in which $N = 1$ (i.e., the sender’s message is equivalent to saying that $s \in [0, 1]$, which reveals nothing about the state, so the receiver retains her prior belief that s is uniform on $[0, 1]$

6. Although all examples that follow exhibit some degree of conflict of interest between the players, this framework can also be used to explore team-theoretic models, which assume common interests. For example, see Section 4.3 of Bolton and Dewatripont (this volume) for a simplified version of Dessein and Santos (2006) that fits our basic framework.

and hence chooses $d = \frac{1}{2}$). For sufficiently small values of b , however, there are also other equilibria with more intervals. For example, if $b < \frac{1}{4}$, then there exists a two-interval equilibrium in which $s_1 = (1 - 4b)/2$. In this equilibrium the sender's message reveals whether $s \in [0, s_1)$ or $s \in [s_1, 1]$, and the receiver's decision is then $d = s_1/2$ or $d = (1 + s_1)/2$, accordingly. Note that the ideal decision for sender type $s = s_1$ is $d = s_1 + b$, so sender type $s = s_1$ is indifferent between the receiver's two decisions in this equilibrium, $d = s_1/2$ or $d = (1 + s_1)/2$, and this indifference is what makes all sender types $s < s_1$ prefer to say $s \in [0, s_1)$ and all those $s > s_1$ prefer to say $s \in [s_1, 1]$.

For sufficiently small values of b , there are more equilibria—one for each number of intervals from $N = 1$ to $N = N(b)$, where $N(b)$ weakly increases as b falls toward zero. In each such equilibrium, the sender type on the boundary between two intervals, $s = s_i$ between $s \in [s_{i-1}, s_i)$ and $s \in [s_i, s_{i+1})$, is again indifferent between the receiver's equilibrium decisions following these messages, and this indifference is again what makes other sender types strictly prefer to send their equilibrium messages. When b falls, the necessary distance between these two decisions decreases, so it becomes possible to have more interval messages in equilibrium (i.e., $N(b)$ increases).

Interestingly, although Crawford and Sobel's original motivation was from bargaining with asymmetric information, their model has recently become a workhorse in the organizations literature. See Sections 3.1, 3.2, 3.3, and parts of Section 5 for the next steps and Sobel (2012) for a comprehensive survey.

2.3. Signal Jamming

One of the central ideas in the Milgrom and Roberts (1988) work on influence activities is the observation that those in control get lobbied.⁷ This idea also fits naturally in our basic model, such as when an owner controls a decision and would like to have the decision tailored to the state of the world but does not know the state, and an employee has an opportunity to influence the signal about the state that the owner observes (and hence to influence the owner's belief about the state and thus influence the owner's decision). The major result of such models is that resources are spent on lobbying even though, in equilibrium, lobbying does not affect the decision.

More formally, consider the following model from Gibbons (2005), which adapts Holmström's (1982/1999) model of career concerns in labor markets to consider influence activities in organizations. A key point is that these models analyze *signal jamming*. That is, in a departure from both the cheap-talk model in Section 2.2 and the signaling model in Section 2.4, here there is symmetric uncertainty about the state s (i.e., player 1's signal θ in stage 2 of the basic model is uninformative). Nonetheless, the employee (player 1) does have an opportunity to influence the signal that the owner (player 2) observes about the state (σ in stage 4 of the basic model). In particular, $\sigma = s + a + \varepsilon$, where $a \geq 0$ at cost $k(a)$ is the employee's choice of "lobbying" activities in stage 3 of the basic model. We assume that s is normally distributed with mean m and variance $1/h$ (i.e., precision h) and ε is normally distributed with mean zero and precision h_ε .

7. Parts of this section draw on Gibbons (2010), with permission from the *Annual Review of Economics*, Volume 2, © 2010 by Annual Reviews, <http://www.annualreviews.org>.

Because the state s is normal, assume that the owner's decision space is $D = \Re$. Finally, let the cost function satisfy $k'(0) = 0$, $k'(\infty) = \infty$, and $k'' > 0$, and suppose that the parties again have quadratic loss functions. The parties' payoffs are then $U_1(s, a, d) = -(d - [s + b])^2 - k(a)$ and $U_2(s, a, d) = -(d - s)^2$, where again $b > 0$ for definiteness.

The signal σ is the crux of the model: even though neither party knows the true state, both parties care about how the eventual decision will relate to the state, so the owner will try to extract from the signal whatever information σ might contain about the state, prompting the employee to try to move the realization of σ upward. In equilibrium, however, the owner correctly anticipates the employee's attempts to influence σ and so correctly accounts for those attempts when interpreting σ as a signal about s . Nevertheless, the employee has an incentive to increase σ . In particular, even though the owner is not fooled, the equilibrium level of lobbying cannot be zero, because if the owner believed the employee to be doing no lobbying, then the employee would have a strong incentive to lobby.

To analyze the model, we work backward. The owner will choose d to solve

$$\max_{d \in D} E_s [U_2(s, d) | \sigma],$$

so the solution is $E_s[s | \sigma]$. If the owner's conjecture about the employee's lobbying is a , then DeGroot (1970: 155–189) shows that

$$E_s[s | \sigma] = \frac{hm + h_\varepsilon(\sigma - \hat{a})}{h + h_\varepsilon}.$$

The employee therefore chooses a to solve

$$\max_{a \geq 0} -E_{s, \varepsilon} \left[\left(\frac{hm + h_\varepsilon(\sigma - \hat{a})}{h + h_\varepsilon} - (s + b) \right)^2 \right].$$

The first-order condition for a is then

$$-2 \left(\frac{h_\varepsilon}{h + h_\varepsilon} \right) \left\{ \frac{h_\varepsilon}{h + h_\varepsilon} (a - \hat{a}) - b \right\} = k'(a),$$

which implicitly defines $a^*(\hat{a})$, the employee's best response to the owner's conjecture.

In equilibrium, the owner's conjecture must be correct, so imposing $a^*(\hat{a}) = \hat{a}$ yields the first-order condition for the equilibrium level of the employee's lobbying activity. Denoting this equilibrium level of lobbying by a^* , we have

$$2 \frac{h_\varepsilon}{h + h_\varepsilon} b = k'(a^*).$$

In words, the equilibrium level of lobbying is positive, even though in equilibrium the owner is not fooled (so the lobbying costs are a deadweight loss). Furthermore, a^* increases with the employee's bias b (because the employee cares more about moving the owner's decision), with

the precision of the public signal h_ε (because the owner will put more weight on the signal, so it is more useful to the employee to influence the signal), and with the prior variance of the state $1/h$ (because the owner will again put more weight on the signal, now for lack of useful prior information about the state).

2.4. Signaling

To complement the foregoing cheap-talk and signal-jamming models illustrating the basic model, we turn next to a third category of games, again familiar from information economics: signaling. (See Fudenberg and Tirole (1991: 324–336) for the basic game theory.) As in a cheap-talk game, player 1 has private information (i.e., $\theta = s$ in stage 2 of the basic model), and player 2 observes player 1's action (i.e., $\sigma = a$ in stage 4), so the sender's choice of a may change the receiver's belief about s and hence change the receiver's choice of d in stage 5. As in the signal-jamming game, but unlike the cheap-talk game, player 1's action (a in stage 3) incurs cost. The major result in the models that follow Spence (1973) is that some actions may convey information because only certain types would be willing to take those actions (and they are willing only because these actions will indeed convey information). This may happen either because the costs of the action to the sender or the sender's benefit from the receiver's response are related to the state in such a way that, on one hand, it is worthwhile expending the costs to have the decisionmaker infer the state correctly for some realizations of the state, and on the other, it is not worthwhile for senders in other states to try to fool the decisionmaker.⁸

Hermalin (1998) uses a signaling model to study leadership. He begins from the view that “a defining feature of leadership . . . [is that a] leader is someone with followers” (Hermalin: 1188), from which it follows that “a central question in understanding leadership is how does a leader induce others to follow?” In his model of “leading by example,” the leader (here, player 1) observes the state of the world and takes an observable action; the follower (player 2) then draws an inference about the state and subsequently makes a decision. In “good” states, where having the followers actually follow is more important, the leader will take a more costly action to signal that his private information really does indicate that following is particularly valuable. Hermalin (this volume) discusses several models in this vein.

When there are benefits to revealing player 1's information about the state, signaling can occur simply by expending resources in an otherwise useless fashion. Such wasting of resources has come to be called “money burning,” but in an organizational context it might be fighting through red tape and bureaucratic sclerosis: being willing to spend one's time on such activities signals one's conviction. For expositional simplicity, we describe a signaling model of money burning adapted from Austen-Smith and Banks (2000) and Kartik (2007); see Kartik et al. (2007) and Kartik (2009) for similar models with lying costs instead of money burning. As in the cheap-talk model, suppose the state is uniformly distributed on $[0, 1]$. As in the signal-jamming model, the parties' payoffs are again $U_1(s, a, d) = -(d - [s + b])^2 - k(a)$ and $U_2(s, a, d) = -(d - s)^2$, with $b > 0$ for definiteness. To capture the idea that player 1's action is burning money, however, assume that $k(a) = a$ for $a \geq 0$. Unlike the cheap-talk model, where

8. This is essentially a matter of the sign of the cross partial derivative of the sender's payoff with respect to the receiver's inference about the state and the sender's action.

the sender's action could not perfectly reveal the state, here a separating equilibrium can exist, as follows.

If the sender's action perfectly reveals the state, then the receiver's optimal decision is equal to the state that the sender's action revealed, so the sender of type s could choose to induce any decision $d' = s'$ by taking the action intended to be taken by sender type s' . To deter such deviations, the sender's action rule $a^*(s)$ must satisfy

$$-b^2 - a^*(s) \geq -(s' - [s + b])^2 - a^*(s')$$

for all s' . It is straightforward to check that $a^*(s) = 2bs$ satisfies the above incentive-compatibility condition for the sender and thus can be the basis for a separating perfect Bayesian equilibrium in this signaling game. Compared to the signal-jamming game (which has symmetric uncertainty about s and, as a result, the cost of influence activities is $k(a^*)$, regardless of the state), here the cost of money burning increases with the state, because, in a separating equilibrium, each sender of type s needs to distinguish himself from those just below.

2.5. Verifiable Information

Grossman (1981) and Milgrom (1981) introduced the possibility that the sender can withhold information but cannot otherwise misrepresent his information. As opposed to the cheap-talk game (where the sender can say anything) and the signal-jamming and signaling games (where the sender's action is not a direct report about the state of the world), here we call any information the sender presents "hard" or "verifiable." Some such models lead to efficient decisions and outcomes, because the incentives for the sender not to be thought to have very negative information lead to full revelation of the state. Thus, a major result in such models is that strategic considerations may carry no cost in communication and decisionmaking.

Formally, as in the cheap-talk game, player 1 learns the state of the world (i.e., $\theta = s$), player 1's action is to send a message to player 2 (i.e., $\sigma = a$), and this message is payoff irrelevant (i.e., payoffs are $U_i(s, d)$). The question is then how to model the idea that player 1 can withhold but not misrepresent information. The simplest approach is to enrich the basic model slightly, by allowing the feasible set A to depend on the state and to assume that $A = \{s, \phi\}$, meaning that player 1's options are to reveal the state ($a = s$) or say nothing ($a = \phi$).⁹

After receiving the signal σ , player 2 then chooses a decision d , and the parties receive their payoffs. Player 1's payoff is increasing in d and independent of s , whereas player 2's is such that, if player 2 knew s , then her optimal choice of d would be strictly increasing and continuous in s . For now, assume $U_1(s, a, d) = d$ and $U_2(s, a, d) = -(d - s)^2$. As a result, player 1 wants to persuade player 2 that the state is high. For simplicity, suppose that s is distributed on $[0, 1]$.

The first (and striking) result in this model is that any equilibrium has full revelation. The key to this revelation result is an "unraveling" argument. Suppose first that the sender announces $a = \phi$ for all s . Then the receiver will optimize given her prior distribution on the state space, choosing $d = E(s)$. However, when $s = 1$ (and actually for any s close to 1), the sender would

9. The same basic results hold if one assumes instead that A is all the subsets of the state space S and player 1 of type s can send any message as long as it contains s .

gain from deviating from announcing the actual state, because this would lead to a higher decision. In fact, if there are any two different states s' and s'' , with $s' > s''$, that both send the same message, then the receiver's decision will be higher if s' reveals itself rather than sending that message, so unraveling will occur. So the equilibrium must have correct revelation (except perhaps at $s = 0$, but this case is immaterial).

Milgrom and Roberts (1986) and Okuno-Fujiwara et al. (1990) extended the basic analysis in a number of directions, such as competition among senders and general Bayesian games (i.e., many players with private types, each taking their own actions). Seidmann and Winter (1997) provide general conditions (on the preferences of players 1 and 2) for existence and uniqueness of a fully revealing equilibrium; in particular, they show that the quadratic-loss, constant-bias payoffs $U_1(s, a, d) = -(d - [s + b])^2$ and $U_2(s, a, d) = -(d - s)^2$ also necessitate full revelation in equilibrium (for overviews, see Milgrom 2008; Sobel 2012).

Finally, although full revelation necessarily occurs in the equilibrium of the basic verifiable-information game above, this result depends on it being common knowledge that the sender is informed (see, for instance, Dye 1985). Suppose instead that in stage 2 there is probability q that $\theta = s$ and probability $1 - q$ that $\theta = \phi$ (i.e., the sender receives no information at all). Straightforward calculations then show that in equilibrium there is a critical value $s^*(q)$ such that

1. if $\theta = s$ and $s > s^*(q)$, then the sender reveals s ;
2. if $\theta = s$ and $s < s^*(q)$, then the sender reports $a = \phi$; and
3. if $\theta = \phi$, then the sender reports $a = \phi$.

To compute $s^*(q)$, suppose that s is uniformly distributed on $[0, 1]$, $U_1(s, a, d) = d$ and $U_2(s, a, d) = -(d - s)^2$. If the sender reveals s , then the receiver chooses $d = s$, whereas if the sender reports $a = \phi$, then the receiver chooses $d = q \times s^*(q)/2 + (1 - q) \times \frac{1}{2}$, so $s^*(q) = (1 - q)/(2 - q)$. Naturally, for $q = 1$, we recover full revelation, whereas for $q = 0$, only the upper half of the type space reveals itself.

2.6. Strategic Management of Public Information

The final illustration of our basic model concerns the strategic management of public information. A major contribution of this emerging literature is to shed light on the conditions under which the ability to manage public information strategically leads to a loss of information.

To introduce this final illustration of our basic model, consider the issue of agenda control. In some settings, for instance, information acquisition and deliberation are followed by voting, but one or more actors can call the question, meaning that the vote must occur immediately, which prevents further information acquisition. For a simple model motivated by Brocas and Carrillo (2007), suppose player 1 has no private information, but he can attempt to influence player 2's belief by affecting what public information she observes. Formally, the state is uniformly distributed on $[\underline{s}, \bar{s}]$, where $\underline{s} < 0 < \bar{s}$, player 1's signal θ is uninformative, player 1's influence action is $a \in A = \{0, 1\}$, and player 2's signal is $\sigma = sa$.

Now suppose that player 2's decision d is binary: either she implements a new project with payoff s for her or she preserves the status quo with payoff 0 for her. Player 1, however, benefits

when the new project is implemented and not otherwise, and player 1's action a is costless. Formally, $D = \{0, 1\}$, $U_1(s, a, d) = d$, and $U_2(s, a, d) = ds$.

In this setting, player 1 has two choices: $a = 0$, in which case player 2 chooses $d = 1$ if and only if $E(s) > 0$, or $a = 1$, in which case player 2 observes $\sigma = s$ and then chooses $d = 1$ if and only if $s > 0$. Clearly, if $E(s) > 0$, then player 1 should choose $a = 0$, and otherwise he should roll the dice by choosing $a = 1$. In a richer model, instead of being uninformative, player 1's signal θ could be publicly observed, in which case analogous reasoning begins by assessing whether $E(s|\theta) > 0$.

Beyond agenda control, now consider a pharmaceutical company designing a clinical trial to influence a regulator. Alternatively, to give an example from inside an organization, imagine a boss, who, as part of rolling out a new program, can commission a study in the hope that its public results will motivate employees to implement the program well. What kind of trial/study should player 1 design?

Formally, the model is as above, except now suppose that player 1's influence action is to choose a critical value $s^* \in [\underline{s}, \bar{s}]$ such that player 2's signal will be $\sigma = (s^*, x)$, where x is a binary random variable: $x = L$ if $s < s^*$, and $x = H$ if $s > s^*$. To keep things interesting, suppose that $E(s) < 0$ (i.e., $|s| > \bar{s}$), in which case player 1's optimal influence action is to choose $s^* = -\bar{s}$, maximizing the probability that player 2 will choose $d = 1$.

Kamenica and Gentzkow (2011) study a general version of this model, which can be interpreted as strategic management of public information by an interested party. This final illustration of our basic model is closer to the signal-jamming than to the cheap-talk, signaling, or verifiable-information illustrations, because we assume that player 1 has no private information and his influence activity is an attempt to change player 2's belief by changing the design of a public signal. Formally, player 1's influence action a is to choose a realization space X and a family of likelihood functions $\{\lambda(x|s)\}_{s \in S}$. Player 2's signal σ is then the family of likelihood functions and a realization $x \in X$. In the clinical trial/corporate study example above, the critical value s^* was all player 2 needed to know to understand the family of likelihood functions $\{\lambda(x|s)\}_{s \in S}$.

Kamenica and Gentzkow (2011) provide necessary and sufficient conditions for player 1's optimal influence action to be uninformative (e.g., X has only one element), and they derive other properties of player 1's optimal influence action, including the case of quadratic loss functions (which we discuss further in Section 2.7). Kolotilin (2012a) analyzes the special case above, where D is binary and player 1's payoff is $U_1(s, a, d) = d$, for which he fully characterizes player 1's optimal influence action. Finally, Rayo and Segal (2010) and Kolotilin (2012b) analyze the case where player 2 has private information, separate from the realization of player 1's likelihood functions. This case is important, both because a single player 2 may indeed have private information and because there may instead be a group of player 2s with known but heterogeneous preferences.

2.7. Summary

We now summarize and assess the models in this section, noting both their similarities and their differences, as well as some of their existing and potential connections to past and future literatures. To emphasize some important similarities, we begin with the special case of our basic

model in which the parties have quadratic loss functions. To encompass the signal-jamming and signaling models, we also include the cost $k(a)$ in player 1's payoff, so the payoff functions are $U_1(s, a, d) = -(d - [s + b])^2 - k(a)$ and $U_2(s, a, d) = -(d - s)^2$.

Under full information about s , the action $a = 0$ and the decision $d = s + (b/2)$ would maximize the parties' total payoff

$$U_1(s, a, d) + U_2(s, a, d) = -(d - [s + b])^2 - k(a) - (d - s)^2,$$

producing a total payoff of $-\frac{1}{2}b^2$. Because d is not contractible, however, in all five models in this section—cheap talk, signal jamming, signaling, verifiable information, and strategic management of public information—player 2's equilibrium decision is $d^*(\sigma) = E_{s|\sigma}(s|\sigma)$. We therefore can write the parties' equilibrium expected total payoff as

$$\begin{aligned} E[U_1(s, a, d) + U_2(s, a, d)] &= E_s[-(d - [s + b])^2 - k(a(s)) - (d - s)^2] \\ &= E_\sigma\{E_{s|\sigma}[-(d - [s + b])^2 - (d - s)^2]|\sigma\} - E_s[k(a(s))] \\ &= -b^2 - 2E_\sigma[Var(s|\sigma)] - E_s[k(a(s))]. \end{aligned}$$

Thus, regardless of the model, the loss the parties suffer between their optimized total payoff under full information, $-\frac{1}{2}b^2$, and their equilibrium expected total payoff in any of our models, $-b^2 - 2E_\sigma[Var(s|\sigma)] - E_s[k(a(s))]$, is

$$\frac{1}{2}b^2 + 2E_\sigma[Var(s|\sigma)] + E_s[k(a(s))].$$

This expression measures the total expected equilibrium loss from strategic communication and decisionmaking in all five models. The first term, $\frac{1}{2}b^2$, captures the loss in total payoff from the noncontractibility of d , so player 2's equilibrium decision is $d^*(\sigma) = E_{s|\sigma}(s|\sigma)$ rather than $E_{s|\sigma}(s|\sigma) + \frac{1}{2}b$. In this sense, the average decision is not optimal, regardless of the state. The parties incur this loss in all five models.

The second term, $2E_\sigma[Var(s|\sigma)]$, measures the loss $E_\sigma[Var(s|\sigma)]$ that each party incurs because the decision is not perfectly adapted to the state, as it would be if the decision were $d = s + (b/2)$ or any other function $d = s + z$ for some constant z . This loss is not about the average decision, but instead about how the decision varies with the state. Because different models produce different equilibrium signals σ , the size of this loss varies across models. For example, the coarse communication in the cheap-talk model does not reduce this term to zero, whereas the full revelation that may occur in the signaling, verifiable-information, and public-information models does, and the way the receiver accounts for the sender's influence activity in the signal-jamming model reduces this term not to zero but at least to as low as it can be, given the noise ε in the signal $\sigma = s + a + \varepsilon$.

Finally, the third term, $E_s[k(a(s))]$, reflects player 1's expected costs of influence activities, so it is zero in the cheap-talk, verifiable-information, and public-information models, but positive in the signal-jamming and signaling models. As we formulated both of the latter models, this cost is a pure waste, undertaken by the sender in equilibrium only to influence the receiver's

beliefs and hence her decision. In alternative formulations of both models, however, the sender's influence activity could also be productive (e.g., in Holmström's (1982/1999) signal-jamming model of wage determination or Hermalin's (1998) signaling model of leadership), but the inefficiency we capture in pure form here would not disappear.

We think the similarities across these models do a nice job formalizing the quotations from Cyert and March (1963) in Section 1 about "attempts to manipulate information as a device for manipulating the decision" and "interpretive adjustment" being an "obvious corollary" of communication bias. Almost two decades later, March (1981: 217) summarized subsequent work (outside economics) by asserting that

information is an instrument of consciously strategic actors. Information may be false; it is always serving a purpose. . . . Thus information itself is a game. Except insofar as the structure of the game dictates honesty as a necessary tactic, all information is self-serving.

Again, this section's models seem consistent with this summary. For example, the full-revelation result in the verifiable-information game could be an example where "the structure of the game dictates honesty as a necessary tactic." Ironically, the models and techniques we have surveyed began to appear in about 1981, whereas this was about the end of this literature outside economics.

Naturally, one of the reasons to build models is to explore the many different environments in which strategic communication and decisionmaking can play out and the many different behaviors and inefficiencies that can then result, so we see the differences among this section's models as useful in that regard. For example, Feldman and March (1981) describe various organizational activities not too distant from money burning in the signaling model: wasteful ways that organization members need to jump through hoops to establish credibility.

More generally, beyond money burning, after presenting several case studies and alluding to many others on information gathering, communication, and decisionmaking in organizations, Feldman and March (1981: 174) summarize these studies with six observations:

1. Much of the information that is gathered and communicated by individuals and organizations has little decision relevance.
2. Much of the information that is used to justify a decision is collected and interpreted after the decision has been made, or substantially made.
3. Much of the information gathered in response to requests for information is not considered in the making of decisions for which it was requested.
4. Regardless of the information available at the time a decision is first considered, more information is requested.
5. Complaints that an organization does not have enough information to make a decision occur while available information is ignored.
6. The relevance of the information provided in the decisionmaking process to the decision being made is less conspicuous than is the insistence on information.

Without taking these small-sample observations as gospel, they fit sufficiently well with our experiences that we suspect there would be steep returns to integrating the kinds of theoretical approaches sketched here with both qualitative and quantitative empirical work on information gathering, communication, and decisionmaking in organizations. To do so, we need to move beyond the relatively simple models described in this section to address more complex and realistic issues in organizational design and performance. In the next section, we begin to undertake this task.

3. Richer Analyses

Having introduced our basic model and its five illustrations, we turn next to several richer analyses. Specifically, we consider

Section 3.1: multidimensional cheap talk;

Section 3.2: more parties (senders, receivers, or both);

Section 3.3: more periods;

Section 3.4: a reinterpretation of the basic model as the choice-to-execution stages of Mintzberg's (1979) timing;

Section 3.5: an enrichment of the basic model to include the information-to-advice-to-choice stages;

Section 3.6: enrichments where some aspect of the model is contractible; and

Section 3.7: models of contests for control, where the right to make decision d cannot be allocated ex ante to player 2 but instead must be secured by one of the parties before d can be chosen in stage 5 of the basic model.

Although one of our main purposes in Section 2 was to specify models clearly enough to analyze and compare them, here we shift gears somewhat, focusing more on sketching applications than on formulating models or deriving results. One exception, however, is Section 3.1, because the recent models of multidimensional cheap talk importantly enrich the basic intuition from Section 2.2.

3.1. Multidimensional Cheap Talk

The cheap-talk model by Crawford and Sobel (1982) captures the fundamental insight that costless communication is less effective when the parties' interests are less aligned. Even our basic model in Section 2.1, however, placed no restrictions on the state space S or the decision space D , and hence allowed the possibility of multidimensional cheap talk. And, interestingly, recent work has shown that multidimensional cheap talk creates new ways for the parties' interests to be aligned and hence costless communication to be effective. Sobel (2012) discusses several papers in this vein; we therefore complement his discussion by giving three additional examples.

Chakraborty and Harbaugh (2007) provide a direct example of how multidimensional cheap talk creates new ways for the parties' interests to be aligned: they show that compar-

ative cheap talk, across dimensions of the state space, can be credible, even if cheap talk about any one dimension would not be. As a simple example, suppose that the state space is $S = S_1 \times S_2$, and the decision space is $D = D_1 \times D_2$, where the state is uniformly distributed on the unit square, each decision is from the real line, and the parties' payoffs are $U_2(s, d) = -(d_1 - s_1)^2 - (d_2 - s_2)^2$ and $U_1(s, d) = -(d_1 - (s_1 + b))^2 - (d_2 - (s_2 + b))^2$. That is, the sender's bias is b on both dimensions, and suppose $b > \frac{1}{4}$, so that cheap talk cannot be effective on one dimension alone.

Chakraborty and Harbaugh (2007) show, however, that comparative cheap talk can be effective. For example, consider the messages " $s_1 > s_2$ " and " $s_2 > s_1$ " (where we ignore equality, because it has zero probability). Because $E[\max\{s_1, s_2\}] = \frac{2}{3}$ and $E[\min\{s_1, s_2\}] = \frac{1}{3}$, in equilibrium, if the sender says " $s_1 > s_2$," then the receiver chooses $(d_1, d_2) = (\frac{2}{3}, \frac{1}{3})$, whereas if he says " $s_2 > s_1$," then she chooses $(d_1, d_2) = (\frac{1}{3}, \frac{2}{3})$. For a given state (s_1, s_2) , the sender's gain from inducing $(d_1, d_2) = (\frac{2}{3}, \frac{1}{3})$ instead of $(d_1, d_2) = (\frac{1}{3}, \frac{2}{3})$ is $\frac{2}{3}(s_1 - s_2)$, so such comparative cheap talk is indeed an equilibrium, and the expression for the sender's gain reveals why: $\frac{2}{3}(s_1 - s_2)$ is independent of the one-dimensional bias b .

Che et al. (2012) also consider comparative cheap talk. For example, suppose the receiver can choose either of two new projects, d_1 or d_2 , or the status quo, d_0 , so $D = \{d_0, d_1, d_2\}$. The parties' payoffs from the new projects depend on the state, but their payoffs from the status quo do not. Unlike in the other models we have discussed, the parties' payoffs are identical for either new project: $U_1(s, d_i) = U_2(s, d_i) > 0$ for $i = 1, 2$, which bodes well for communication. There is a difference in their payoffs from the status quo, however: the sender receives zero from the status quo, but the receiver receives a positive payoff, $0 = U_1(s, d_0) = U_{10} < U_2(s, d_0) = U_{20}$, which complicates communication. In particular, the sender would like to persuade the receiver to choose the superior new project (or, failing that, even the inferior new project), but the receiver might prefer the status quo.

As a numerical example, suppose that the payoff from d_1 is either 1 or 7, the payoff from d_2 is either 4 or 6, and all four payoff combinations are equally likely. In a full-revelation equilibrium, if the sender says " d_1 is better than d_2 ," then the receiver compares $E[U_2(s, d_1)|U_2(s, d_1) > U_2(s, d_2)] = 7$ to U_{20} , whereas if the sender says " d_2 is better than d_1 ," then the receiver compares $E[U_2(s, d_2)|U_2(s, d_2) > U_2(s, d_1)] = 5$ to U_{20} . For full revelation, where the sender's recommendation is always accepted, the receiver's payoff from the status quo must be sufficiently small: $U_{20} \leq 5$. For somewhat larger values of U_{20} , the sender panders to project 1, sometimes recommending it when it is the inferior new project. For example, if $U_{20} = 5.25$, then there is a mixed-strategy equilibrium where the sender recommends the superior new project unless the payoffs are (1, 4), in which case he recommends project 1 with probability $\frac{2}{3}$ (even though it is the inferior project). This strategy by the sender strengthens the receiver's belief about project 2 when it is recommended, so that the expected payoff from project 2 can compete with U_{20} . In response, the receiver always accepts project 1 but rejects project 2 in favor of the status quo with probability $\frac{3}{4}$.

Finally, in an intriguing model of the development and exercise of expertise, Callander (2008b) imagines that one dimension of the state is simple (e.g., what project to adopt), but another is potentially quite complex (e.g., expertise about the probability distribution over outcomes from adopting a project). Callander assumes that an expert can talk about the first dimension but not the second, and he finds that equilibrium communication depends importantly on

the correlation between the two. As we discuss in Section 5.2.1, these ideas have important implications for the feasibility and desirability of delegation. For now, however, we simply provide a third example of multidimensional cheap talk, inspired by Callander's (2008b: 124) critique of existing models in which "a single recommendation by an expert can render an intelligent layperson an expert."

Our setting is more abstract than Callander's. Here, the state space S consists of pairs $s = (s_1, s_2)$. The probability distribution over S puts zero weight on pairs (A, A) , (B, B) , and (C, C) , but puts positive weight on each realization of s_2 : $\Pr(s_2 = X) > 0$, $X = A, B, C$. Player 1 observes $\theta = s_1$, and his cheap-talk message a is an element of $\{A, B, C\}$. Think of it as his claim as to the value of s_1 . (For simplicity, we depart from Callander (2008b) by assuming that player 1 does not observe s_2 .) Player 2 then observes $\sigma = a$ and selects d , an element of $\{A, B, C\}$.

The sender wants the decision d to match the first element of the state, but the receiver wants to match the second. Because the two elements of the state are always different, the parties' interests are always conflicting in this respect. However, neither wants the decision to differ from both s_1 and s_2 , because both would then receive negative payoffs. Formally, if $d = s_1$, then $U_1 = b_1 > 0$ and $U_2 = 0$. Symmetrically, if $d = s_2$, then $U_1 = 0$ and $U_2 = b_2 > 0$. In addition, if d is not equal to either s_1 or s_2 , then both parties receive $K < 0$.

Depending on the probability distribution over states, it may be possible for the receiver to invert the sender's message if he reports honestly, as in Crawford and Sobel (1982). For example, suppose that, conditional on s_1 , the probability distributions over s_2 are degenerate, in each case placing probability zero not just on $s_2 = s_1$ but also on one of the two remaining options. For example, $\Pr(A|A) = \Pr(B|A) = 0$, $\Pr(B|B) = \Pr(C|B) = 0$, and $\Pr(C|C) = \Pr(A|C) = 0$, so that if the first element of the state is A , then the second is C ; if B , then A ; and if C , then B . If the sender announced truthfully, $a = s_1$, then the receiver could immediately determine the value of s_2 and choose accordingly, $d = s_2$. The sender would then have a profitable deviation from the action that induces $d = s_1$, so the equilibrium cannot involve full revelation by the sender.

Alternatively, suppose each of the alternatives to $s_2 = s_1$ is equally likely—for example, $\Pr(B|A) = \Pr(C|A) = \frac{1}{2}$. If the sender is presumed to report honestly, then the receiver faces a choice between accepting the sender's "recommendation" (setting $d = a$, which by hypothesis is equal to s_1) or picking one of the remaining two options, each of which is equally likely to be the receiver's preferred decision. The first alternative yields $U_2 = 0$, whereas the second gives expected value $EU_2 = (b_2 + K)/2$. If K is sufficiently negative, then the first alternative is more attractive, and the receiver simply rubber-stamps the sender's choice, knowing it is surely not the option she would prefer. In this case, a single recommendation by the sender does not render the receiver an expert.

3.2. More Parties

Many organizational settings involve more than the two parties envisioned in the basic model in Section 2.1. Here we briefly discuss three such settings: more senders, more receivers, and more of both (e.g., because each party is both sending and receiving).

3.2.1. *More Senders*

In a cheap-talk setting, when two senders share the same information but different preferences about how the decision should be tailored to the state, there is an opportunity for their separate reports to discipline each other, together providing more information to the receiver than had either sender reported alone. In applied models, Gibbons (1988) and Gilligan and Krehbiel (1989) study arbitration and legislative committees, respectively. Krishna and Morgan (2001) and Battaglini (2002) analyze more abstract cheap-talk models, and Milgrom and Roberts (1986) analyze competition among senders in a verifiable-information game. See Sobel (2012) for a review of these and subsequent papers.

3.2.2. *More Receivers*

Complementing the idea that two senders might discipline each other's reports in a cheap-talk game, one can also imagine how two receivers with different preferences about how the decision should be tailored to the state could discipline the report sent by a single sender. In addition, with two receivers, one can analyze whether communication should be in public, in private, or both. Farrell and Gibbons (1989) offer a simple first analysis of these issues; Goltsman and Pavlov (2011) provide a considerable generalization.

Switching from cheap talk to verifiable information, Caillaud and Tirole (2007) develop another model with multiple receivers, asking how a project's sponsor, who is known to benefit if the project is implemented, can recruit necessary support from potentially skeptical group members. Potential applications include flat organizations—such as a partnership, committee, or consortium—as well as such settings as a matrix organization, where an employee has multiple bosses.

In the Caillaud and Tirole model, implementing the project may or may not be in the interest of a given group member. To attempt to gain a member's support, the sponsor can supply partial but verifiable information to the member, who can then further investigate the project at a cost. A member with a sufficiently strong prior that the project is in her interest does not find it worthwhile to investigate (because the resulting information is too unlikely to sway the member's decision), whereas a member with an intermediate prior does find it worthwhile to investigate, and a member with a sufficiently weak prior again does not find it worthwhile to investigate (because the resulting information again is too unlikely to sway the member's decision).

Members potentially differ in the payoffs they would receive if the project were implemented, but they know that their payoffs are correlated, so learning about another member's payoff would be useful. As a result, the sponsor may attempt to induce a "persuasion cascade." For example, the sponsor may supply information to a slightly skeptical first member, in the hope that this member's endorsement may then persuade a more skeptical second member, even if the sponsor herself could not have persuaded this second member directly. Such persuasion by the first member may result in the second member either investigating when she would originally have rejected the proposal outright or supporting the proposal without investigation when she would originally have insisted on investigating. Alternatively, sometimes the optimal cascade for the sponsor is to supply information to the more skeptical member first, because her approval may then convince the less skeptical member to support the proposal without investigation.

3.2.3. *More of Both*

A third setting may be especially natural and interesting, where some or all parties both have information and control a decision, so they have both sender and receiver roles. Because this literature is fairly new, we start by noting recent contributions from team theory, where the parties share common interests, such as Dessein and Santos (2006) and Calvó-Armengol et al. (2011). This work serves as a benchmark for models that introduce strategic considerations.

Okuno-Fujiwara et al. (1990) analyze communication of verifiable information in a Bayesian game, where different players have private information and control their own actions in the game. Hagenbach and Koessler (2010) and Galeotti et al. (2011) explore related settings with cheap-talk communication. In the latter papers an interesting issue arises because, building on the multisender case, the effectiveness of one party's cheap-talk communication with a second party now depends not only on the divergence in these parties' preferences but also on how communication from a third party may already have changed the second party's beliefs and hence in effect her preferences. This logic has implications for the equilibrium level of communication in a network, for example.

3.3. *More Periods*

Another stark limitation of our basic model is that it has only one period, thereby eliminating reputation effects and other consequences of learning.

In a two-period model with a unique (or, at least, specified) second-period continuation equilibrium as a function of first-period outcomes, one can substitute the second-period equilibrium payoffs into the first-period analysis, thereby hinting at a dynamic analysis in a one-period model (albeit one with possibly unusual payoff functions). Ottaviani and Sorensen (2006a,b) take this kind of reduced-form approach to analyzing how first-period cheap talk by a professional advisor can affect the advisor's second-period reputation. Prendergast (1993) uses a similar reduced-form modeling strategy to analyze "yes men"—that is, workers whose incentives are to distort their reports in the direction of what they believe their manager wants to hear.

Sobel (1985), Bénabou and Laroque (1992), and Morris (2001) take the next step, building dynamic models that repeat our basic model but also include a permanent type for the sender. Their models analyze cheap talk; more could be done by building on the other approaches discussed in Section 2.

3.4. *Reinterpretation: From Choice to Execution*

Van den Steen (2010b) makes a fundamental observation about the large literatures on authority and delegation—surveyed, respectively, by Bolton and Dewatripont (this volume) and in Section 5: almost without exception, these models do not involve a principal giving an agent an order. Rather, these literatures focus on what should be called "decision" authority, to distinguish it from what Van den Steen calls "interpersonal" authority, where the former analyzes who should control a decision right and the latter analyzes when orders will be given and whether they will be followed.

As Barnard (1938) emphasizes, orders are not simple—either to enforce or, therefore, to model:

A most significant fact of general observation relative to authority is the extent to which it is ineffective in specific instances. [Barnard 1938: 161]

The decision as to whether an order has authority or not lies with the persons to whom it is addressed, and does not reside in “persons of authority” or those who issue these orders. [Barnard 1938: 163]

I suppose all experienced executives know that when it is necessary to issue orders that will appear to the recipients to be contrary to the main purpose, especially as exemplified in prior habitual practice, it is usually necessary and always advisable, if practicable, to explain or demonstrate why the appearance of conflicts is an illusion. . . . Otherwise the orders are likely not to be executed, or to be executed inadequately. [Barnard 1938: 166]

Motivated by these cautionary tales, we now reinterpret the basic model from Section 2.1 as describing the choice and execution stages of Mintzberg’s decision process in Figure 1. Our main purpose in doing so, however, is to surface these issues for further modeling, not to propose this simple model as anything beyond a first attempt.

Although most of our interpretations of the models in Section 2 have so far been that player 1 (who seeks to influence a decision) is the agent and player 2 (who controls the decision) is the principal, we now reverse the roles: player 1 is the principal, whose influence action a is an order (in the suggestive sense of the term emphasized by Barnard), and player 2 is the agent, whose decision d concerns whether or how well to execute the order. In addition to reinterpreting the players, we also impose new structure on the payoffs. For example, it seems important to distinguish between orders and advice (even if the advice comes from the principal), so we interpret the cheap-talk model in Section 2.2, where the principal’s action a does not affect the parties’ payoffs, as more the latter than the former. Also, the typical order does not seem to be directly costly to the principal, in the sense in which signal jamming and signaling involved a cost $k(a)$ in Sections 2.3 and 2.4, so we do not directly use those models, either.

We therefore imagine a setting where neither the principal’s order (a) nor the agent’s execution of that order (d) has much impact on the parties’ payoffs on its own. Instead, the best payoffs arise when the order and the execution are well matched—to each other and also to the state s . There are of course many ways to formalize ideas like these, including not only Van den Steen (2010b) but also Landier et al. (2009) and Marino et al. (2010). The approach described below is inspired by Blanes i Vidal and Möller (2007). The resulting model does not focus on an order by the principal but instead explores another aspect of the choice and execution stages of Mintzberg’s (1979) decision process, where the principal’s action is a project choice, and the agent’s decision is execution effort.

To keep things simple, suppose that there are only two states, $s = A$ or B . There are also two projects, but the parties can achieve positive payoffs only if the project is appropriate for the state. In addition, the parties are more likely to realize these positive payoffs if the agent’s execution effort is high.

The principal’s signal θ consists of two parts, public and private, both of which are noisy measures of the state. That is, $\theta = (\theta_{\text{pub}}, \theta_{\text{pvt}})$, where $\theta_i \in \{A, B\}$, and θ_{pub} and θ_{pvt} are conditionally independent given the state. To keep things interesting, suppose that the principal’s private signal is more accurate: $\text{Prob}(\theta_i = s | s) = p_i$ and $p_{\text{pvt}} > p_{\text{pub}} > \frac{1}{2}$.

The principal's action is a project choice, $a = A$ or B , and the agent's signal then consists of the public signal and the principal's project choice, $\sigma = (\theta_{\text{pub}}, a)$. After receiving her signal, the agent chooses execution effort $d \in [0, 1]$ at convex cost $c(d)$. Finally, the project's output is $y = L$ or H , where $y = L$ if $a \neq s$ but $y = H$ with probability d if $a = s$. For simplicity, the parties split the project's output, so the payoffs are $U_1 = \frac{1}{2}y$ and $U_2 = \frac{1}{2}y - c(d)$.

Because the principal's private signal is more accurate, the first-best project choice is for the principal to follow his private signal, $a = \theta_{\text{pvt}}$. Because the public and private signals are conditionally independent, the first-best execution effort by the agent then depends on both signals. In particular, first-best effort is higher when the signals agree with each other and with the principal's project choice.

In equilibrium, however, the principal may not follow his private signal in choosing the project, exactly because the agent's execution effort is higher when she thinks that the project and both signals all agree. Instead, if the private signal is not too much more accurate than the public one, in equilibrium the principal may choose the project indicated by the public signal when the public and private signals disagree. Of course, the agent understands this and chooses her effort based on a correct belief about whether the project matches the private signal. Such a model thus takes a first step toward Barnard's (1938: 166) observation that contrary "orders are likely not to be executed, or to be executed inadequately."

3.5. Enrichment: From Information to Advice to Choice

Casual observations suggest that shareholders often rubber-stamp the board's decisions, the board rubber-stamps the CEO's decisions, the CEO rubber-stamps the division managers' decisions, and so on. Aghion and Tirole (1997) model such outcomes by distinguishing between formal authority held by an owner versus real authority held by an employee. Their model expands the basic model from Section 2.1 to include information acquisition as well as advice and choice.¹⁰

Suppose there are three possible projects, indexed by $k = 1, 2, 3$. Project k delivers benefits B_k to the owner and b_k to the employee. One project is terrible for both parties: $B_k = b_k = -\infty$. The other two projects deliver benefits of 0 and $B > 0$ to the owner and 0 and $b > 0$ to the employee. With probability α , the payoffs from the latter two projects are (B, b) and $(0, 0)$; with probability $1 - \alpha$, the payoffs from these projects are $(B, 0)$ and $(0, b)$. Thus, a higher value of α means that the owner's and the employee's interests are more likely to be aligned.

The problem is that, initially, neither the owner nor the employee knows which project is which. That is, each party can see the three possible projects, but neither party knows which project is the terrible one or which is the good one for him or her. Because of this uncertainty (and the severity of the terrible project), if no information is collected about which project is which, neither party will want any project to be chosen.

Both the owner and the employee can try to collect information about which project is which, but at a cost. If the owner incurs the cost $c_B(E)$, then the owner learns her own payoff on each project with probability E but learns nothing with probability $1 - E$. Similarly, if the employee

10. Parts of this section draw on Gibbons (2010), with permission from the *Annual Review of Economics*, Volume 2, © 2010 by Annual Reviews, <http://www.annualreviews.org>.

incurs the cost $c_s(e)$, then the employee learns his own payoff on each project with probability e but learns nothing with probability $1 - e$ (where these events for the employee are independent of those just described for the owner).

To analyze the parties' incentives to collect information, consider what happens in the following three situations. First, if the owner becomes informed about her payoffs on the three projects, then she will choose the project that pays her B . Second, if the owner remains uninformed but the employee becomes informed, then the employee will recommend the project that pays him b ; even though the owner cannot observe the projects' payoffs (and, by assumption, the employee cannot communicate them), the owner will accept the employee's proposed project, because its expected payoff to the owner is $\alpha B + (1 - \alpha) \times 0 = \alpha B > 0$. Finally, if neither the owner nor the employee becomes informed, then neither party will want any project to be chosen, as described above.

From these three situations, we can write the expected payoffs to the owner and the employee if the owner incurs the cost $c_B(E)$ and the employee incurs the cost $c_s(e)$:

$$U_B = EB + (1 - E)e\alpha B - c_B(E)$$

and

$$U_s = E\alpha b + (1 - E)eb - c_s(e),$$

respectively. From these expected payoffs, we can compute the Nash equilibrium choices of E and e . Assuming that the cost functions have the usual properties (namely, convexity, zero slope at zero, and infinite slope at one), the Nash equilibrium (E^*, e^*) satisfies:

$$B(1 - e\alpha) = c'_B(E)$$

and

$$b(1 - E) = c'_s(e).$$

In our view, the Aghion and Tirole (1997) model is an elegant and insightful explanation of equilibrium rubber-stamping: with probability E^* , the owner becomes informed and chooses the project; but with probability $(1 - E^*)e^*$, only the employee becomes informed, in which case he proposes a project, and the owner rubber-stamps the proposal. This rubber-stamping can be seen as the difference between formal and real authority: the owner does not cede formal authority, but rather cedes real authority when the employee has superior information and sufficiently similar preferences. (To see the role of similar preferences, imagine revising the model to allow projects with payoffs $B_k = -\infty$ and $b_k = b$: now the owner would not dare to cede real authority.) For further approaches to this section's information-acquisition issue, see the discussions of Che and Kartik (2009) and Rantakari (2012) in Section 5.1.4.1.

3.6. Enrichments: Contractibility

We emphasized in Section 2.1 that nothing in our basic model was contractible: not player 1's action, player 2's decision, or the parties' payoffs, so there cannot be bargaining over either player's move, mechanisms to elicit their signals, or outcome-contingent incentive contracts. As we explained, we made this assumption not only for simplicity but also to some extent for

realism, given that our focus is on organizations. That is, if everything were contractible, then any governance structure would suffice, as argued by Coase (1960). And, loosely considering settings somewhat shy of that extreme, if contracts were only slightly imperfect, then markets might do fine at inspiring and implementing the acquisition and dissemination of information, as argued by Hayek (1945). As Arrow (1974: 33) puts it, however, “organizations are a means of achieving the benefits of collective action in situations where the price system fails.” And recall from Section 1 March’s (1962/1988: 110–112) view of “the business firm as a political coalition” in which “the executive . . . is a political broker” who cannot “solve the problem of conflict by simple payments to the participants and agreement on a superordinate goal.”

In this section, therefore, we begin to relax our stark assumption in Section 2.1 that nothing is contractible, but we hasten to add that this must be done with care. That is, if too much is contractible, then the transaction should probably be conducted in a market rather than in an organization. Analyzing this macro-level choice of governance structure, between organization and market, is of course both important and well beyond the scope of this chapter; see Bresnahan and Levin (this volume) and Tadelis and Williamson (this volume).

As a first exploration of contracting issues, we return to the information-acquisition problem of Section 3.5. Lambert (1986) and Demski and Sappington (1987) were the first to analyze models in which player 1 does not have a direct interest in player 2’s decision (i.e., player 1’s payoff is independent of d) but can exert effort to improve the quality of his information. To induce such effort, the parties can write contracts that specify payment schemes for the expert that are contingent on the outcome of the decision. As in the standard agency framework, the only source of friction in these models is that the expert must be induced to exert effort. In contrast to the standard framework, however, here effort generates information rather than output. As Dewatripont and Tirole (1999) show, when effort is about acquiring information, the Monotone Likelihood Ratio Property is lost. A major insight of this literature is that, to provide better incentives for information acquisition, a contract may have to create an endogenous conflict of interest regarding the decision to be made; see, for example, Inderst and Klein (2007), Malcomson (2009, 2011), and Zermeno (2012).

Another organizational literature that assumes some contractibility studies committees. Indeed, such models are close to those described in Section 3.2, where more parties are added to our basic model. For example, each committee member might receive private information, then engage in cheap talk, and finally vote; see Feddersen and Pesendorfer (1998), Persico (2004), Levy (2007), and Visser and Swank (2007) for related models. A key assumption in such models, however, is that the eventual decision is a predictable consequence of the votes, such as by majority rule, thus raising the question of whether the parties might instead use direct-revelation mechanisms, mapping type reports into decisions, rather than use voting schemes. See Mookherjee (this volume) for more on this approach.

Another approach is to assume that, although the state s and the decision d are non-contractible, messages are. For example, in a cheap talk equilibrium with a finite number of messages, one could imagine payments to the sender to be contingent on the message he sends. Krishna and Morgan (2008) examine such a model, assuming that the sender has limited liability (i.e., cannot be forced to pay money to the receiver). They then show that full revelation is always feasible but never optimal. Instead, for the standard example with uniform state s , quadratic loss functions, and sender bias $b > 0$, they show that, because of the standard argu-

ment that integrates the local incentive-compatibility constraints, inducing revelation by high types requires large payments to lower types if they are to reveal themselves. As a result, the optimal payment and communication scheme has positive payments and full revelation for low states but no payment and no communication for high states. We see this kind of analysis, where limited contractibility relaxes the stark assumption in Section 2.1 that nothing is contractible, as a productive vein for further work.

3.7. Contested Control

As a transition to our discussion in Sections 4 and 5 of decision architectures that are designed *ex ante*, here we consider situations where decision rights are not allocated *ex ante* but are contested *ex post*. Tullock (1980) provided an elemental model of rent seeking in such an environment. Two contestants (A and B) purchase lottery tickets in amounts x_A and x_B , respectively, each hoping to win a prize of \$100. Contestant i 's expected payoff is then $x_i/(x_i + x_j) \times 100 - x_i$, so the symmetric Nash equilibrium has positive expenditures on lottery tickets, but in this equilibrium the contestants have the same probabilities of winning as if neither had spent anything—namely, one-half. Skaperdas (1992) and Rajan and Zingales (2000) used similar models to analyze battles for control (in organizations and other settings).

As a simple version of some of Skaperdas's ideas, suppose that each of two parties ($i = 1, 2$) is endowed with resources r_i that can be spent either on producing output (y_i) or on developing "arms" (a_i) that can be used in a later conflict over dividing the aggregate output. Specifically, let $y_i = y(r_{yi})$ and $a_i = a(r_{ai})$, where $r_{yi} + r_{ai} = r_i$, and suppose that the payoff to party i is $p(a_i, a_j)[y_i + y_j]$, where $p(a_i, a_j)$ can be interpreted as the probability that party i wins the conflict and so receives the aggregate output. Skaperdas derives conditions under which the equilibrium allocations of the parties' resources into outputs and arms are efficient (i.e., both parties put all their resources into output) or partially so (one party puts all its resources into output). More often, however, as in Tullock's model, the equilibrium is inefficient and sometimes dramatically so.

Rajan and Zingales analyze a two-period model that can be seen as having fully contractible trade in the first period and Skaperdas's model in the second. Trade in the first period endogenizes heterogeneous resource endowments (r_i) and heterogeneous production functions (now $y_i(r_{yi})$) for the second period. The second-period consequences of this heterogeneity can be so severe that the parties forgo a contractible and seemingly Pareto-improving trade in the first period. For example, consider two divisions in a company (or two adjacent countries). Suppose that party i has a machine that it could sell to party j , and suppose that party j is already more productive than party i and so could make better use of the machine ($y'_j > y'_i$). Selling the machine increases i 's endowment for the second period (r_i increases) but reduces its productivity (y'_i falls), and the reverse holds for j . What then happens to the equilibrium allocations of the parties' resources into outputs and arms? Loosely, reducing i 's productivity increases i 's incentive to invest in arms, and increasing j 's productivity (more precisely, j 's output) also increases i 's incentive to invest in arms, but an increase in a_i then increases j 's incentive to invest in arms, and so on. In equilibrium, these increases in arms (and reductions in output) can be severe enough to overwhelm the supposed efficiency advantages from allocating the machine to the more productive party j , so no trade occurs in the first period.

In all these rent seeking models, control is valuable, because it allows one party to consume the prize in question—\$100 in Tullock's (1980) model and aggregate output in those of Skaperdas (1992) and Rajan and Zingales (2000). As a slight variant on this approach, suppose instead that control allows one party to take a decision (e.g., about the organization's strategy). The argument is then similar, with the new feature that different parties may place different values on being able to take the decision in question, thus creating different incentives for gaining control.

As a concrete example, consider the following game (which is intended to illustrate some of the central governance challenges in decision architectures involving shared control, e.g., joint ventures, consortia, and matrices): (1) the parties publicly observe the state of the world, $s \in S$; (2) the parties engage in a battle for control (specifically, to keep things simple, we follow Tullock—each party expends x_i for probability $x_i/(x_i + x_j)$ of winning control); (3) the party who wins control then chooses a decision $d \in D$; and (4) the parties receive payoffs $U_i(s, d)$, gross of their expenditures in stage 2. Now the prize to party i for winning control is not \$100 but rather $U_i(s, d_i^*(s)) - U_i(s, d_j^*(s))$, where $d_i^*(s)$ maximizes $U_i(s, d)$ over $d \in D$. Because the prizes are asymmetric, so are the equilibrium expenditures in the battle for control: the party with the larger prize fights harder. This example is of course extremely stark, but it nonetheless captures some of the tensions that commonly arise under shared control.

4. Endogenous Architectures: Fixed Decision Allocations

In the previous sections we explored the inefficiencies that can arise in organizations from strategic communication under fixed decision processes and (except for Section 3.7) a fixed allocation of decision rights among the interested parties. One reason to have done so was to focus on situations where the decision rights are inalienable. For instance, the right to appoint a CEO in a corporation is vested in the board of directors. The board can seek advice on its choice, and it may even sometimes rubber-stamp the advisors' recommendation, but it cannot formally delegate the actual decision. One can also view our discussion in the previous sections as having been about the second stage of a two-stage game in which the owner of the organization allocates decision rights in the first stage and the different members of the organization take their actions in the second.

In this section we turn to actions that the owner can take in the first stage to mitigate the inefficiencies of organizational communication and decisionmaking in the second stage. In particular, in Section 4.1 we explore three suggestions put forward by Milgrom and Roberts (1988) aimed at controlling influence activities:

1. the owner could close communication channels, at least for some decisions;
2. she could commit not to respond to information provided by others; or
3. she could try to align incentives through compensation, promotion, and similar policies, including altering the decision processes and even the boundaries of the firm itself.

In Section 4.2, we move away from the rich organizational descriptions that characterize the discussion in Section 4.1 to a more abstract formulation, based on our model from Section 2, that allows us to explore just what responses may be feasible and effective.

Alternatively, of course, the owner could simply delegate the decision directly to the employee. Although delegation might be considered an instance of the Milgrom-Roberts's third option (change the organizational design), it has been the focus of most of the recent formal literature on responses to inefficiency in decisionmaking. Thus we make it the focus of Section 5.

4.1. Organizational Responses in the Case of Fixed Decision Rights

The first published work on influence costs is Milgrom (1988). A simplified version of the model he considered is the following. There are a manager and an employee, both risk neutral, and the former contracts with the latter to deliver unobservable effort. The employee can allocate a fixed amount T of effort between productive activities t and influence x . (Effort is thus not directly costly to him.) The manager may be able to make a change decision that gives benefits k to the employee that are, in effect, a transfer from another (unmodeled) employee. Thus, k enters the employee's utility function but not the aggregate welfare. Implementing the change brings benefits $r(x)I$ to the manager.

If the manager is allowed discretion over adopting the change, then the probability that she does adopt it is a function $q(x)$ that is assumed to be increasing. The employee's productive effort, $t = T - x$, produces a benefit π with a probability $p(t)$ that is increasing in t , with $p(0) = 0$. The problem is to determine a wage for the agent as a function of whether the benefit π was realized and whether the change was implemented, with the objective to maximize total surplus, namely, $p(t)\pi + q(x)r(x)I$, subject to t and x maximizing $p(t)q(x)w_{11} + p(t)(1 - q(x))w_{10} + (1 - p(t))q(x)w_{01} + (1 - p(t))(1 - q(x))w_{00} + q(x)k$ given $t + x = T$. Meanwhile, if the manager does not have discretion, then the payoff is simply $p(T)\pi$, because the agent has no incentive to exert influence and so can be assumed to devote all his time to production.

The key result is that it may be optimal to deny the decisionmaker discretion over implementing the change: there are values of I and k such that eliminating discretion (i.e., fixing $q(x)$ at zero rather than using pay to deter influence) is optimal, and this is true for all higher values of k (when redistribution effects are greater) and lower values of I (when the change is less valuable). This is an example of Milgrom and Roberts's (1988) second suggestion: limiting discretion can be valuable.

The logic behind the q and r functions is not explored in Milgrom (1988). Note, however, that delegation might be an attractive alternative here, especially if $r(x)$ is not increasing. In this case, if the implementation decision could be and were delegated, then the first best would be achieved.

Milgrom and Roberts (1988, 1999) considered a problem with two employees, each of whom has to allocate a fixed amount of time between influence activity and productive effort, with the principal unable to observe their choices. The principal values the output that results (probabilistically) from their efforts, but she also wants to promote one of the two workers to another job, where his underlying, unknown ability will be valuable. (Ability does not influence productivity in the current job.)

The new job is desirable to the workers in that it must, for competitive reasons, carry a wage that exceeds the outside option of the person appointed to it. There is symmetric information about the workers' abilities, which are identically distributed. The impact of influence activity

and determination of its equilibrium level are not modeled in detail. Instead, the influence activity is assumed to “build credentials,” making the worker’s ability appear greater but also providing information about ability. One possibility that Milgrom and Roberts (1999) suggest is a test on which promotion might be based, with the employees’ influence activities consisting of diverting time to prepare for the test. Simply taking the test generates information, but once the test is scheduled and its results will be used in the promotion decision, there will be incentives to try to increase one’s performance on the test.

In this context, the principal has to decide on wage payments for the current period, wages to pay to each employee once the promotion decision is made, and the criteria to use in promotion.

Milgrom and Roberts (1988) consider only a limited class of possible decision rules, to any of which the employer can commit. Even so, a full solution to this design problem has not been obtained. However, several points can be established. First, if the importance of assigning the better person to the new job is sufficiently low and the productivity of effort is high, then the employer will choose not to use apparent qualifications at all in the promotion decision. In this case, both employees will devote full time to work. Further, no incentive pay will be needed (because the work is not itself costly, and there is no reward to diverting time to influence). Promotion will be random. This can be interpreted as an instance of option 1, cutting communication.

If the marginal impact of employee quality on performance in the new job is sufficiently high, however, then the employer will want to use apparent qualifications in the promotion choice. The danger is now that, unless there is a reward to productive effort, the employees will concentrate solely on building credentials. This in turn results in several possible adjustments. One is to pay a bonus for individual output, even though there is no inherent cost of effort. A second is to raise the wage of the employee who is not promoted closer to the level paid the promoted employee. This adjustment reduces the return to being promoted and thus the incentives to exert influence to get a raise (this works only once there is pay for performance). Finally, it may be worthwhile to promote partially on current performance, even though it is not informative about the candidate’s actual ability, because this lowers the amount of performance pay necessary to induce productive effort. Thus, all aspects of the organizational design can be altered to limit the cost of influence activities, in line with the third suggestion of Milgrom and Roberts (1988).¹¹

An important organizational decision that has been much studied, both theoretically and empirically, is the allocation of capital inside firms. In particular, Meyer et al. (1992) modeled a situation in which failing businesses in a multidivisional firm exert influence to try to obtain more corporate resources to keep themselves alive. In equilibrium, the top decisionmaker is not fooled by these attempts, so the allocation of capital is not distorted. As in the signal-jamming model in Section 2.3, however, resources are wasted on attempts at influence. The solution Meyer et al. suggested is to spin off units that are prone to attempt influence.

More recently, several papers, beginning with Rajan et al. (2000), Scharfstein and Stein (2000), and Wulf (2002), have examined in more detail situations where lower level managers seek to use strategic communication so that more capital is allocated to them than is optimal for the firm. In these models, the allocation rules are distorted to reduce the costs of such strategic behavior. The resulting misallocation is costly. In addition, Wulf (2002, 2007) investigated the

11. Note that delegation is not a real option in this model.

interplay between the design of capital budgeting processes and the basis for and extent of performance pay in light of influence activities, and in Wulf (2009) she documents patterns in these variables consistent with limiting the costs of influence. For a discussion of this literature, including newer contributions, see Gertner and Scharfstein (this volume).

Finally, Powell (2012) analyzed a rich formal model of influence, building on the signal-jamming models in Holmström (1982/1999) and Gibbons (2005) discussed in Section 2.3. In Powell's framework, there are two parties and two decisions. Before these decisions can be made, the parties decide who will be empowered to make each decision, but once this allocation of decision authority is set, contracting difficulties prevent renegotiation. If the other party is to make a decision, then the disempowered party may have incentives to try to affect the decision by undertaking (unobserved) influence activities.

Given an arbitrary allocation of decision rights, Powell solves for the equilibrium level of influence. In equilibrium the party making a decision will correctly anticipate the amount of influence the other party is undertaking and, using that correct estimate, will back out the effect of the influence and make the decision that is best for him. So, again, the influence does not distort decisions, but it does occur and it imposes costs.

The optimal allocation of decision rights maximizes the sum of utilities, given that the parties will choose their levels of influence in the equilibrium fashion. This allocation may consist of either divided control, with each controlling one decision (which is advantageous, because the costs of influence are convex, and so it is better to have the total amount of influence split between the two parties), or unified control under the party who cares more about the outcome.

Powell then examined some suggestions made by Milgrom and Roberts (1988) for limiting influence activities and mitigating influence costs. A "closed-door" policy of limiting communication is modeled as no public signal being observed (because the parties agreed not to hire the needed staff, loaded their calendars so they were too busy, and limited their meetings). This policy eliminates the disempowered party's incentive to attempt influence, but it also deprives the party in control of useful information. However, if the initial uncertainty was not great, then not much is lost, and the closed-door policy may be preferred to the alternative of playing the game as originally specified.

Also, if there is a lot of disagreement about how to tailor decisions to the state of the world, then again it may become worthwhile to adopt the closed-door policy. Then a selection story applies: as disagreement increases, both the open- and closed-door policies do worse, but the closed door does relatively better at high levels of disagreement. Thus, the rigid, apparently bad management practice of limiting communication obtains when circumstances are bad, and observed firms with these practices are worse performers than those that are observed adhering to open-door policies. However, the closed-door firms perform better in the environments they inhabit than would firms with apparently "better" management practices. See the right-hand side of Figure 1 in Gibbons and Roberts ("Economic Theories of Incentives in Organizations," this volume) for a graphical representation of this selection argument.

4.2. An Abstract Approach

Having analyzed potential inefficiencies in communication and decisionmaking under fixed decision processes in Sections 2 and 3, our focus here in Section 4 has been on ways the parties might design their environment *ex ante* so as to ameliorate some of these inefficiencies. Similar to

the way that the Milgrom and Roberts (1988) focus on the costs of influence activities animated many models we discussed in Section 2, their suggestions of strategies for reducing influence inefficiencies motivated the organizational responses described in Section 4.1.

Consistent with Milgrom and Roberts (1988), the models in Section 4.1 are detailed enough to suggest and analyze concrete organizational responses to influence costs. But each considers a separate organizational environment, making it hard to assess whether the full range of possible interventions has been considered. In this section, therefore, we pursue an abstract approach that we see as complementary to the more grounded analyses in Section 4.1. This abstract approach allows us, for a simple environment, to characterize a set of responses to influence inefficiencies that are collectively exhaustive and, in a sense, mutually exclusive.

The environment we consider in this section is the basic model from Section 2.1. For this model we follow Kolotilin et al. (2012) by describing five ways that the parties might respond to influence activities by reshaping their environment *ex ante*. (Kolotilin et al. do this for a cheap-talk model, but we apply their ideas to our basic model, thus covering not only cheap talk but also the other four illustrations discussed in Section 2.) As we discuss below, these five potential responses to influence inefficiencies overlap partially with both the three Milgrom-Roberts approaches described in Section 4.1 and the delegation models described in Section 5, but they also include other options, so we discuss all five here, as well as note papers that investigate these five options.

Imagine enriching our basic model to add a nonstrategic player who accepts an informational input and returns a (possibly stochastic) output according to some prespecified mapping. This nonstrategic player can be seen as a machine, which could be designed by the parties *ex ante* and then inserted into various moments of our basic model. Proceeding sequentially through the timing of our basic model, there could then be the following five interventions (after each of which the timing of the basic model resumes):

- a. “information control,” where the new player, instead of the sender, observes the sender’s signal θ in stage 2 of the model in Section 2.1 and delivers a signal θ' to the sender in stage 2.5, according to the distribution $\gamma(\theta'|\theta)$, after which the sender chooses the influence action a in stage 3;
- b. “influence control,” where the new player replaces the sender, receiving the signal θ in stage 2 and choosing the action $a \in A$ in stage 3 according to the distribution $q(a|\theta)$, after which the receiver receives the signal σ in stage 4;
- c. “communication control,” where the new player, instead of the receiver, observes the receiver’s signal σ in stage 4 and then delivers a signal σ' to the receiver in stage 4.5 according to the distribution $\eta(\sigma'|\sigma)$, after which the receiver chooses a decision $d \in D$ in stage 5;
- d. “decision control,” where the new player replaces the receiver, receiving the signal σ in stage 4 and choosing a decision $d \in D$ in stage 5 according to the distribution $r(d|\sigma)$, after which the parties receive their payoffs; and
- e. “execution control,” where the receiver observes the signal σ in stage 4 and then in stage 5 recommends a decision $d \in D$ to the new player, who then chooses a decision $d' \in D$ in stage 5.5 according to the distribution $\rho(d'|d)$, after which the parties receive their payoffs.

To interpret just one of these five interventions, “execution control” includes the case where the parties agree *ex ante* that the receiver can choose from only a specified set of decisions *ex post*. In this abstract approach, there are no natural limits on the size or composition of such a decision set; deriving such limits is one of the complementary benefits one can get from the more grounded models in Section 4.1.

We note that although these five interventions are collectively exhaustive (in that there are no other moments in the timing of our basic model at which one could intervene), they are in some sense not mutually exclusive, because influence control and decision control, where the new player replaces the sender or receiver, weakly dominate the other options, where the new player is injected into the information flow of the model. In particular, influence control weakly dominates information control, and decision control weakly dominates both communication control and execution control.¹² However, it may be impossible to replace a player in intervention b or d, but it may still be possible to intervene as envisioned in a, c, or e, so we present all five interventions here.

Compared with the approaches that Milgrom and Roberts (1988) consider, communication control encompasses their first approach (reducing communication channels), and execution control encompasses their second (limiting the receiver’s discretion to respond), but their third approach (changing the alignment of interests by changing organizational policies) does not fit easily in this framework.

One way to interpret their third approach is as changing the parties’ payoff functions, such as modifying the bias b in the quadratic-loss functions illustrated throughout Section 2. Although literally changing utility functions is perhaps outside the standard toolkit of economics, their third approach can instead be interpreted in more standard terms by imagining that there are multiple periods, as described in Section 3.3, and the parties’ payoff functions at the end of this basic model reflect the continuation equilibrium for the remainder of the game. Under this interpretation, the Milgrom-Roberts ideas of changing organizational policies for the remainder of the game could well be represented in our basic model as changing the bias b . Absent a grounded model like those in Section 4.1, however, it is unclear what changes in b can be accomplished and at what costs, so we sidestep this question for the remainder of this section.

In addition to the three Milgrom-Roberts approaches discussed in Section 4.1, we also discuss delegation as a response to influence inefficiencies in Section 5, which relates to decision control, and influence control is akin to the strategic management of public information model described in Section 2.6. Finally, there is information control, which is related to our discussion in Section 3.5 of the information-to-advice-to-choice parts of Mintzberg’s (1979) decision process. In particular, whereas Aghion and Tirole (1997) envision keeping the receiver busy, so as to increase her marginal cost of becoming informed and thus empower the sender, here one can imagine keeping the sender busy, so as to increase his marginal cost of becoming informed and then being motivated to engage in influence activities.

There are several papers that analyze some of interventions a–e for cheap-talk games, including Green and Stokey (2007) and Ivanov (2010) on information control; Krishna and Morgan (2004), Blume et al. (2007), and Goltsman et al. (2009) on communication control;

12. For example, to see that delegation weakly dominates limited authority, note that if the receiver’s strategy under limited authority is $d(\sigma)$, then delegation can mimic limited authority by choosing the rule $r(d'|\sigma) = \rho(d'|\sigma)$.

and Kolotilin et al. (2012) on execution control, as well as many of the papers on delegation discussed in Section 5. It would be interesting to explore some of these interventions in the other settings illustrated in Section 2, beyond cheap talk. Regardless of the setting, we see this framework as complementing Section 4.1 in two ways: it exhaustively categorizes what interventions are possible, and it allows analysis of the maximum reduction in influence inefficiencies that any one of these interventions can achieve.

5. Endogenous Architectures: Delegation

In Sections 2 and 3 we explored the inefficiencies that can arise in organizations from strategic communication under fixed decision processes. In Section 4 we then discussed possible organizational responses that attempt to reduce these inefficiencies. One such response—which was ignored in Section 4 but is prominent in the literature—is delegation of the decision right to the employee. In this section we survey this literature on delegation.

We start by looking at an organization that consists of an owner and an employee. As in the previous section, the organization has to make a decision that is both *ex ante* and *ex post* noncontractible. The parties, however, can now contract over the right to make the decision. At the beginning of the game, the owner offers the employee a contract that specifies a wage and an allocation of the decision right. If the employee rejects the offer, both parties realize a zero outside option. For the time being, we assume that neither the wage nor the decision right can be made contingent on any information that is revealed during the game. Moreover, we assume that if the employee accepts the contract, it cannot be renegotiated at any point.

In the next section we discuss some of the main reasons for delegation that have been examined in the literature. The models that we discuss in that section focus on the choice between centralization and delegation, and they abstract from some factors that complicate delegation in real organizations. The models, for instance, assume that the owner is able to delegate decision rights formally and irrevocably to her employee. In practice, however, legal barriers make full delegation in organizations impossible. The models also abstract from actions the owner can take to control the employee, such as constraining the decisions he can make or aligning his incentives through incentive contracts. We discuss these additional issues in Sections 5.2 and 5.3.

Throughout, we focus on the economics literature on delegation in firms. We therefore do not discuss the related political science literature on the delegation of public policymaking from elected politicians to bureaucrats (see, e.g., Epstein and O'Halloran 1999; Huber and Shipan 2006) and from legislatures to standing committees (e.g., Gilligan and Krehbiel 1987, 1989; Krishna and Morgan 2001).

5.1. Why Delegate?

In this section we discuss some of the main reasons for delegation that have been examined in the literature.

5.1.1. *To Economize on Limited Resources*

Probably the most common reasons for assigning a task to another person that one could do oneself are to add capacity to carry out the task and to tap into comparative advantage. In the

context of delegated decisionmaking, both factors can be at work. Gathering information and analyzing it to support good decisions is a time-consuming activity. Sharing the load allows decisions to be made more quickly. This in turn may be desirable because “time is money” or because, in a dynamic context, decisions are made on the basis of more up-to-date information. At the same time, there may be efficiency gains from using someone who is especially efficient in developing information, analyzing it, and making the needed choices. This efficiency could come from experience or ability. In addition, as Jensen and Meckling (1992) accentuated, delegation of decisions might be driven by the difficulties of communication that limit the possibility of informing the original decisionmaker, a phenomenon they referred to as “specific information.” We discuss this motivation for delegation in Section 5.1.3.

The most prominent model of delegation of decision rights to increase capacity is Geanakoplos and Milgrom (1991). They consider the problem of allocating a target output among n production facilities whose costs are random. The amount of information a manager can obtain about these costs is an increasing function of the time he spends and his ability. Geanakoplos and Milgrom show that a hierarchical structure, in which targets tumble down to the next level, where new targets for the succeeding level are calculated, is an efficient approach to the problem. However, the model is formulated as a team problem, so there are none of the incentive issues that are the focus of this chapter. Moreover, this model is analyzed in detail in Garicano and Van Zandt (this volume). Thus we will not develop it further here.

The models of organization based on distributed computing of an associative operation that begin with Mount and Reiter (1990) can also be thought of as delegation to increase the speed of arriving at a solution. And although the interpretation of the knowledge-based hierarchy in Garicano (2000) as delegation seems a stretch, his model does feature the use of multiple agents to add processing power. Again, incentive issues are ignored in these literatures, so we simply refer the reader to the extensive discussions in Garicano and Van Zandt (this volume).

One literature in which incentive issues are central that can be interpreted as involving delegation to increase capacity (although it is not usually formulated this way) concerns using an agent to select a risky investment. This literature begins with Lambert (1986), who posed the problem of motivating a risk-averse agent to gather information about the returns to a risky investment and then choose between this investment and a safe alternative. To think of this as a delegation problem, we could imagine that the principal could make the choice herself, and perhaps even develop the information, but assume that the agent is more efficient at doing so. Lambert (1986) noted an interesting nonmonotonicity: increasing the sensitivity of the agent's pay to the performance of the investment does not always increase his effort, because at some point he bears too much risk and switches to choosing the safe investment. Even under the optimal contract, the agent does not always choose the investment the principal would prefer. For details of this model, see Gibbons and Roberts (“Economic Theories of Incentives in Organizations,” this volume).

A second literature that can be interpreted in the same way as involving delegation to a more efficient agent concerns delegated portfolio management. The models here, beginning with Bhattacharya and Pfleiderer (1985) and Admati and Pfleiderer (1997), have assumed that the manager to whom selection of a portfolio of safe and risky assets is delegated knows *ex ante* if he is good or bad at his task. In addition, there is a moral hazard problem in inducing him to invest in information about the risky assets. Clean, positive results in these models are difficult to obtain (see Stracca 2006 for a survey).

A third context involves “referrals” (Garicano and Santos 2004), where a party must decide whether to delegate a task to another party who may be better suited to doing it. Referring the task means, however, that the referring party will not get the rents that attach to carrying it out. Garicano and Santos (2004) analyze the complex incentives that arise when the original party is privately informed about the returns to the task and effort exerted in carrying it out is unobservable. They suggest that *ex ante* sharing arrangements (partnerships) may arise.

Finally, Athey et al. (1994) investigate a model of management by exception, where managers delegate decisions to lower level employees to preserve managerial time, even if the managers might make better decisions than the employees. Which level is better equipped to make a decision depends on the state of the world. As the probability distribution over states shifts to increase the likelihood of decisions where the manager is the better decisionmaker, the range of decisions delegated to the employees increases to free up managerial bandwidth.

5.1.2. *To Pay the Employee Less*

Many employees value the right to make decisions. Employees may, for instance, believe that being in charge allows them to make decisions that are better for them personally. Or they may believe that being in charge is good for their careers, for instance, because it allows them to signal their abilities or develop their human capital. And, of course, they may simply value the right to make decisions *per se*, even if they end up making the same decisions that their superiors would have made. Whatever their reasons, if employees value the right to make decisions, firms may be able to charge them for this right by cutting wages. Delegation is then optimal if the reduction in wages is larger than any adverse effect that delegated decisionmaking may have on gross profits. This basic motivation for delegation has been explored in several papers, including (the first part of) Aghion and Tirole (1997) and Bester (2009). Our discussion below is based on the first part of Bester (2009).

To explore this motivation for delegation, recall the cheap-talk model discussed in Section 2.2, but suppose now that both parties can observe the state. Also, payoffs are now given by

$$U_1(d, w) = K - k_1(d - s - b)^2 + w \quad (1)$$

and

$$U_2(d, w) = K - k_2(d - s)^2 - w, \quad (2)$$

where w is the wage, K is a constant, and k_1 and k_2 are parameters that measure the importance of the decisions to the employee and the owner, respectively. We assume throughout that K is sufficiently large for joint surplus to be positive. Moreover, we now assume that the state is drawn from a uniform distribution with support $[-L, L]$.

If the owner has the right to make the decision, she will always make her preferred decision $d^C = s$, where C stands for centralization. To ensure participation, she then has to offer the employee a wage $w^C = -(K - k_1b^2)$. If, instead, the owner delegates the decision right to the employee, the employee will always make his preferred decision $d^D = s + b$, where D stands for delegation. The owner then has to offer the employee only $w^D = -K$ to ensure participation. On one hand, delegation therefore reduces gross profits by k_2b^2 . On the other hand, it also allows the owner to cut wages by k_1b^2 .

In the case of quadratic preferences, delegation is therefore optimal if the employee's payoff is more sensitive to the decision than is the owner's, that is, if $k_1 \geq k_2$. More generally, delegation is optimal if the decision is more important to the employee than to the owner, in the sense that his willingness to pay for the right to make the decision $E[U_1(d^D, w) - U_1(d^C, w)]$ is larger than the owner's willingness to pay $E[U_2(d^C, w) - U_2(d^D, w)]$. Notice that this is equivalent to saying that delegation is optimal if the expected surplus $S(d) \equiv E[U_1(d, w) + U_2(d, w)]$ is larger when the employee makes the decision than when the owner makes it herself. In the next few sections we explore different reasons this may be the case.

Before we do so, it is worth making two observations. First, our focus on the efficient allocation of decision rights is different from some papers in the literature that instead focus on the allocation that maximizes expected profits gross of wages. This difference does not affect the main insights from these papers, but it does affect some of the comparative statics.

Second, the prediction that organizations allocate decision rights to whomever values them the most is not uncontroversial. Rotemberg (1993), in particular, argues that firms instead allocate decision rights to those employees they most want to retain. To explain why this may be so, he points to a difference between paying with cash and paying with control that we abstracted from above. In particular, he observes that some benefits of being allowed to make a decision today accrue to an employee only if he is still with the firm tomorrow. Rotemberg therefore views control as a form of deferred compensation. He then shows that if the manager cannot commit to future wages, and the determination of future wages is hindered by asymmetric information, the owner may find it optimal to give decision rights to the employees she most wants to retain rather than to the ones who value decision rights the most.

5.1.3. To Make Better Use of the Employee's Information

A common argument for delegation is that it allows the owner to make better use of her employee's information. Two early papers that explore this argument are Holmström (1977, 1984) and Jensen and Meckling (1992). Both papers focus on the trade-off between the benefit of making better use of the employee's information and the costs that arise because the employee's decisionmaking is biased toward decisions that are good for him but not necessarily good for the organization as a whole. The papers differ, however, in their explanation for why the owner cannot retain the decision right and simply have the employee communicate his information to her. In particular, whereas Jensen and Meckling (1992) focus on communication costs that arise because of bounded rationality, in Holmström (1977, 1984) communication is costly because of the employee's incentives to use his information strategically.

Below we start by discussing Dessein (2002), who provides a more recent exploration of these issues. Similar to Holmström (1977, 1984), Dessein focuses on communication costs that arise because of the employee's incentives to use his information strategically. In contrast to both Holmström (1977, 1984) and Jensen and Meckling (1992), however, Dessein does not allow the owner to constrain the employee's decision or align his preferences through incentive contracts. Dessein's focus on the choice between centralization and unconstrained delegation is in line with the other models that we discuss in this section. As mentioned above, we discuss models that allow the owner to control the employee by constraining his decisions or by using incentive contracts in Section 5.3.

A feature of Dessein (2002) is that there is a single decision, and all information that is relevant for this decision is concentrated in a single employee. We first discuss this case. We then turn to an extension of Dessein (2002) in which information is vertically dispersed, in the sense that the employee knows more about some factors that are relevant for the decision and the owner knows more about others. Finally, we discuss recent work by Alonso et al. (2008) and Rantakari (2008), in which there are multiple decisions that have to be coordinated and relevant information is dispersed horizontally among multiple employees.

5.1.3.1. Concentrated Information. For an illustration of the main arguments in Dessein (2002), recall the model we described in the previous section, but suppose now that the owner cannot observe the state of the world s . Suppose also that the decision is more important to the owner than to the employee, that is, $k_2 > k_1$. It follows from our discussion in the previous section that if this were not the case, delegation would always be optimal.

If the owner delegates the decision right to the employee, the employee will make his preferred decision, just as in the previous section. The difference between first-best expected surplus and expected surplus under delegation is then given by

$$S(d^{FB}) - S(d^D) = \frac{k_2^2}{k_1 + k_2} b^2, \quad (3)$$

where the right-hand side is the inefficiency that arises because the employee's preferences are different from first best.

If the owner does not delegate the decision right to the employee, the employee sends the owner a cheap-talk message, after which the owner makes her preferred decision. Under centralization, the model is therefore the same as the cheap-talk model we examined in Section 2.2, except that the owner now has to pay the employee a wage to ensure participation. In Section 2.2 we saw that if $b > 0$, communication is imperfect. Moreover, the quality of communication is measured by the residual variance

$$V(b) = \frac{\text{Var}(s)}{N(b)^2} + \frac{N(b)^2 - 1}{3} b^2, \quad (4)$$

where $\text{Var}(s)$ is the variance of s , and $N(b)$ is the maximum number of partitions given by the smallest integer larger than or equal to

$$-\frac{1}{2} + \frac{1}{2} \sqrt{1 + \frac{4L}{b}}, \quad (5)$$

where $2L$ is the length of the support. The difference between first-best expected surplus and expected surplus under centralization is then given by

$$S(d^{FB}) - S(d^C) = \frac{k_1^2}{k_1 + k_2} b^2 + (k_1 + k_2) V(b), \quad (6)$$

where the first term on the right-hand side is the distortion that arises because the owner's preferences are different from first best, and the second term is the distortion that arises because the owner is imperfectly informed about the state.

It follows from (3) and (6) that the owner will delegate to the employee if and only if

$$(k_2 - k_1) b^2 \leq (k_1 + k_2) V(b). \quad (7)$$

One implication of this expression is that delegation can be optimal even though the decision is more important to the owner than to the employee. The reason, of course, is that delegation now has the additional benefit of allowing the owner to make more efficient use of the employee's information. Another implication of the above expression is that the optimal allocation of the decision right depends on the quality of communication between the employee and the owner. To understand the effect of changes in the environment on the efficient allocation of decision rights, one therefore has to understand how such changes affect the flow of information in organizations.

In particular, consider a reduction in the divergence parameter b . On one hand, such a reduction leads to more efficient decisionmaking under delegation. On the other hand, it also improves communication under centralization. A reduction in b therefore favors delegation only if it has a more beneficial effect on decisionmaking under delegation than on communication under centralization. To see that this is indeed the case, consider (4), (5), and (7). It follows from these expressions that delegation is optimal if and only if

$$(k_2 - k_1) b^2 \leq (k_1 + k_2) \text{Var}(s), \quad (8)$$

where we are using the fact that delegation is always optimal when informative communication is feasible. Delegation is therefore optimal if the divergence in preferences is small relative to both the employee's informational advantage and the importance of the decision to the owner. Moreover, more congruent preferences can lead to a switch from centralization to delegation but not the reverse.

5.1.3.2. Vertically Dispersed Information. A key implication of Dessein (2002) is that the efficient allocation of decision rights depends on the endogenous flow of information. Extending the model by allowing for dispersed information further highlights the importance of taking into account the endogenous flow of information. Our discussion of this case is based on Harris and Raviv (2005).

For an illustration of their main arguments, suppose that there is another state $\hat{s}$, which is independently drawn from a uniform distribution with support $[-\hat{L}, \hat{L}]$ and variance $\text{Var}(\hat{s}) = \hat{L}^2/3$. The state $\hat{s}$ is observed by the owner but not by the employee. Under either organizational structure, the party without the decision right sends a single cheap-talk message to the decisionmaker, after which the decisionmaker makes his or her preferred decision. Finally, the owner's and the employee's payoffs are now given by

$$U_1(d, w) = K - k_1(d - s - \hat{s} - b)^2 + w \quad (9)$$

and

$$U_2(d, w) = K - k_2(d - s - \hat{s})^2 - w. \quad (10)$$

Proceeding as we did above, one can show that delegation is now optimal if and only if

$$(k_2 - k_1) b^2 \leq (k_1 + k_2)(V(b) - \hat{V}(b)), \quad (11)$$

where the residual variance $\hat{V}(b)$ characterizes the quality of communication under delegation and can be obtained by replacing $\text{Var}(s)$ with $\text{Var}(\hat{s})$ in (4) and L with $\hat{L}$ in (5). As in the model with concentrated information, a reduction in the divergence parameter improves both decisionmaking under delegation and communication under centralization. In addition, however, a reduction in b now improves communication under delegation. As a result, such a reduction can actually lead to a switch from delegation to centralization. Although this result contradicts the prediction of the model with concentrated information, it underlines that model's central insight that the efficient allocation of decision rights depends on the endogenous flow of information.

5.1.3.3. Horizontally Dispersed Information. So far we have focused on a setting with a single decision. Additional issues arise when there are multiple decisions that have to be coordinated and the information that is relevant for the decisions is dispersed among multiple employees. Coordinated decisionmaking then requires aggregation of the dispersed information. Some recent papers explore the allocation of decision rights in such a setting (Alonso et al. 2008; Rantakari 2008; Dessein et al. 2010; Friebe and Raith 2010). In line with the models we just discussed, these papers focus on communication costs that arise because of the employees' incentives to use their information strategically, which is why we concentrate on this branch of the literature below. For related models in which communication is not strategic, see, in particular, Aoki (1986), Hart and Moore (2005), Dessein and Santos (2006), and Crémer et al. (2007).

To illustrate the main insights in Alonso et al. (2008), suppose now that there are two employees. We think of the owner as the CEO of a multidivisional firm and the employees as the division managers.

Profits depend on two decisions, one of which is associated with Division 1 and the other with Division 2. For each decision, the firm faces a trade-off between coordination and adaptation. On one hand, each decision should be adapted to the business environment faced by the relevant division; on the other hand, decisions should also be coordinated with each other. Suppose, for instance, that the firm is a car manufacturer and that each division serves a particular country. Moreover, the firm has to decide what car it should produce for, and sell in, each country. The firm then faces a trade-off between tailoring the car types to the local tastes in each market—and thus increasing revenue—and coordinating the car types across markets—and thus reducing costs. This trade-off is captured in the profit functions

$$\pi_1 = K - (d_1 - s_1)^2 - \delta (d_1 - d_2)^2 \quad (12)$$

and

$$\pi_2 = K - (d_2 - s_2)^2 - \delta (d_1 - d_2)^2, \quad (13)$$

where K is a constant and $\delta \geq 0$ is the parameter that measures the relative importance of adapting each decision to the state and setting them equal to each other. Consistent with the

notation in the previous sections, d_1 and d_2 are the two decisions, and s_1 and s_2 are the states that summarize the business environment faced by each division.

All managers are risk neutral and thus care about expected profits. They differ, however, in how much weight they put on the expected profits of the different divisions. In particular, although the CEO cares about the firm's overall profits, each division manager puts weight λ on the profits of his own division and only $1 - \lambda$ on that of the other division. The parameter $\lambda \in (1/2, 1]$ therefore measures each division manager's own-division bias.

In line with the models in Section 5.1, we are interested in comparing the efficiency of two organizational structures, centralization (in which case both decisions are made by the CEO) and decentralization (in which case each division manager makes his decision without knowing what decision the other division manager has made). Under centralization the division managers communicate vertically with the CEO, and under decentralization they communicate horizontally with each other. In either case, communication takes the form of a single cheap-talk message that each division manager sends to either the CEO (in the case of centralization) or to his counterpart (in the case of decentralization). These messages are always sent simultaneously.

The endogenous quality of communication is crucial for the main result of the model. To see this, suppose first that the quality of communication is exogenously given. This would be the case, for instance, if communication were imperfect because of physical constraints rather than because of the division managers' strategic incentives to manipulate their information. And to keep things simple, suppose also that the exogenously given quality of communication is the same across organizational structures.

In such a setting, it is not immediately obvious whether the firm should centralize or decentralize. On one hand, the division managers know more about the states of the world than the CEO; on the other, their incentives to make the right decisions are distorted. If the quality of communication were perfect, centralization would therefore be optimal. If communication were entirely uninformative, however, decentralization would always be optimal. And in between these two extremes, the choice between the two organizational structures is determined by the need for coordination δ : whatever value λ takes, centralization is always optimal provided that the need for coordination is sufficiently strong. This conclusion is also illustrated in Figure 2. In the limit, however, in which δ goes to ∞ , expected profits under the two organizational structures converge to the same level. The reason is that as coordination becomes all important, the division managers understand that setting decisions equal to each other is all important, and they act accordingly. In spite of this convergence, however, it is still the case that for any large but finite δ , centralization is optimal. And this result, of course, is in line with the received wisdom that if coordination is important, centralization outperforms decentralization.

The main insight of the model is that this intuitive result depends crucially on the assumption that communication is exogenous. To see this, we need to understand the division managers' incentives to misrepresent their information under the two organizational structures. Consider, then, the incentives of one of the division managers, say, Manager 1, the division manager in charge of Division 1. From his perspective, when the CEO makes decision d_1 , she puts too little weight on adapting it to s_1 and too much on coordinating it with d_2 . Thus if Manager 1 would truthfully communicate his state, he would expect the CEO's choice of d_1 to be too close to zero. To induce the CEO to make a more extreme decision, Manager 1 therefore exaggerates his state and reports that its absolute value is larger than it actually is. Crucially, the more important is coordination, the more weight the CEO will put on setting d_1 equal to d_2 and

Figure 2. Exogenous communication.

the less weight she will put on setting d_1 equal to s_1 . Under centralization, therefore, the more important is coordination, the more the division managers will exaggerate their states, and the less information will be communicated in equilibrium.

This comparative static is the exact opposite under decentralization. To see this, consider Manager 1's incentives to misrepresent his information under decentralization. From his perspective, Manager 2 puts too little weight on coordinating d_2 with d_1 and too much weight on adapting d_2 to s_2 . Thus if Manager 1 truthfully communicated his state, he would expect Manager 2's choice of d_2 to be too close to zero. To induce Manager 2 to make a more extreme decision, Manager 1 will therefore once again exaggerate his state. In contrast to the centralized structure, however, Manager 1's incentive to exaggerate his state is weaker, the more important coordination is. Essentially, the more important is coordination, the more weight Manager 2 will put on coordinating d_2 with d_1 and the less weight he will put on adapting d_2 to s_2 . Under decentralization, therefore, the more important coordination, the less the division managers will exaggerate their states, and thus the more information will be communicated in equilibrium.

This difference between horizontal and vertical communication has important implications for the choice between the two organizational structures. In particular, with endogenous communication it is no longer the case that centralization is optimal when coordination is sufficiently important. This is illustrated in Figure 3. As with exogenous communication, decentralization is optimal if coordination is sufficiently unimportant. If λ is small, however, decentralization now remains optimal even if coordination becomes arbitrarily important. This model therefore once again highlights the importance of taking into account the endogenous nature of communication when predicting how changes in the environment affect the optimal allocation of decision rights.

5.1.4. To Motivate the Employee

Another common argument for delegation is that it motivates employees to provide more effort (Aghion and Tirole 1997). In line with our discussion in Section 3.5, it is useful to

Figure 3. Endogenous communication.

distinguish between motivating the employee to put more effort into information acquisition and motivating him to put more effort into execution.

5.1.4.1. Motivating Information Acquisition. Delegation not only allows the owner to make more efficient use of the employee's information, as we saw in the previous section. It may also allow the employee to use his information more effectively in pursuing his own goals. One would therefore expect delegation to increase the value of information to the employee and thus increase his incentives to become informed. In this section we first explore this motivational effect of delegation in the context of Aghion and Tirole (1997). We then return to Che and Kartik (2009), who show that in some cases delegation may actually reduce the value of information to the employee and thus weaken his incentives to become informed.

To explore the motivational effect of delegation, we make three changes to the version of Aghion and Tirole (1997) described in Section 3.5. First, at the beginning of the game, the owner now offers the employee a contract that specifies a wage and an allocation of the decision right. Second, we assume that the decision is more important to the owner than to the employee, that is, $B > b$. If this were not the case, delegation would be optimal even if both parties were perfectly informed. Third, to focus on the employee's incentives, we assume for now that the probability E with which the owner becomes informed is fixed. This would be the case, for instance, if her expertise were based on past experience rather than on current efforts to acquire information.

In Section 3.5 we saw that if the owner retains the right to make the decision, the employee benefits from becoming informed only if the owner is uninformed. Specifically, the employee's marginal benefit of getting informed is given by $(1 - E)b$.

If, instead, the owner delegates the decision right to the employee, the employee benefits from becoming informed even if the owner is informed too, because he can then insist on his preferred decision being made rather than having to accept the owner's. As a result, under delegation,

the employee's marginal benefit of becoming informed is given by $(1 - E)b_E + E(1 - \alpha)b = b(1 - \alpha E)$.

Delegation therefore increases the employee's marginal benefit of becoming informed, which in turn induces him to provide more effort. Delegation is then optimal if this motivational effect is sufficiently large relative to the cost of having decisions made by someone whose preferences are further from first best. In particular, delegation is optimal if

$$S^D - S^C = \left[(1 - E)(e^D - e^C)(\alpha B + b) - (c(d^D) - c(d^C)) \right] - Ee^D(1 - \alpha)(B - b) > 0, \quad (14)$$

where the first term on the right-hand side captures the benefit of a more motivated employee, and the second term captures the loss of control.

So far we have taken the owner's effort as exogenous. If effort is endogenous, delegation discourages information acquisition by the owner, for the same reason that it encourages information acquisition by the employee. As in Grossmann and Hart (1986) and Hart and Moore (1990), a change in residual control rights therefore leads to changes in the equilibrium levels of effort or investment.

The observation that delegation may involve a trade-off between losing control and motivating the employee is a central insight of Aghion and Tirole (1997). Although this trade-off is intuitive, some papers have explored conditions under which delegation may actually discourage the employee. The model in Rantakari (2012), for instance, can be viewed as a multitasking version of Aghion and Tirole (1997) in which the employee can choose both how much effort he puts into information acquisition and the type of decisions that he investigates. In such a setting, delegation motivates the employee to put effort into finding decisions that are good for him personally, but it discourages him from finding decisions that are good for the owner.

Another model in which delegation can discourage the employee is Che and Kartik (2009). They consider a model in which the owner and the employee have the same preferences over decisions but different priors about the state of the world and thus about what decision to make. One motive for the employee to acquire information is then to persuade the owner of his own opinion (see also Van den Steen 2002). Under delegation, the employee no longer needs to persuade the owner and may thus be less motivated to acquire information. This complacency effect of delegation can arise even if the employee and the owner have the same priors. To see this, notice that in Aghion and Tirole (1997) the allocation of the decision right does not matter if both parties are uninformed, because they then agree to make the default decision. Suppose in contrast that there are two default decisions, one that gives the owner zero but costs the employee $c > 0$ and another that gives the employee zero and costs the owner c . Under centralization, the employee's marginal benefit of becoming informed is then given by $(1 - E)(b + c)$, whereas under delegation it is still given by $b(1 - \alpha E)$. Delegation then discourages the employee, provided that c is sufficiently large. In the terminology of Che and Kartik (2009), delegation makes the employee "complacent," because it makes it less costly for him to be uninformed.

5.1.4.2. Motivating Execution. Delegation might motivate the employee to put more effort not only into information acquisition but also into implementing and executing decisions. The employee may, for instance, believe that his preferred decision has a higher chance of

succeeding than that of the owner (Zábojník 2002; Van den Steen 2006). Or he may simply receive a larger private benefit from successfully implementing his preferred decision (Bester and Kräbmer 2008).

Delegation can motivate execution; however, the need to motivate execution may actually make delegation less efficient relative to centralization (Bester and Kräbmer 2008). The reason is that if the owner has to motivate execution, she needs to take the employee's preferences into account when she makes a decision. The need to motivate execution therefore acts as a disciplinary device on the owner that makes centralized decisionmaking more efficient relative to delegated decisionmaking.

To see this more clearly, consider a simplified version of the model in Bester and Kräbmer (2008). In particular, recall the model in Section 5.1.2, but suppose now that after a decision has been made, the employee has to choose his implementation effort $e \in \{0, 1\}$. The decision succeeds if and only if the employee provides effort and success is not contractible. The parties' payoffs are then given by

$$U_1(d, e) = e \left[K - k_1(d - \theta - b)^2 \right] - ce + w \quad (15)$$

and

$$U_2(d, e) = e \left[K - k_2(d - \theta)^2 \right] - w, \quad (16)$$

where c is the employee's cost of effort. Suppose also that effort costs satisfy

$$K - k_1b^2 < c < K - k_1E \left[(d^{FB} - \theta - b)^2 \right], \quad (17)$$

where d^{FB} is the first-best decision if the employee does provide effort. Finally, suppose that $k_1 > k_2$, so that the decision is more important to the employee than to the owner.

If effort is contractible, motivating execution is not a concern. As in the model in Section 5.1.2, it is then efficient to give the decision right to the party that values this right more highly, which in this case is the employee. If effort is not contractible, however, motivating execution does become a concern. Under centralization, the owner then cannot simply make her preferred decisions, because if she did, the employee would not put any effort into execution. To motivate execution, the owner therefore has to bias her decision toward the employee's preferred decision, which makes her decision more efficient. In contrast, if the owner delegates, the employee will still make his preferred decision. The need to motivate execution therefore makes centralized decisionmaking more efficient relative to delegation. As a result, the owner may find it optimal to centralize when she has to motivate execution, even though she would delegate if motivation were not a concern.

5.1.5. To Learn More about the Employee

Delegation can also be a tool to test the employee and to learn more about his ability or preferences. For instance, a CEO may delegate control over a division to a senior executive to test the executive's ability to run his own business. Or she may delegate to the executive to find out more about his preferences, such as whether he is an empire builder or is focused on generating

profits. Aghion et al. (2002, 2004) explore this second possibility. In doing so, they also challenge the assumption in most of the literature that the allocation of decision rights is deterministic. In this section we first discuss the use of delegation as a means to learn more about the employee's preferences and then discuss contingent allocations of decision rights.

5.1.5.1. Learning about the Employee's Preferences. To see some of the insights in Aghion et al. (2002, 2004), consider the following two-period model. In the first period an organization has to decide on the type of project it wants to design, and in the second it has to decide on whether to implement the project. In the first period Aghion et al. make three changes to the model in Aghion and Tirole (1997), which we described in the previous section. First, wages are fixed at zero. Second, the owner and the employee both know the payoffs of all the projects, that is, $E = e = 1$. Third, the employee is privately informed about his type, either bad (which happens with probability $\mu < \frac{1}{2}$) or good (which happens with probability $1 - \mu$). If the employee is a good type, the congruence parameter α is equal to one, and if he is a bad type, it is equal to zero. For reasons that will become apparent, we assume that $b > 1$.

In the second period, the owner decides whether to implement the project that was designed in the first. If the owner does not implement the project, both parties receive a zero payoff, regardless of whether the employee is a good or a bad type. But if the owner does implement the project, she gets $+1$ if the employee is a good type and -1 if he is a bad type, while the employee obtains $+1$ in either case. Implementing the project is therefore in the owner's interest only if the employee is a good type.

In this setting, if the owner does not delegate the design decision, she will choose her preferred design in the first period and then implement it in the second period. In this case, the owner's expected payoff is therefore given by $E[U_2^C] = B + 1 - 2\mu$. If, instead, the owner does delegate the design decision, the employee will always choose his preferred design and thus reveal his type. In the second period, the owner then implements the design if and only if the employee is a good type. In this case, the owner's expected payoff is therefore given by $E[U_2^D] = (1 - \mu)(B + 1)$.

The gain from delegation is then given by $E[U_2^D - U_2^C] = \mu - \mu B$, which is positive if $B < 1$. In this setting, delegation is therefore a tool that allows the owner to learn more about the employee's preferences. For the owner to make use of this tool, however, her future benefit of knowing the employee's preferences must outweigh current costs of learning them, that is, $B < 1$. At the same time, the employee's current benefit of using authority in his favor must outweigh the future costs of a ruined reputation, that is, $b > 1$.

5.1.5.2. Contingent Allocations of Decision Rights. The models we have examined so far assume that, although decision rights are contractible, their allocation cannot be made contingent on any information that is revealed after the initial contract is signed. This assumption is typically justified informally by arguing that the reallocation of decision rights in organizations takes too long relative to the time frame in which most decisions have to be made. In practice, reallocations certainly appear to be rare relative to the frequency with which decisions are made.

In the confines of the models that we have examined so far, however, there is no reason the owner should not be able to commit to contingent allocations of the decision rights. And as

shown in Aghion et al. (2002, 2004) and Krähmer (2006), doing so can indeed make the owner better off.

To see why contingent allocations can make the owner better off, consider the setting we sketched above, and suppose that the allocation of the first-period decision right is made contingent on a message sent by the employee. In particular, if the employee admits to being a bad type, he is rewarded by receiving the decision right with probability $1/b$; if, however, he claims to be a good type, the owner retains the decision right for sure. The probability $1/b$ with which the decision right is delegated to the employee ensures that a bad employee is just indifferent between revealing his type (in which case he expects to make $(1/b)b$ today and zero tomorrow) and claiming to be a good type (in which case he makes zero today and $+1$ tomorrow). In this setting, contingent delegation therefore allows the owner to learn the employee's type at a lower cost and thus makes her better off.

If contingent delegation can make the owner better off, why would she ever delegate to the employee unconditionally? One reason is that the contingent allocation requires the owner to delegate to the employee when she has learned that the employee is a bad type. One can imagine situations in which the owner is unable to commit herself to such an ex post inefficient action, even if it is ex ante efficient to do so.

Notice also that in a slightly more general setting than the one we examined above, the optimal revelation mechanism may call for the unconditional transfer of the decision right to the employee. In particular, suppose that the good employee does not have the same preferences as the owner. Aghion et al. (2002, 2004) show that if the owner's preferences are sufficiently different from those of both types of employees, it is no longer possible to induce the employee to reveal his type. The owner can then no longer be made better off by making delegation contingent on the employee's messages.

Finally, as we discuss in Section 5.2, legal barriers prevent organizations from committing to contracts that transfer decision rights from the top to others in the organization. Below we argue that organizations may still be able to implement deterministic allocations through other means that do not require formal contracts. It is unclear, however, whether these other mechanisms would also allow for the implementation of contingent allocations of decision rights. For these reasons, in the remainder of this chapter we return to the assumption that the allocation of decision rights is deterministic.

5.1.6. *Anything Else?*

Alfred Sloan, the longtime President and CEO of General Motors, is widely regarded as one of the inventors of the multidivisional organization that is now common in large corporations. A major theme in his autobiography is the importance for corporate performance of properly allocating decision rights between headquarters and the divisions. As he puts it in the last chapter of his autobiography:

It has been a thesis of this book that good management rests on the reconciliation of centralization and decentralization, or "decentralization with coordinated control." . . . From decentralization we get initiative, responsibility, development of personnel, decisions close to the facts, flexibility—in short, all the qualities necessary for an organization to adapt to new conditions. From coordination we get efficiencies and economies. It must be apparent

that co-ordinated decentralization is not an easy concept to apply. There is no hard and fast rule for sorting out the various responsibilities and the best way to assign them. The balance which is struck between corporate and divisional responsibility varies according to what is being decided, the circumstances of the time, past experience, and the temperaments and skills of the executives involved. [Sloan 1964: 429]

Much of what Sloan says in this quotation is reflected in the literature on delegation that we have discussed so far. Just like Sloan, for instance, the literature has focused on “initiative,” “flexibility,” and “decisions close to the facts” as primary benefits of a decentralized structure. And the trade-off between adaptation and coordination that Sloan describes has been at the center of much recent work. The quotation, however, also points to some issues that we have not yet addressed.

For instance, Sloan is not the only practitioner who believes in the importance of delegation for the “development of personnel.” Nevertheless, little, if any, work has been done on the role of delegation in the development of managerial human capital. More generally, the literature has so far focused largely on static models of delegation. The dynamics of delegation is an important and potentially fruitful area of future research.

The models that we have discussed so far are also quite stark in that they force the owner to choose between centralization and unconstrained delegation and do not allow her to control the employee through different means. As such, these models do not capture Sloan’s policy of “decentralization with coordinated control.”

In the rest of this chapter we explore some of these additional issues. In particular, in the next section we discuss the issues that arise if the owner cannot commit to contracts that transfer decision rights to the employee. This is one area of the literature in which dynamic models of delegation do play a prominent role. In Section 5.3 we then discuss models that allow the owner to better control the employee by either constraining the decisions he can make or by using incentive contracts to align his preferences.

5.2. How to Delegate

The models we have discussed so far ask *why* the owner may find it optimal to delegate decision rights, but they do not examine *how* the owner may do so. This is potentially problematic, because, by law, formal authority resides at the top of organizations and the “business judgment rule” makes it impossible to write legal contracts that transfer formal authority to other parties in the organization (see Kornhauser and MacLeod, this volume).

One way for the owner to transfer formal authority to an employee is to sell him the assets that are necessary to make the decision and thus turn him into an independent subcontractor (Grossman and Hart 1986; Hart and Moore 1990). Given our focus on internal organization, however, we are interested in how the owner can delegate formal authority to an employee without changing the boundaries of the organization.

In this section we review some papers that show that even if the owner cannot write legal contracts delegating formal authority to another party in her organization, she may be able to commit to behaving as if formal authority had been delegated. We first discuss how the owner may be able to do so by committing to an information structure in which it is optimal for her

to rubber-stamp any recommendation that the employee might make. We then discuss models in which reputational concerns induce the owner to rubber-stamp the employee's recommendations, even if it is not in her short-term interest to do so.

5.2.1. *Delegation through Ignorance*

The old saying that knowledge is power suggests that information can lead to the separation of real and formal authority, which is a central observation in Aghion and Tirole (1997). We saw above that in their model an uninformed owner finds it optimal to rubber-stamp her employee's recommendation, even if she knows that the employee is selfishly recommending his own preferred decision. This suggests that an owner who cannot commit to delegation contractually may still be able to do so by committing to an appropriate information structure.

For an owner to delegate by committing to an appropriate information structure, two conditions have to hold. First, it must be the case that even if the owner knows that the employee is simply recommending his preferred decision, she cannot invert the recommendation and thus infer his information. Second, there must be an underlying congruence in the two parties' preferences: the owner must prefer the employee's preferred decision to her either doing nothing or making a decision at random.

Both conditions are satisfied in Aghion and Tirole (1997). First, if the employee recommends a decision, the owner cannot infer the payoffs associated with the other decisions. Second, because the owner expects a positive payoff from the employee's preferred decision, she prefers that decision to her either doing nothing, in which case she gets zero, or making a decision at random, in which case she expects to be wiped out. In this setting, the owner can therefore transfer real authority to the employee by committing to not becoming informed. Aghion and Tirole (1997) suggest that the owner may be able to do so, for instance, by becoming overloaded with other decisions.

In Aghion and Tirole (1997) the employee's recommendation is entirely noninvertible. Callander (2008b) instead develops a model in which an employee's recommendations are partially invertible. To see a simple version of his model, suppose that an owner and an employee have quadratic preferences over an outcome $x \in \mathfrak{R}$, with the employee preferring a larger outcome than does the owner. An outcome function maps the decision d into the outcome. The crucial feature of the model is that the outcome function is generated by Brownian motion. Both parties know the drift and variance of the Brownian motion, and they know the outcome associated with a default decision. However, only the employee knows the full realization of the Brownian motion.

In this setting, if the employee recommends the decision that leads to his preferred outcome, and the owner is aware of this, the owner can infer some information about the outcomes associated with other decisions. Callander (2008b) shows that the owner finds it optimal to rubber-stamp the employee's selfish recommendations if the variance of the Brownian motion is above a threshold, in which case the owner is very uncertain about the outcomes associated with the other decision. If the variance is below the threshold, however, the owner may find it optimal to use the information that she can infer from the employee's recommendation to overrule the employee and make another decision. This model suggests that the owner's ability to delegate through ignorance depends on the complexity of the decision, where the complexity is captured by the variance of the Brownian motion.

5.2.2. Informal Delegation

We now turn to papers that explore the feasibility and optimality of informal delegation. The first section examines the conditions under which an owner is able to maintain a reputation for rubber-stamping her employee's recommendations, even if it is not in her short-term interest to do so. In the second section we then ask whether an owner who is able to maintain such a reputation finds it optimal to do so. The reason she may not is that if she can implement delegation, she may be able to implement other decision processes that do even better than either centralization or delegation.

5.2.2.1. Feasibility of Informal Delegation. We first examine the conditions under which an owner is able to resist the short-term temptation of overruling her employee and thus is able to engage in informal delegation. Baker et al. (1999) show that these conditions can be different from, and sometimes the opposite of, the conditions under which the owner would want to delegate to the employee in the first place.

To capture some of their insights, we make four changes to the version of Aghion and Tirole (1997) that we discussed in Section 5.1.4. First, we now assume that the owner is never informed about the decisions, that is, $E = 0$. Second, the employee's cost of effort is now given by $c(e) = ce^2$. Third, if the employee recommends a decision, the owner learns the payoffs from that decision. Information is therefore now assumed to be hard. Finally, we continue to assume that with probability α one of the decisions pays the owner B and the employee b , whereas the other pays each party zero. With probability $1 - \alpha$, however, one of the decisions now pays the owner B and the employee zero, whereas the other pays the owner and the employee $-B$ and b , respectively. In this case, the owner therefore prefers the default decision to the employee's preferred decision.

Before we turn to the infinitely repeated version of this game, consider a once-off interaction in which the owner is able to commit to delegation contractually. If the owner does delegate to the employee, the employee will always make his preferred decision. Effort and expected surplus will then be given by

$$e^D = \arg \max_e w + eb - ce^2 \quad (18)$$

and

$$S^D = e^D[\alpha(B + b) + (1 - \alpha)(-B + b)] - c(e^D)^2. \quad (19)$$

Suppose now that the owner does not delegate to the employee. If the employee becomes informed, he will then recommend his preferred decision if it coincides with the owner's preferred decision, but he will recommend the default decision if their preferred decisions do not coincide. Effort and expected surplus will then be given by

$$e^C = \arg \max_e w + e\alpha b - ce^2 \quad (20)$$

and

$$S^C = e^C\alpha(B + b) - c(e^C)^2. \quad (21)$$

We are interested in the case in which delegation is more efficient than centralization, but the owner is not able to commit to delegation contractually. For the rest of this section, we therefore

suppose that $S^D > S^C$, which will be the case if the congruence parameter α is sufficiently large.

Consider then an infinitely repeated version of the game in which a long-lived owner faces a series of short-lived employees, each of whom she interacts with only once.¹³ We focus on trigger strategies in which the owner promises to rubber-stamp any recommendation an employee might make and in which the parties revert to the best static equilibrium if the owner breaks her promise.

Standard arguments then show that the owner can implement delegation informally if and only if

$$S^D - S^C \geq rB, \quad (22)$$

where r is the discount rate. As one would expect, the owner is therefore able to replicate delegation informally, provided that she is sufficiently patient. More interestingly, the model predicts that the feasibility of informal delegation depends on the owner's reneging temptation, which, in turn, depends on both the average and the extreme realizations of payoffs. Suppose, for instance, that we increase B but also adjust b and α in such a way that $S^D - S^C$ stays constant. Even though such a change does not affect the efficiency of delegation, it makes it more difficult to implement it, because the change increases the owner's reneging temptation. Finally, notice that when preferences are highly congruent, delegation is efficient but cannot be implemented informally, because the owner's fallback option is then too attractive. This result is in stark contrast to models with contractible control, many of which predict that the owner will engage in delegation when preferences are highly congruent (e.g., see Dessein 2002; Alonso et al. 2008).

5.2.2.2. Optimality of Informal Delegation. We now turn to whether a long-lived owner who is able to replicate delegation informally finds it optimal to do so. Baker et al. (1999) and Alonso and Matouschek (2007) show that she may not, even if delegation is more efficient than centralization. As mentioned above, the reason is that if the owner is able to engage in informal delegation, she may also be able to commit to other, more efficient decision processes.

To understand the argument in Alonso and Matouschek (2007), consider an infinite repetition of the version of Dessein (2002) model that we described in Section 5.1.3. In line with the model in the previous section, suppose that the owner is long-lived and that she faces a series of short-lived employees. Delegation can then be implemented informally if and only if

$$S^D - S^C \geq rb^2, \quad (23)$$

where S^D and S^C are given by (18) and (20), and we are again assuming that if the owner reneges on her promise, the parties revert to centralization. Notice that the maximum reneging temptation is given by b^2 , because when an employee truthfully reveals the state, the owner can always implement her preferred decision rather than that of the employee.

13. The main insights of the model would be unchanged if the long-lived owner interacted with a single, long-lived employee. The above formulation highlights that we are focusing on the owner's reputational concerns rather than those of the employees.

The key observation now is that if the owner is patient enough to engage in delegation, she is also patient enough to engage in threshold delegation. Under this scheme, the owner makes the employees' preferred decision if they report a state below the threshold $s^* = L - 2bk_2/(k_1 + k_2)$, and she implements $d = s^* + b$ otherwise. Threshold delegation involves the same maximum reneging temptation as delegation, but it is more efficient.

If an owner is sufficiently patient to replicate delegation informally, she may therefore also be able to commit to decision processes that perform better than either centralization or delegation. On one hand, this provides a challenge to our analysis, because it requires us to consider many more decision processes than the two that we have focused on so far. On the other hand, it also brings the analysis closer to the real world, because firms clearly do use many different types of decision processes. In the next section we go beyond the simple example in this section and examine optimal decision processes in more general environments.

5.3. How to Control the Employee

The models we have discussed so far focus on the choice between centralization and delegation and mostly abstract from any actions that the owner might be able take to control the employee. The ability of the owner to take actions to control the employee in many settings has been noted by Holmström (1977, 1984) and Jensen and Meckling (1992), among others. For instance, the owner may be able to constrain the decisions the employee can make. Or she may be able to use incentive contracts to align the employee's incentives. In this section we discuss these two options in turn.

5.3.1. Optimal Decision Processes

In the previous section we saw that even if decisions are *ex ante* and *ex post* noncontractible, a sufficiently patient owner can implement decision processes other than just centralization and delegation. This raises the question of what is the optimal process among all deterministic decision processes. A related question is what the owner should do if she is able to constrain the decisions the employee can make. It turns out that these two questions are actually the same, at least if one restricts attention to deterministic decision rules. In particular, Holmström (1977, 1984) observes that searching for the optimal deterministic decision rule is equivalent to figuring out how to optimally constrain the set of decisions from which the employee is allowed to choose. In this section we discuss Holmström (1977, 1984) and the literature built on his contributions.

Holmström (1977, 1984) starts by posing a general class of problems in which an owner needs to make a decision that affects her payoff and that of her employee. The employee privately observes the state of the world that determines each party's preferred decision. In contrast to the models we have examined so far, Holmström allows the owner to commit to any deterministic outcome function that maps the employee's recommendations to decisions. He does, however, continue to rule out contingent payments between the two parties.

In this setting, the Revelation Principle implies that one can restrict attention to direct mechanisms in which the employee truthfully reveals the state. Any deterministic direct mechanism in turn can be implemented through a constrained delegation scheme in which the owner of-

fers the employee a set of decisions from which the employee can then choose. The contracting problem therefore reduces to finding the optimal delegation set. However, the optimal delegation set can take essentially any form, the only requirement being that the employee's choice is well defined.

In practice, constrained delegation of this type is very common. Alfred Sloan, for instance, delegated the pricing decisions of the different types of cars to his division managers but allowed them to choose only prices between certain thresholds (Sloan 1964).

However, notice that although constrained delegation is weakly optimal in this setting, there may be other decision processes that might perform equally well. Mylovanov (2008), for instance, shows that when the optimal delegation set takes the form of a single interval, and the owner's and employee's preferred decision functions intersect at most once, the optimal delegation set can be implemented through veto delegation.

After posing the general problem and showing that a solution exists, Holmström (1977, 1984) shows that in the standard uniform-quadratic-constant-bias case the optimal delegation set takes the form of a single interval. As mentioned above, some papers have built on Holmström's work. For instance, Melumad and Shibano (1991), Martimort and Semenov (2006), Alonso and Matouschek (2008), and Amador and Bagwell (2011) characterize the optimal delegation set for more general settings. Koessler and Martimort (2012) and Frankel (2012) extend the standard setting by allowing for multidimensional decisions. Szalay (2005) endogenizes information acquisition by the employee. And Ambrus and Egorov (2009) allow for the owner to impose decision-contingent costs on the employee. All these papers focus on deterministic mechanisms. In contrast, Kovac and Mylovanov (2009) allow for stochastic mechanisms and provide sufficient conditions under which the optimal mechanism is in fact deterministic.

One insight from this literature is that even if the owner is able to commit to essentially any decision process, delegation can arise as the optimal one. And if delegation is not optimal, other commonly observed decision processes often do arise. For instance, Alonso and Matouschek (2008) and Amador and Bagwell (2011) provide necessary and sufficient conditions for the optimal delegation set to consist of a single interval. Even though commonly observed decision processes can arise as optimal, however, some of the widely held beliefs about how changes in the environment affect decisionmaking may no longer hold. For instance, Alonso and Matouschek (2008) show that if one allows for any decision process, the owner may give less discretion to an employee whose preferences are more aligned with the owner's or to one with a greater informational advantage.

To illustrate an application of this literature, albeit in a different context, consider the classic problem of regulating a monopolist who is privately informed about his costs (Baron and Myerson 1982). But in contrast to Baron and Myerson, suppose that transfers between the regulator and the monopolist are ruled out by law, as is often the case in practice. In particular, suppose that the monopolist can produce $q \geq 0$ units of a good at costs θq and faces a linear demand curve $d = A - Bq$, where d is the price, and A and B are both strictly positive parameters. Marginal costs s are drawn from a unimodal distribution with support $[0, 1]$. The monopolist's preferred price is then given by $d_S(s) = (A + s)/2$, whereas the regulator would like to set the price equal to marginal costs. Finally, suppose that the maximum willingness to pay A is larger than the largest marginal cost, that is, $A > 1$. Our discussion of this example follows Alonso and Matouschek (2008).

A first question is whether the regulator should give the firm any discretion over pricing. The answer is that the regulator should do so if and only if $A/2 < E(s)$. This condition is more likely to be satisfied the smaller is A , which is intuitive, because a reduction in A reduces the firm's preferred price. However, notice that the condition depends only on the mean of the cost distribution and not on any measure of its dispersion. The magnitude of the firm's informational advantage therefore has no effect on whether the regulator should give it any discretion over pricing.

The second question is then what prices the firm should be allowed to choose from, if the above condition is indeed satisfied. The answer turns out to be very simple: for any unimodal cost distribution, the regulator cannot do better than to let the firm choose any price below a threshold. This result is consistent with the widespread use of price-cap regulation in the United Kingdom and the United States (Armstrong and Sappington 2007). Finally, it can be shown that the price cap is decreasing in A and that the effect of a change in the firm's informational advantage is in general ambiguous. Even though this example deals with the organization of a regulatory system, it does suggest that the results from this literature can be fruitfully applied to similar issues that arise in firms, such as the design of capital budgeting rules and the design of transfer pricing schemes.

The general problem that this literature examines has been further explored in the context of various economic problems. For instance, Athey et al. (2005) study the optimal degree of discretion for a monetary authority. Amador et al. (2006) explore how an agent may want to restrict his future decisions in a setting where the agent expects to receive relevant information in the future but also knows that he suffers from self-control problems. Martimort and Semenov (2006) examine a delegation problem with multiple employees to analyze the organization of lobbying by interest groups. And in a setting with a different information structure than the one shared by the models that we have described so far, Armstrong and Vickers (2010) develop a model of delegated project choice and apply it to the optimal design of competition policy.

5.3.2. *Endogenous Incentives*

In addition to constraining the decisions the employee can make, the owner might be able to control the employee through the use of incentive contracts. Most of the literature on delegation assumes that the owner cannot rely on incentive contracts to align the employee's incentives, just as most of the literature on incentive contracts assumes that the owner cannot contract on the allocation of decision rights. One reason for ruling out incentive contracts is that they can be difficult to reconcile with the assumption that contracts are highly incomplete (see, for instance, Mookherjee, this volume), which is central to all the models of delegation discussed in this chapter. As observed by Jensen and Meckling (1992) and others, however, in practice the design of incentive contracts and the allocation of decision rights are interdependent. Indeed, there is a strong sense that the use of incentive contracts and delegation are not only interdependent but also complementary. For instance, Milgrom and Roberts (1992: 17) observe that "incentives and delegated authority are complements: each makes the other more valuable." In this section we discuss papers that explore this interdependence. In line with our discussion above, we distinguish between models in which there is only one employee and one decision and others in which there multiple employees and decisions.

5.3.2.1. Incentive Contracts for a Single Employee. The trade-off between risk and incentives is a central insight of the literature on incentive schemes. But as Prendergast (2002) observes, there is only weak empirical support for this trade-off. Indeed, if anything, firms appear to be using steeper incentives in more, rather than less, uncertain environments. To provide an explanation for this empirical pattern, Prendergast develops a model in which incentives and the allocation of decision rights are jointly determined. In the model, the more uncertain is the environment, the more discretion an owner gives her employee over what he can do on the job. And the more discretion the employee has over what he can do on the job, the more important it is that his pay be closely tied to his performance. In line with the observation above, incentives and discretion are therefore complements.¹⁴ And because incentives and discretion are complements, an increase in uncertainty that leads to more discretion also leads to steeper incentives.¹⁵

Krishna and Morgan (2008) also allow for endogenous incentives in a setting with a single employee. In their model, however, incentives and delegation are substitutes. Specifically, they consider a version of the model in Dessein (2002) in which the owner can make wages contingent on messages sent by the employee. They then show that even if wages cannot be negative, contingent wages improve communication under centralization. Because message-contingent wages do not improve decisionmaking under delegation, the owner's ability to commit to incentive contracts then makes centralization more likely. In this setting, incentive contracts and delegation are therefore substitute tools that the owner can use to make decisions more sensitive to the state.

A key difference between Prendergast (2002) and Krishna and Morgan (2008) is that in Prendergast's model incentive contracts improve decisionmaking under delegation, whereas in Krishna and Morgan's model they improve communication under centralization. In practice, incentive contracts may improve both decisionmaking and communication. For incentive contracts and delegation to be complements, as is often argued, incentive contracts must more effectively improve decisionmaking under delegation than they do communication under centralization. This observation once again highlights the importance of taking into account the endogenous nature of communication for the analysis of efficient organization.

5.3.2.2. Incentive Contracts for Multiple Employees. Some papers also explore the joint determination of incentives and the allocation of decision rights in a setting with multiple employees, who are typically thought of as division managers.

In Athey and Roberts (2001) there are two division managers who have two tasks: to put effort into increasing their divisions' profits and to select a project. A central insight of the paper is that there is a trade-off between motivating effort provision and project selection. In particular, effort provision is best motivated through relative pay, which filters out shocks that are common to both divisions; however, relative pay distorts project selection, because it gives

14. The literature has identified additional reasons for why incentives and delegation may be complements. For instance, Van den Steen (2010a) explores a setting in which the owner and the employee have different priors about what decision is most likely to lead to the successful conclusion of a project. In his setting, income and decision rights should be concentrated in the same party, because the party with the income right cares the most about the decision being correct, and the party with the decision right has the highest valuation of the project.

15. For a further discussion on why more uncertainty may lead to steeper incentives, see Raith (2008).

the division managers poor incentives to internalize externalities. Instead of letting the division managers decide on projects, it may then be better to move this decision to a third employee who gets paid a small fraction of overall profits. The model therefore provides a rationale for the incentives that are assumed in Alonso et al. (2008), Rantakari (2008), and other papers. As discussed in Section 5.1.3, these models assume that the CEO cares about overall profits, whereas division managers are biased toward their divisions.

In a related paper, Dessein et al. (2010) develop a model in which it is optimal to bias functional managers toward standardization and division managers toward local adaptation. They then explore the interdependence between the endogenously created incentive conflict and the allocation of decision rights. Friebe and Raith (2010) also explore the joint determination of incentives and the allocation of decision rights in a multidivisional firm. However, they focus on the boundary of the firm, which they allow to be endogenously determined. Rantakari (2011) takes the boundary of the firm as given but endogenizes the degree of operational integration, in addition to incentives and the allocation of decision rights. He argues that stable environments give rise to tightly integrated and centralized organizations with firm-wide incentives for division managers, whereas volatile environments induce firms to adopt more loosely integrated and decentralized organizational structures with division-level incentives for division managers.

6. Conclusion

A number of the first scholars to examine organizations (both within and outside the field of economics) identified both the crucial role of decisionmaking and the inherently strategic nature of communication. In the intervening years, a large volume of economic research has explored these ideas (although often without being aware of their origins). In this chapter we have surveyed this work.

It should be clear that there remain many open theoretical questions. For example, each individual line of inquiry could be deepened, as we described the cheap-talk literature moving from its origins in Section 2.2 to recent work in Section 3.1. Furthermore, there are likely to be advances from combining some of the approaches described here, such as by adding limited opportunities for contracting to several of the existing research streams, as we began to describe in Section 3.6. Finally, the question of what an organization might do to ameliorate some of the inefficiencies we describe has only just begun to be analyzed, so there is much work to do in continuing that described in Sections 4 and 5.

Probably more important than all these opportunities for more theory, however, we believe that—as is true throughout most of organizational economics—the greatest need is for empirical work in this area. We hope this need will begin to be met soon.

Leadership and Corporate Culture

Benjamin E. Hermalin

1. Introduction

Much of the economics of organization deals with the formal rights and rules that govern organizations, both in normative and positive analyses. Who should have legal claim to what resources? Who should have authority over whom or what? What contracts should be utilized? But importantly, the operation of organizations is also determined by informal means. Two such means are *leadership*, a concept distinct from authority, and *corporate culture*, a broad concept covering the informal rules and expectations that affect operations. This chapter surveys the literature on these informal aspects of organization.¹

1.1. What Is Leadership?

The word “leadership” has many meanings and connotations. Some pertain to roles assigned to certain offices. For instance, a prime minister is often the leader of her party and her nation. Yet leadership is also distinct from any office or formal authority. For although being prime minister might enhance a politician’s capacity to serve as a leader, one presumes that she became prime minister in part because of her leadership abilities. Furthermore, in organizations and institutions, a person can be a leader without office or portfolio; a politician can, for instance, be a leader of her party (although perhaps not *the* leader) even if she holds no title in the party or the government. Leadership is, thus, distinct from formal authority.² Indeed, history is replete with examples of important leaders who held no official position (e.g., Jeanne d’Arc).

1. For other surveys of leadership from an economics perspective, see Bolton et al. (2010) and Zupan (2010). For another survey of corporate culture from an economics perspective, see Hermalin (2001). Langevoort (2006) offers a partial survey on corporate culture from a law and economics perspective.

2. Some authors, rather than distinguish leadership from (formal) authority, use leadership to refer to both formal authority (e.g., deriving from an office) and the less-formal idea of leadership adopted in this chapter. Typical means of referring to this distinction are, respectively, “formal leadership” and “emergent leadership” (House and Baetz 1979) or “de jure leadership” and “de facto leadership” (Peters 1967).

Leadership is, therefore, a phenomenon that exists independent of office or title. Without office or title, a leader's ability to influence the behavior of others is limited. Without office or title, she lacks authority to order others to undertake actions, and she lacks the right to provide them incentives via contract. Even when a leader possesses an office or title, the formal authority so provided could be limited; for instance, the president of a school's Parent-Teacher Association (PTA) cannot order its members (i.e., other parents) to show up for a school clean-up day. As Weber (Gerth and Mills 1946: 248–249) puts it:

The [leader] does not deduce his authority from codes and statutes, as is the case with the jurisdiction of office; nor does he deduce his authority from traditional custom or feudal vows of faith, as in the case with patrimonial power.

As the PTA example suggests, one of the essences of leadership is the ability to induce others to follow absent the power to compel or to provide formal contractual incentives. This notion of leadership is perhaps most closely related to Weber's idea of *charismatic* leadership. Indeed, in this chapter, the operational definition of leadership is that a leader is someone with followers *who follow voluntarily*. The critical question then becomes how does a leader induce others to follow?³

Even when the leader has *formal authority*—the power to coerce (directly or indirectly through incentives)—such authority is rarely absolute. Certainly, sociology, political theory, and organizational behavior still see a need for leaders to encourage and motivate a following.⁴

1.2. What Is Corporate Culture?

"Culture," too, is a word with many meanings. With respect to organizations, the most relevant meaning in the dictionary would be "the distinctive customs, achievements, products, outlook, etc., of a society or group; the way of life of a society or group," a meaning that the word acquired in the late nineteenth century (Brown 1993: 568). Some definitions from the social sciences include:

A pattern of shared basic assumptions that the group learned as it solved its problems of external adaptation and internal integration, that has worked well enough to be considered valid and, therefore, to be taught to new members as the correct way to perceive, think, and feel in relation to those problems. [Schein 1992: 12]

[V]alues that are shared by the people in a group and that tend to persist over time even when group membership changes. [Kotter and Heskett 1992: 4]

3. Handy (1993: 97) describes answering this question as one of the "Holy Grails" of organization theory.

4. See, for example, chapter 19, "On Avoiding Being Despised and Hated," and chapter 21, "How a Prince Should Act to Acquire Esteem," of Niccolò Machiavelli's *The Prince* (Bondanella and Musa 1979); part III, chapter 9 of Max Weber's *Wirtschaft und Gesellschaft* (Gerth and Mills 1946: 245–252); part II of McGregor (1966: 49–80); chapter 4 of Handy (1993: 96–122); and chapter 2 of Wrong (1995: 21–34). Motivating a following is also a large part of "how-to" analyses of leadership, such as Kouzes and Posner (1987), Bennis (1989), Heifetz (1994), and Kotter (1996).

[C]orporate culture [is] partly . . . the interrelated principles that the organization employs and partly the means by which [its] principle[s are] communicated to hierarchical inferiors and hierarchical superiors. It says how things are done, and how they are meant to be done. . . . Because it will be designed through time to meet unforeseen contingencies as they arise, it will be the product of evolution inside the organization and will be influenced by the organization's history. [Kreps 1990: 224]

In economics, the modeling of corporate culture has taken a number of different paths. Kreps (1990), for instance, focuses on culture as a way of dealing with unforeseen contingencies. Others consider culture as convention (Young 1993, 1998) or as a means of equilibrium selection (Kreps 1990). Related to this idea, some model culture as an economizing device (Cr  mer 1993). Culture is sometimes seen as equivalent to organizational reputation (Cr  mer 1986; Kreps 1990). There is also the question of how culture arises; some have sought to model its transmission (Lazear 1998) or its emergence through forces that lead to homogeneity of beliefs (Van den Steen 2010c).

1.3. Culture and Leadership

There is some reason the volume editors chose to combine the discussion of corporate culture and leadership into one chapter (other than, perhaps, the convenient fact that I have written on both in the past). There are at least five reasons the topics might profitably be linked:

1. *Leaders are proselytizers.* Leaders are the people who disseminate culture within an organization. For example, chapter 11 of Schein (1992: 211–227) deals with the role of leadership in building culture (consider, e.g., the role often attributed to Herb Kelleher at Southwest).⁵ Chapter 12 of Schein (1992: 228–253) discusses how leaders embed and transmit culture.
2. *Leaders are judges.* Leaders are the people who determine whether behavior adheres to the organization's norms and set sanctions on those who violate those norms.
3. *Culture makes leaders trustworthy.* Being part of the corporate culture can serve to make leaders trustworthy. Followers follow because they trust the leader to share their concerns and interests (see, e.g., Rotemberg and Saloner 1993).
4. *Leaders are change agents.* Along the lines of the first point, but somewhat contrary to the previous one, leaders are those who can break from an existing culture and lead an organization to a new way of doing things; that is, leaders can be "change agents" (what Burns [1978] refers to as "transforming leaders"). "How-to" books often focus on this role (e.g., Kotter 1996).
5. *Asabiyyah.* The effectiveness of the leader may depend on the strength of the corporate culture. One version of this idea was set forth by Ibn Khald  n, the 14th century North African historian, who argued that a group's success depended on its *asabiyyah* or "group

5. There are numerous business school cases on the role played by Mr. Kelleher in building Southwest's culture. See also the chapter on Mr. Kelleher in Pandya et al. (2004: 21–46).

feeling,” and the leader who can best harness a group’s *asabiyyah* will be the most successful (Ibn Khaldūn 2004).

2. Leadership

Leadership should be seen as a phenomenon distinct from authority or the exercise of some office or title. The defining feature of leadership is that a leader is someone with *voluntary* followers. A central question is, therefore, why do they follow? What is it that leaders do that make followers want to follow? Before turning to these questions in Section 2.2, it is worth considering the notion of “voluntary” a bit further.

2.1. How Voluntary Is Voluntary?

2.1.1. Psychological Predispositions

It is possible that followers follow, at least in part, because of a psychological predisposition to be a follower. Such a predisposition could represent learned behavior. For instance, as children, we are taught to follow instructions, and we may consequently become predisposed to follow orders. An objective of military drilling and discipline is to impose a reflexive response to orders (see, e.g., Akerlof and Kranton [2005] on West Point).

Additionally, a psychological predisposition to be a follower could be innate. One of the few economic articles to take a behavioral approach to “followership” (Huck and Rey-Biel 2006) explicitly assumes that followers have a desire to conform; that is, they have an inherent distaste for choosing actions that are different from those of others.

One reason that following could, to an extent, be innate is that humans are primates and primate social groups typically possess dominance relations (de Waal 1998; McFarland 1999). To be sure, the alpha male of a chimpanzee tribe is not a leader in the sense meant here; such males coerce, rather than induce, a following through actual or threatened violence. Nevertheless, being able to assume subordinate status when necessary is a critical survival skill.⁶ Therefore, it is possible that many of us are predisposed to take a subordinate status in social groupings even subconsciously.⁷ Certainly, there is evidence that we respond to many nonverbal cues with respect to who we tend to follow as leaders (e.g., age, height, gender).⁸

2.1.2. Fear of Sanctions

In normal parlance, voluntary means without compulsion or duress; that is, freely decided. However, as members of a profession that has ruled out the free lunch, we know that there are trade-offs in most decisions, and presumably that applies to following the leader. If, for instance, I disregard the PTA president’s request to participate in a school clean-up day, then there are

6. This skill is critical both because young males typically are not in a position to challenge for leadership (de Waal), so must bide their time, and because even subordinate males can find mating opportunities if they are crafty (Sapolsky 2005).

7. To be more accurate, we likely have a predisposition to grasp social structures and hierarchies and to slot ourselves into them accordingly. It has been argued that the relatively large and sophisticated brains of primates are the consequence of an evolutionary arms race to outsmart others in social settings (see, e.g., Sapolsky 2005).

8. See, for example, House and Baetz (1979) for a discussion of such leadership attributes.

likely some adverse consequences, such as having her speak poorly of me or having her be less responsive to my suggestions for PTA activities.

In other words, rarely, if ever, is a leader without recourse to sanctions against followers who fail to follow her lead. A distinction, however, exists between circumstances in which the power to sanction comes with the office (e.g., a military officer has the right to demand punishment for insubordination, a manager can dismiss a disobedient worker) and circumstances in which the power to sanction arises because other followers will carry out sanctions imposed by a leader (e.g., agree to treat a disloyal follower as an outcast). The power of, say, a PTA president to sanction me for not participating in a PTA activity arises not from her office but is granted her by her followers, who effectively agree they will apply a social stigma to me at her behest. Consequently, if they lose faith in her leadership—they conclude, for example, that she is acting like a martinet—then her power to impose sanctions is also lost. In contrast, the power of my commanding officer to sanction me is essentially independent of what my fellow subordinates think of her leadership.⁹

Some of the most dramatic examples of a leader being granted social-sanctioning power can be seen among teenaged girls, where cliques (sometimes called “posses”) form around a leader, the “queen bee” (Wiseman 2003).¹⁰ The queen bee’s ability to sanction members of her posse is wholly a function of the power over them that the other girls grant the queen bee. Similar phenomena no doubt exist in gangs and other voluntary groupings. Queen bees also illustrate a particularly important dynamic by which a leader obtains power: The leader is bestowed by her followers with the power to determine who is in—that is, who obtains the benefits of membership—and who is out.

It has long been known that the power to exclude (by labeling or outright ostracizing) is a strong form of control, particularly with regard to discipline within prestigious “in groups” (Becker 1963; Goffman 1963; Erikson 1966; Goode 1978; Sidanius and Pratto 1999). To an extent, this power has recently been recognized in economics (Kandel and Lazear 1992; Bowles and Gintis 2004; see also the survey articles Hermalin 2001; Akerlof and Kranton 2005), although it would also be fair to say this is an area where further work would be productive. Yet the question of why members of a group would bestow this power on a leader has, to the best of my knowledge, been largely ignored. Certainly in the economics literature, social sanctions have been modeled in a leaderless fashion (e.g., Kandel and Lazear 1992; Kandori 1992; Bowles and Gintis 2004).

2.2. What Do Leaders Do?

So what is it that leaders do? There are many ways that question can be answered, as, in part, evidenced by the large number of books on leadership that have been written over the years. For the purposes of this chapter, I divide what leaders do into three categories with, admittedly, considerable overlap:

9. Although perhaps not completely independent; in extreme circumstances (e.g., those depicted in the *Caine Mutiny*; Wouk 1951) the loss of faith by all subordinates can preclude an officer from sanctioning insubordination by any one.

10. See Lohéac (2005) for an economic study of this phenomenon.

1. Leaders serve as judges.
2. Leaders serve as experts.¹¹
3. Leaders serve as coordinators.

This list is not exhaustive. Other leadership activities are not covered here:

4. Leaders are symbols. This has two meanings. First, the leader can be a living representation of the group, so that the honors she receives provide positive utility—basking in the glory—for followers and the dishonors she suffers harm followers (e.g., cause anger or shame). Second, the leader symbolizes the group's ideals with respect to beliefs and deportment. In essence, the leader exemplifies the norms of the group.¹² This second meaning overlaps with the idea of leaders as experts.
5. Leaders are shapers of preferences. In standard theory, preferences are fixed. Yet preferences must, ultimately, come from somewhere, and it seems logical that they derive in part from the actions of others (e.g., what we are fed as children, or the music our parents play). It is plausible, therefore, that a person with a strong personality—a charismatic leader—will influence the preferences of others.¹³ But proving this idea, if true, is difficult: We observe behavior, not motives. So, for example, does seeing a hero do something make one inherently wish to do it? Or does it simply signal that one gains more status from doing so than previously thought?¹⁴

2.2.1. Leaders as Judges

Within an organization or group, a leader can serve as a judge; that is, she is the arbiter of disputes and the determiner of sanctions.¹⁵ This is not to say all informal judges are leaders; nevertheless, there is a tendency to have a leader serve as the group's judge. For instance, in days gone by, Eastern European Jews would call on their local rabbi to settle disputes.¹⁶

There are a number of reasons a single individual would be selected to be the group's judge:

- Predictability. When the judge is known *ex ante*, there is less uncertainty and risk about how cases will be resolved than if the judge were to be chosen at random.
- Reputation building. A group presumably wants a judge who is impartial or incorruptible. Depending on the benefits of being a judge (leader), an individual might wish to establish

11. For an interesting—if perhaps limited—empirical assessment of leaders as experts, see Goodall et al. (2011).

12. Pfeffer (1981) makes a similar point.

13. To the extent that others teach us about our preferences (e.g., help us learn we like sushi by taking us to a Japanese restaurant), the shaping-of-preferences role overlaps with the expertise role.

14. In an earlier survey, Hermalin (2001: 258) referred to this as the “directive versus internalization issue.” It is a debate to which I return later. See also Kreps (1997).

15. Interestingly, the section of the Bible that presents the history of the Israelites in the period between Exodus and the Davidic dynasty, a period when the Israelites had informal leaders, is called *Judges*.

16. Although the rabbi held an office and, thus, his judicial powers might, in part, be seen to come from that, it is also true that (1) the rabbi had no authority by which to enforce his decisions, and (2) the parties could, in some circumstances, have selected another arbiter, such as the secular courts.

a reputation for impartiality and incorruptibility. Reputation building, however, requires frequent repeat play, which is an argument for bestowing the judgeship on a single individual.

- Efficient division of labor. If there are economies of scale or scope in being the judge, then it could be most sensible to have only one individual make the relevant investments.
- Avoidance of free riding. If no one were responsible for monitoring behavior and passing judgment on it, then it would be the group's responsibility, which could lead to free-riding problems if group members shirked their responsibilities.

From the earlier discussion of queen bees, for instance, it is clear that leaders frequently play a role as a group or organization's judge. This judicial role is also an important way in which the organization's culture is transmitted, because followers infer the cultural norms from the leader-judge's decisions (see the discussion in Schein 1992: 228–253; this also relates to labeling theory: Becker 1963). Yet why a single leader is necessary or how followers empower her with this authority is less well studied. It is to be hoped that the four possibilities listed above will eventually be fleshed out by future research.

2.2.2. *Leaders as Experts*

One reason to follow a leader is that you believe the leader knows better than you what should be done. This is what I mean by the *leader as expert*. There are three ways in which a leader can be an expert: (i) she is endowed with the relevant expertise; (ii) she undertakes an activity to learn the relevant knowledge; and (iii) she defines what is the truth. The last of these refers to situations where the leader is a lawgiver (e.g., in a religious sense or by defining the corporate culture). One might argue that this third way is subsumed by the first two. A devout person would certainly argue that religious lawgivers were given their knowledge by a higher authority. Alternatively, lawgivers use their expertise to derive laws (customs, norms, etc.), where their expertise has been endowed previously or results from their actively acquiring the relevant knowledge. Yet, to the extent there is no clear rationale for a law (e.g., Deuteronomy 22:11, the prohibition on wearing wool and linen together), its purpose being only to divide adherents from nonadherents, this third category of expertise could be considered separate from the first two.¹⁷

2.2.3. *Leaders as Coordinators*

Many organizational issues can be modeled as games, and games often have multiple equilibria. A role, therefore, for the leader could be to select the equilibrium to be played. Consider, for instance, the game in Figure 1. It has three Nash equilibria: both players play A as pure strategies, both play B as pure strategies, and a mixed-strategy equilibrium. Total expected welfare is,

17. A law such as Deuteronomy 22:11 is known as a *chok*. *Chukim* (plural of *chok*) are rules that are seen by commentators on the Torah (e.g., Talmudic scholars) as having apparently no rational justification. A less religious example would be the requirement that once existed that IBM salesmen wear white shirts. Harris (1978) suggests that one justification is to maintain group integrity by brightening the line demarcating in-group from out-group. This interpretation is bolstered in the case of Deuteronomy 22:11, given that book was written in a time of conflict between two priestly castes (Friedman 1997). Such a *chok* could have served to distinguish one side from the other (and give one side a better claim to righteousness).

	B	0, 0	2, 2

Figure 1. A coordination game.

respectively, 6, 4, and 12/5 across these equilibria. Clearly, it behooves the players to coordinate on the first. A leader could announce that players are to play A. Given that a Nash equilibrium is a self-enforcing contract—that is, the followers would have an incentive to voluntarily follow the leader's direction—this should be sufficient to ensure that the A-equilibrium is played.¹⁸

It is also conceivable that the leader can cause coordination when coordination is not necessarily warranted by starting an informational cascade or causing herding (Banerjee 1992; Bikhchandani et al. 1992; Smith and Sørensen 2000).¹⁹ For instance, in network economies, the technology adopted in equilibrium will depend heavily on the behavior of early adopters (Katz and Shapiro 1986). In situations in which the leader is wrong or when more heads are better than one (i.e., private signals should be shared), the group can readily end up conforming to a standard or to actions that are not optimal. As an extreme example, suppose that members of an organization must choose between two options (e.g., a word-processing program, or how to treat customers), each of which is equally likely *ex ante* to be the correct option. Imagine the population is divided between those with information relevant to choosing the right option and those without. If the first person who chooses is known to be at least as knowledgeable as anyone else and his choice is more likely to be correct than wrong, then his choice will determine the organization's choice; that is, everyone will follow his lead.²⁰ The probability that the leader's information is correct thus becomes the probability the organization makes the correct choice. If, however, the organization could have polled people before choices were made, then the organization's probability of making the correct decision would be greater.²¹

18. Other arguments for why the A-equilibrium would be played include that a Pareto-optimal equilibrium is focal and the money-burning argument of Dekel and Ben-Porath (1992).

19. Chamley (2004) is a good introduction to this literature.

20. A given follower can believe, when it is his turn to choose, the common choice of those who went before is wrong with no more than probability 1/2 (and typically less). Even if it is 1/2, if there are network effects or he breaks ties by following the consensus, he will follow suit.

21. Assume $2M + 1 > 1$ informed individuals, each of whom gets a signal that is correct with probability p (assume the signals are independent draws conditional on the truth). Then, under majority rule, the probability the group would make the correct decision, assuming information could be pooled before any actions are taken, is

$$1 - \sum_{m=0}^M \binom{2M+1}{m} p^m (1-p)^{2M+1-m} > p,$$

where the right-hand side is the probability the correct decision is made absent pooling of information when the group follows the leader. For example, if $M = 20$ and $p = .6$, then collective decisionmaking implies a better than 90% chance of making the correct decision.

2.3. The Economic Analysis of Leadership

2.3.1. *Leading by Example and Sacrifice*

Hermalin (1998) recognizes that followers often face the danger that the leader is tempted to mislead them. Figure 2 illustrates this tension. Suppose the leader knows which state “nature” has chosen. If she would report honestly, the follower would adjust his effort based on her report, working hard if she says the state is good and working “easy” if she says the state is poor. The leader, however, always does better if the follower works hard; thus, she has an incentive to mislead the follower, always claiming the state is good regardless of what it truly is. A rational follower anticipates this, however, and disregards her announcement. If the probability of the good state is less than $1/2$, then a rational follower will always work easy regardless of the leader’s announcement.

The outcome that the follower disregards the leader’s announcement is suboptimal. Welfare would be greater if the leader would announce the state truthfully and the follower could believe her announcement.

The leader gains 3 if she convinces the follower the state is good when it is truly good, but she gains only 1 when she misleads the follower into thinking the state is good when it is not. A convincing signal that the state is good is for the leader to destroy D units of her utility when the state is good, where $D \geq 1$.²² Imposing the Cho and Kreps (1987) intuitive criterion as an equilibrium refinement, the unique equilibrium is the one in which the leader publicly destroys one unit of utility when the state is good, but not when it is bad. The follower responds to this signal by working hard when he sees a unit destroyed and by working easy when he does not. Hermalin (1998) calls this form of leadership *leading by sacrifice*; depending on the circumstances, it may be only one of the ways in which the leader can signal.²³

2.3.1.1. Leading by Example. As noted earlier, leaders often serve as examples. Moreover, their example can be effective because it can serve as a signal that what the leader is advocating (e.g., working hard) is a true reflection of her knowledge. Historical examples include civil rights leaders (e.g., Martin Luther King, Jr. or César Chávez) being at the front of a march or Stalin’s decision to remain in Moscow to lead resistance to the approaching *Wehrmacht*. Presumably these leaders would not have put themselves in danger if they did not truly believe the struggle could be won.

22. It is beyond the scope of this chapter to review signaling fully. Signaling games, first studied by Spence (1973), are games of asymmetric information in which the better-informed party can act so as to convey—“signal”—her information to the less-well-informed party. The classic example (Spence) is a worker who signals her ability to potential employers through the amount of education she gets. An equilibrium of a signaling game is *separating* if the equilibrium actions of the informed player vary with her information (e.g., talented workers acquire more education than less-talented workers). A *pooling* equilibrium is one in which the equilibrium actions of the informed player don’t vary with her information (e.g., all workers get the same level of education). The multitude of equilibria can sometimes be reduced via a forward-induction refinement, such as the intuitive criterion (Cho and Kreps 1987).

23. In Hermalin (1998), the sacrifice went from the leader to the followers. While this affects the welfare analysis of the model, it is not essential to the signaling function of the sacrifice. A real-life example might be a PTA president who springs for simple refreshments for an event as a way of signaling the importance of the event (the refreshments are too simple to constitute a reasonable payment to the other parents; that is, it is the signal, not the desire for a free donut, that gets the parents to participate).

		Follower	
		Work hard	Work easy
Nature	Good state	5 4 2 3	2 3
	Bad state	2 0 1 1	1 1

Figure 2. A leadership game. The leftmost number in each cell is the leader's (i.e., not nature's) payoff.

A model of this (Hermalin 1998) is the following: a team has N identical individuals indexed by n . Each simultaneously supplies effort. The value to the team of these efforts is $V = \theta \sum_{n=1}^N e_n$, where $\theta \in [0, 1]$ is a stochastic productivity factor realized after efforts, the e_n s, have been supplied. Individual n 's utility is $w_n - e_n^2/2$, where w_n is his payment.²⁴

Assume, keeping with Holmström (1982), that although contracts can be written contingent on V , they cannot be written contingent on the individual team members' efforts. Assume, too, that contracts cannot be contingent on θ directly. Credible contracts must be balanced (i.e., pay out exactly V in total to the team members). Given these conditions, there is no loss of generality in restricting attention to the following contracts: individual n is paid $s_n(\hat{\theta})V + t_n(\hat{\theta})$, where $\hat{\theta}$ is a possible announcement about the value of θ ; $\sum_{n=1}^N s_n(\hat{\theta}) = 1$ for all $\hat{\theta} \in [0, 1]$; and $\sum_{n=1}^N t_n(\hat{\theta}) = 0$ for all $\hat{\theta} \in [0, 1]$. Ruling out negative shares (i.e., $s_n < 0$ for some n), it can further be shown that, if all team members hold the same belief about θ , then the optimal contract is an equal-shares contract: $s_n(\hat{\theta}) = 1/N$ for all n and $\hat{\theta}$.²⁵

Let $\tilde{\theta}$ denote the expected value of θ given common beliefs. Then each team member maximizes

$$\frac{\tilde{\theta}}{N} \left(e_n + \sum_{j \neq n} e_j \right) + t(\hat{\theta}) - \frac{e_n^2}{2}. \quad (1)$$

The cross-partial derivative of (1) with respect to $\tilde{\theta}$ and e_n is positive; hence, an individual's effort is increasing in his expectation of θ under an equal-shares contract.

Make one of the team the leader, and suppose she is endowed with knowledge of what θ will be. This is her private information. Suppose, hypothetically, that she truthfully announces what θ will be. Then all team members would be symmetrically informed. The optimal contract would thus be equal shares, and the effort of a follower, $e(\hat{\theta})$, would be increasing in the leader's announcement of θ , $\hat{\theta}$ (because the followers are identical, the subscript n can be dispensed with). The only question, then, is would the leader announce truthfully? Her utility is

$$\frac{\theta}{N} \left((N-1)e(\hat{\theta}) + e_L \right) + t_L(\hat{\theta}) - \frac{e_L^2}{2}, \quad (2)$$

24. Hermalin (1998) assumes a more general disutility of effort function than $e^2/2$.

25. See the discussion in Hermalin (1998) for why negative share contracts can be ruled out.

where L indexes the leader. Suppose that $t_L(\hat{\theta})$ is a constant. Then the leader does best to make $e(\hat{\theta})$ as large as possible regardless of the true value of θ . Hence, the leader would always announce the maximum value of θ . The hypothesis that she will tell the truth is false.

Of course, rational followers understand this. Hence, if $t_L(\hat{\theta})$ is a constant, then they will rationally disregard the leader's announcement and always choose effort $e(\bar{\theta})$, where $\bar{\theta} = E\{\theta\}$, where E is the expectation operator. Hermalin (1998) shows it is inefficient for the followers not to base their effort on the true value of θ ; hence welfare would be improved if the leader could be given an incentive to tell the truth.

One way around this problem would be leading by sacrifice. From (2), this would require making $t_L(\hat{\theta})$ vary in such a way as to provide the leader an incentive to tell the truth. It can be shown that she will tell the truth if

$$t_L(\hat{\theta}) = T - \int_0^{\hat{\theta}} z \frac{N-1}{N} e'(z) dz, \quad (3)$$

where T is a constant and $e(\cdot)$ is a follower's optimal response function to a truthful revelation of θ (proposition 3 of Hermalin 1998).

The focus here, however, is on leading by example. To that end, set $t_n(\hat{\theta}) \equiv 0$ for all n and $\hat{\theta}$. Furthermore, suppose that the leader can choose her effort before the rest of the team in a way that is observable to them (but not verifiable). From (2), the leader has a greater incentive to raise her effort the greater is θ . Consequently, her choice of effort—her example—can serve as a signal to her followers. To begin, consider the contract

$$s_L = \frac{1}{1 + N(N-1)} \quad \text{and} \quad s_n = \frac{N}{1 + N(N-1)} \quad (4)$$

for $n \neq L$. It can be shown that under this contract, the equilibrium is for the followers to mimic the leader; that is, choose the same effort level that she does. Moreover, aggregate expected welfare is greater under this contract than under optimal leading by sacrifice or symmetric information.

The welfare gain from leading by example is a demonstration of the theory of the second best. Because the followers make inferences about θ based on the leader's effort, the leader's effort serves as a signal of the state. In particular, the harder the leader works, the harder the followers will work. This gives the leader an additional incentive beyond that generated by her share of the value created. In fact, her incentives are sufficiently increased that the team can reduce her share, thereby increasing the shares (incentives) for the other workers. Consequently, each member of the team works harder than under symmetric information. Because the free riding endemic to teams means too little effort to begin with, inducing harder work is welfare improving.²⁶

As it turns out, (4) is not the welfare-maximizing contract. The general formula for the welfare-maximizing contract is lengthy and not worth repeating here. It can be shown that the

26. A related reasoning lies behind Zhou (2011), which explores how information should flow through an organization. If credible transmission of information can only be by example and the organization can control who sees whose actions, then the organization can boost all but one team member's effort by having each team member set an example for one follower, who then sets an example for the next follower, and so forth.

leader's share is decreasing in N but is bounded below by a positive constant. Consequently, in small teams ($N \leq 6$), the leader's share is less than that of any of her team members if the objective is to maximize welfare; but in large teams ($N \geq 7$), her share is greater.

If, for some reason, the team were required to have equal shares, it is still true that leading by example is welfare superior to symmetric information or leading by sacrifice (proposition 6 of Hermalin 1998). Again, this is because the need to set an example provides the leader extra incentives to supply effort.

2.3.2. More on Leaders Conveying Information: Extensions of the Hermalin Model

2.3.2.1. Repeated Leadership Games. A drawback to Hermalin (1998) is that it is a one-shot model, whereas leadership is often a repeated phenomenon; today's leader tends to be tomorrow's as well. As is well known from the theory of repeated games, behavior that is unsupportable in the equilibrium of a one-shot game can often be supported in a repeated setting. In particular, could a leader simply develop a reputation for truthful announcements in a repeated game?

Hermalin (2007) addresses some issues that arise when the one-shot game of Hermalin (1998) is infinitely repeated.²⁷ The same leader plays in all stage games, but the followers are new in each stage game. Each generation of followers knows, however, the history of the game prior to it; in particular, the time t generation knows the realizations of θ in the first $t - 1$ periods, and it knows the leader's announcements of θ in those periods.²⁸ There is no correlation in the productivity parameter, θ , across periods.

To begin, assume there is no scope for the leader to signal. Hence, if her reputation for making honest announcements about θ is ruined, play reverts to infinite repetition of the equilibrium of the one-shot announcement game. In that game, talk is cheap, so the equilibrium is a garbling one in which the followers ignore the leader's announcement. The threat of such reversion is most effective at keeping the leader honest when uncertainty about θ is greatest—an equilibrium with honest announcements exists for a wider range of parameters the greater is the uncertainty about θ . Intuitively, if there were little uncertainty about θ , then the leader's gain from honesty is relatively small—the followers essentially know what θ will be anyway. When, however, uncertainty is large, considerable surplus—some of which would go to the leader—is lost when the followers do not know θ and thus, their efforts tend to be highly inefficient.

Now suppose the leader can signal if she wishes. This changes the equilibrium of the one-shot stage game; it is now one in which the followers adjust their efforts to the state, but only because the leader has engaged in signaling that is costly to her. Because a distrusted leader needs to signal in the good state only, her loss from a tarnished reputation is increasing in the probability of the good state. Consequently, an equilibrium of the infinitely repeated game in which the leader is truthful (and does not signal) is sustainable for a wider range of parameters the greater is the probability of the good state.

The followers, as well as the leader, benefit if they know the true state. They have an incentive, therefore, to pay the leader for being truthful. Indeed, in real life, followers often bestow tribute

27. In Hermalin (2007), attention is limited to equal-share contracts, and the state space is the binary set $\{\theta_0, \theta_1\}$, $\theta_1 > \theta_0 > 0$.

28. The assumption of short-lived followers avoids issues of cooperation in the teams problem. Hermalin (2007) offers some economic justifications for this assumption.

on their leaders.²⁹ Tribute can be financial, in kind, or emotional. In a one-shot game (e.g., Hermalin 1998), tribute would never be paid, because there is no way to contract on the truthfulness of the announcements. But once the game is repeated, the followers can make future tribute contingent on past honesty and thus can effectively contract on truthfulness (for details, see Hermalin 2007).

Tribute is especially effective in supporting honest leadership when tribute costs the followers nothing (e.g., tribute is the prestige of office). In this case, the followers' incentive constraint to pay tribute is trivially met. A game with "free" tribute might be seen as corresponding closest to Weber's image of charismatic leadership.

2.3.2.2. Informational Issues. In Hermalin (1998), the leader's signaling action (i.e., amount of sacrifice or exemplary effort) fully reveals the state (i.e., θ). What would happen if the leader's action only partially revealed the state?

Komai et al. (2007) explores this issue.³⁰ Suppose $e \in \{0, 1\}$ and $\theta \in (0, 1)$. If the leader leads by example, then the followers know only that the state is in the subset of states in which the leader chooses e . Agent n 's payoff is

$$\pi(\theta, e_n, \mathbf{e}_{-n}) = \frac{\theta}{N} \left(\sum_{j=1}^N e_j \right) - ce_n,$$

where $\mathbf{e}_{-n}$ is the vector of actions chosen by the other team members, and $c > 0$ is the cost of effort (participation). The sharing rule is equal shares.

If θ is common knowledge, then $e_n = 1$ if $\theta \geq Nc$ and $e_n = 0$ otherwise. Efficiency, however, requires that $e_n = 1$ if $\theta \geq c$. Full information does not, therefore, yield an efficient solution because of the teams problem.

Assume $\bar{\theta} \equiv E\{\theta\} < Nc$; absent any information, no team member would choose $e = 1$. Critically, assume

$$\frac{1}{1 - F(c)} \int_c^1 tf(t)dt \geq Nc, \quad (5)$$

where $F(\cdot)$ is the distribution function over θ , and $f(\cdot)$ is the corresponding density. Suppose only the leader learns θ , and she publicly chooses her e first. Let θ^e be the followers' expectation of θ based on the leader's action, e . It is not an equilibrium strategy for the leader to play $e = 1$ if and only if $\theta \geq Nc$. If it were, then $\theta^1 > Nc > \theta^0$, and the followers would mimic the leader. Consider the state $\theta = Nc - \varepsilon$, where $\varepsilon > 0$ but small. If the leader deviated and chose $e = 1$ for such a θ , then her payoff would be

$$Nc - \varepsilon - c > 0.$$

29. Max Weber (Gerth and Mills 1946), for instance, considers tribute, either in material or emotional terms, as a principal reward for charismatic leaders.

30. A further exploration, in a somewhat richer model, can be found in Komai and Stegeman (2010).

Zero is her payoff were she to play $e = 0$; hence, for ε small enough, it is not an equilibrium for her to play the strategy $e = 1$ if and only if $\theta \geq Nc$.

In fact, (5) implies an equilibrium exists that achieves full efficiency. In this equilibrium, the leader plays $e = 1$ if $\theta \geq c$ and $e = 0$ otherwise, and the followers mimic her. This is an equilibrium because, if the followers will mimic her, the leader plays $e = 1$ if and only if $\theta - c \geq 0$. Given this rule, $\theta^0 < c$, and

$$\theta^1 = \frac{1}{1 - F(c)} \int_c^1 t f(t) dt \geq Nc.$$

Hence, mimicry is a best response for the followers. This illustrates that there exist scenarios in which it is better for the leader to signal limited rather than full information.³¹

If (5) does not hold, then an equilibrium exists in which the followers play a mixed strategy. Whether the mixed-strategy equilibrium (MSE) is superior to symmetric information depends on the parameter values. This reflects the following trade-off. In the MSE, there is a positive amount of effort for $\theta \in [\hat{\theta}, Nc)$, whereas there is none under symmetric information. But the amount of effort is less in the MSE when $\theta \in [Nc, 1)$ than under symmetric information.

In Hermalin (1998), the asymmetry of information has no impact ultimately on the teams problem with respect to the followers' effort.³² In contrast, in Komai et al. (2007), by preventing full revelation of the state, the followers are induced to work harder than they would were the leader's action to reveal the state fully. In the Komai et al. setup, there is thus a benefit to keeping information from the followers; an organization could have a motive to limit the amount of information the leader can credibly communicate.

2.3.2.3. Sequential Provision of a Public Good. Hermalin (1998) provides insights about the private provision of a public good. Briefly, rather than efforts, imagine the team members are donating to a public good. One donor knows the marginal value of a donation. Having her make her donation first and publicly—leading by example—improves welfare both vis-à-vis the situation in which θ is unknown and vis-à-vis the situation in which it is known to all donors.

This observation suggests an explanation for the real-world phenomenon of fund raising campaigns being launched with a large public donation by a well-respected individual and then followed up by solicitations of others. Absent an information story, it is difficult to explain this pattern of sequential donation: theory predicts that, under symmetric information, sequential donating raises less than simultaneous donating (Varian 1994). The issue of informational signaling by lead donors has been further studied by Vesterlund (2003) and Andreoni (2006).

The private-provision-of-public-goods interpretation of Hermalin (1998) lends itself well to experiments. Experiments have generally found support (see Gächter and Renner 2003; Potters et al. 2005, 2007; Gächter et al. 2010) for the leading-by-example model, although some experimental work (Meidinger and Villeval 2002) suggests that it is not signaling that is being

31. In a very different modeling context, Blanes i Vidal and Möller (2007) reach a different conclusion, at least with respect to a self-confident leader. They argue that a self-confident leader fares better in a transparent organization.

32. Assuming the shares are not optimally adjusted; but even then, information creates no changes in the incentives of the followers given their shares.

observed but reciprocity (e.g., as suggested by Rabin 1993). Methodological issues in Meidinger and Villeval—specifically, the use of repeated interactions between leader and follower—make their analysis less than definitive insofar as they could be observing the truth-telling-with-no-signaling equilibrium of Hermalin (2007).

2.3.2.4. Choice of Leader. Recently, economists have turned to the question of which group member becomes the leader (Kobayashi and Suehiro 2005; Andreoni 2006; Huck and Rey-Biel 2006). The first two develop models based on Hermalin (1998). The third utilizes a different model and is discussed later.

Andreoni adds a stage prior to the beginning of the Hermalin (1998) game in which, by expending c , any team member can learn θ . Andreoni limits attention to the case of small c : not only is it socially optimal to expend c , but it is also privately optimal for any given individual to invest it if she knew the alternative was she invests or no one invests. The problem is that, absent any compensation mechanism, each team member would prefer that someone else make the investment. This is both because each team member wishes to avoid paying c and because, absent an adjustment in shares, the leader does worse than her followers under either leading by example or leading by sacrifice. For the public-goods problem in Andreoni, it makes sense to suppose that the other team members (the rest of society) can neither compensate an individual for expending c nor adjust shares so as not to be disadvantageous to the leader.

In Andreoni's (2006) model, the goal is a mechanism to coordinate on the leader. Absent such a coordination, the outcome will be inefficient with positive probability; either no one will invest or more than one person will invest.

Consider a simple model based on Andreoni's. The utility function is the same as (1) in Section 2.3.1. Assume there is a single moment in time at which anyone can buy the signal. Like Andreoni, limit attention to equal shares.

Assume, first, that if θ is learned by anyone, then it is honestly shared with all. That is, the problem is solely one of coordination. Absent coordination on who is to be leader, the team members play a mixed-strategy equilibrium. The equilibrium symmetric mixed strategy is to spend c with probability p and to not spend with probability $1 - p$. The total expected social loss vis-à-vis a situation in which there was coordination is $(N - 1)c$. Intuitively, relative to a situation of coordination, $N - 1$ team members are taking independent gambles with an expected loss of c , so the expected welfare loss must be $(N - 1)c$.³³

This loss is increasing in N and equals the welfare loss (relative to coordination) that would result if everyone collected the information with probability 1.

Clearly, there is a social benefit to leadership, and it is increasing in the size of the group. Presumably, when feasible, the group will therefore wish to coordinate on a leader. Although each individual would, in this setting, prefer someone else be the leader (i.e., let someone else incur

33. An individual's expected loss if no information is obtained vis-à-vis if it were obtained is

$$\text{Var}(\theta) \frac{2N - 1}{2N^2}.$$

So an individual is willing to mix if

$$c = (1 - p)^{N-1} \text{Var}(\theta) \frac{2N - 1}{2N^2}.$$

c), no individual would shirk leadership if appointed. If followers believe the appointed leader will collect the information, then they have no incentive to do so themselves. The appointed leader will, therefore, have a strict incentive to collect the information.

What if the information collected by the appointed leader cannot be honestly and freely transmitted to the followers, so she faces the problem in Hermalin (1998)? Would the leader have an incentive to save c by not collecting the information and simply playing as if she had collected it? The answer is no, at least if c is small enough. A leader who does not collect information when expected to by followers is in exactly the same situation as a leader who has observed the mean value, $\bar{\theta}$. Signaling is fully revealing, so the followers each expend effort $\bar{\theta}/N$, where $\bar{\theta}$ is their belief about θ . Let $\Pi(\theta, \bar{\theta})$ be the leader's payoff if the true state is θ and everyone believes it to be $\bar{\theta}$. Under signaling by sacrifice, the leader's payoff is then

$$\Pi(\theta, \bar{\theta}) = \frac{\theta}{N} \bar{\theta} - \int_0^{\bar{\theta}} \frac{z(N-1)}{N^2} dz - \frac{\bar{\theta}^2}{2N^2}$$

if she has not learned the state (but is expected to have) and

$$\Pi(\theta, \theta) = \frac{(2N-1)\theta^2}{2N^2} - \int_0^{\theta} \frac{z(N-1)}{N^2} dz$$

if she has learned the state. The leader, therefore, has an incentive to learn the information if and only if

$$c \leq E \left\{ \Pi(\theta, \theta) - \Pi(\theta, \bar{\theta}) \right\} = \frac{N}{2N^2} \text{Var}(\theta).$$

A similar result can be shown to hold when signaling is leading by example.

Although it is clear that the team should coordinate on a leader, it is worth returning to the question of who might arise endogenously as the leader. To study that, return to the assumption that the leader reveals what she learns truthfully and costlessly (i.e., she need not signal). If all group members are identical, then the analysis is not particularly illuminating, so assume that each team member n has a unique cost of information acquisition, c_n . Were the team able to coordinate on a leader, efficiency would dictate that the leader be the member with the lowest c . Assume, however, no ex ante coordination is possible, and consider the mixed-strategy equilibrium. A team member is willing to mix when his cost of obtaining the information equals his expected loss if he does not, namely, the probability that no one else obtains the information times the expected loss from not having the information:

$$c_n = \text{Var}(\theta) \frac{2N-1}{N^2} \times \prod_{j \neq n} (1 - p_j). \quad (6)$$

The solution to this system of equations can be expressed as

$$\log(1 - p_n) = \frac{1}{N-1} \sum_{j \neq n} \log \left(\frac{c_j N^2}{\text{Var}(\theta)(2N-1)} \right) - \frac{N-2}{N-1} \log \left(\frac{c_n N^2}{\text{Var}(\theta)(2N-1)} \right).$$

Surprisingly, the equilibrium probability that a given team member obtains the information is increasing in his own cost and decreasing in the other team members' costs. Intuitively, from (6), for a player to mix, he must be indifferent between the cost of obtaining the information and the expected cost of not doing so. If the former goes up, then the latter must also, if he is to remain willing to mix. The latter goes up if the probability that the others will not get the information goes up. To keep the others playing a mixed strategy, it follows that the team member in question must obtain the information with a greater probability.

If c_n is too large, then (6) does not have a solution in which all $p_j \in (0, 1)$; in this case, team member n plays the pure strategy of not obtaining the information. Consequently, the probability of becoming the leader is, first, increasing in the cost of obtaining the information, but then falls to zero. Although counterintuitive, this result is not necessarily at odds with reality. My informal observation of organizations with endogenous leadership (e.g., academic departments, PTAs) suggests that it is the people in the middle of the opportunity-cost-of-time distribution who are the most likely to take the lead on a given issue.³⁴

Kobayashi and Suehiro (2005) consider a different variant of Hermalin (1998). Suppose, now, all team members are endowed with information, but the information is imperfect. Specifically, each team member gets a realization of a binary signal, $s \in \{B, G\}$, where G is good news about the productivity state and B is bad news. Conditional on the true state, each team member's signal is determined independently. Assume a team member can publicly (but not verifiably) expend effort in one of two periods, $t = 1$ or 2 . If a team member knew that his teammates would expend effort at $t = 1$, he does better to wait until $t = 2$, because he then can base his effort on the inferences he draws from their efforts. However, if he knew that his teammates would wait until $t = 2$, then he may wish to expend effort at $t = 1$ if he can convey information that increases their efforts; that is, if he can lead by example.

Among the possible equilibria of the game is one in which a team member who observes $s = G$ expends effort at time $t = 1$ and a team member who observes $s = B$ expends effort at time $t = 2$. In this equilibrium, there is endogenous leadership, insofar as who leads by example (if anyone does) is not predetermined but arises as part of the equilibrium play of the game.

Kobayashi and Suehiro (2005) is a clever attempt to endogenize leadership, but it is not without problems. One is the possibility that both team members attempt to lead by example. Although leadership battles are by no means unheard of, they typically arise when would-be leaders hold different views; not, as in Kobayashi and Suehiro, when they hold the same view. Leadership battles, it should be noted, have not been explored in the economics literature, although they have certainly received considerable attention in other literatures (e.g., Machiavelli [Bondanella and Musa 1979]; Wrong 1995; de Waal 1998).

2.3.3. *The Role of Conformism*

Huck and Rey-Biel (2006) consider the endogenous emergence of leadership in a two-member team. Unlike earlier models, there is no uncertainty about the state of the world; it is commonly known that the value of the team's efforts are $V = 2(r_1e_1 + r_2e_2)$, where r_n is the commonly

34. This observation is consistent with one of my father's sayings: "If you want something done, ask a busy person."

known productivity of team member n . The sharing rule is equal shares.³⁵ Unlike earlier models, team members have a bias, $b_n \geq 0$, toward conformity: team member n 's utility is

$$u_n = \frac{V}{2} - \frac{1}{2}e_n^2 - \frac{b_n}{2}(e_n - e_m)^2,$$

where e_m is his teammate's effort.

Team member n 's best response to e_m is readily shown to be

$$e_n(e_m) = \frac{r_n + b_n e_m}{1 + b_n}. \quad (7)$$

If $b_n = 0$ (i.e., no conformity bias), then $e_n(e_m) = r_n$, the usual result for the teams problem.

Given simultaneous play, the equilibrium is the solution to the simultaneous equations (7):

$$e_n^{\text{SIM}} = \frac{r_n(1 + b_m) + r_m b_n}{1 + b_n + b_m}. \quad (8)$$

Observe that if the biases are the same and the marginal productivities are the same, then the standard solution to the teams problem results; that is, $e^{\text{SIM}} = r$. If the team members' conformity bias is the same, then the greater this common bias, the lower is output (unless bias is irrelevant because $r_1 = r_2$, so the team members naturally choose the same level of effort). Because teams produce an inefficiently low level of output and bias is directly taxing on the team members, it follows that an increase in bias lowers welfare.

Now consider sequential play. One team member leads by choosing her effort first, followed by the other, who chooses his effort after observing the leader's. The follower's response is given by (7). The leader's problem is thus

$$\max_e r_L e + r_f \frac{r_f + b_f e}{1 + b_f} - \frac{1}{2}e^2 - \frac{b_L}{2} \left(\frac{r_f - e}{1 + b_f} \right)^2,$$

where the subscripts L and f refer to the leader and follower, respectively. Algebra readily reveals that the resulting output is greater than the output under simultaneous play (if $b_f > 0$).

If $r_f = r_L = r$ and $b_f = b_L = b$, then welfare is increasing in bias. This result is not surprising: the follower's conformity bias increases the leader's incentives to work hard. Moreover, hard work by the leader increases, via the conformity bias, the follower's incentive to work hard. Given that the teams problem means too little effort, it follows that a conformity bias can increase welfare.

35. Equal shares are not an optimal contract under the usual teams problem if $r_1 \neq r_2$; in that case, optimal shares are

$$s_n = \frac{r_n^2}{r_n^2 + r_m^2}.$$

Because of how leading and following change incentives, the Huck and Rey-Biel (2006) model offers insights on who the leader should be. If the bias parameters are the same, but one worker is more productive than the other, then the leader should be the less-productive team member. If the productivity parameters are the same, but one worker has a greater bias toward conforming, then the less-biased worker should be the leader.

2.3.4. Leadership Styles

Rotemberg and Saloner (1993, 1998) focus not on what leaders do, but how they do it. Specifically, they seek to fit leadership style into models of organizations. The first article considers the effect of an empathetic or participatory leadership; the second deals with the effect of vision. In both, leadership style is taken to be an innate, immutable, and known characteristic of the leader. Because leadership style shapes the leader's behavior, it can serve as a commitment to certain behaviors. The organization can lever that commitment to compensate, at least partially, for an assumed inability to write complete contracts.

To illustrate their ideas, consider a model with a leader and a follower. The follower can incur private cost c to devise a project for the organization to undertake; if he does not spend c , there is no project. Prior to sinking c , the gross profit, π , from the to-be-devised project is uncertain; that it is distributed $F(\cdot)$ is commonly known. Assume $F(0) > 0$ and $E\{\pi\} > c$. Once devised (once c is sunk), the project's π is learned with certainty by the leader and follower. At this point, the leader has the authority to decide either to undertake the project, yielding the organization π , or to forgo the project, yielding it zero. Critically, neither whether the follower has devised a project nor the prospective or actual outcome of the project are verifiable (can serve as a contractual contingency). The leader's decision to undertake the project is, however, verifiable. Thus, a contract can stipulate a payment, w , should the project be implemented. The leader's utility is $\lambda w + (1 - \lambda)(\pi - w)$ if the project is undertaken and zero otherwise, where $\lambda \in [0, 1)$ is the extent to which she is empathetic with the follower (has a participatory leadership style).³⁶ A λ of zero is a pure profit-maximizing ("autocratic") leader. A follower devises a project if and only his expected payment, w times the probability he devises a project the leader implements, exceeds his cost.

In the first best,³⁷ a project is undertaken if and only if $\pi \geq 0$. In the first best, the expected payoff to devising a project is $\int_0^\infty \pi dF(\pi)$, which exceeds $E\{\pi\}$, which exceeds c ; projects should be devised in the first best.

In the actual situation, the leader undertakes a project if and only if

$$\pi \geq \frac{1 - 2\lambda}{1 - \lambda} w. \quad (9)$$

36. The Rotemberg and Saloner (1993) identification of empathy with a participatory leadership style is motivated by studies that show a participatory leadership style exhibits empathetic behaviors (e.g., "solicit opinions, facts, and *feelings* from . . . participants"; House and Baetz 1979: 364 [emphasis added]). See also Gächter et al. (2010) for experimental evidence on the importance of leaders having cooperative dispositions.

37. To be precise, first-best actions are here defined as those that maximize the organization's expected net profit; that is, they maximize the expected value of the difference $\pi - c$. This is a standard welfare measure if $\lambda = 0$ and upfront noncontingent transfers can be made. When $\lambda > 0$, this definition is less obviously the right one.

If $\lambda = 1/2$, then this rule replicates the first-best rule; otherwise—including if the leader is a pure profit-maximizer—the decision is distorted. The follower's expected payment if he devises a project is

$$\bar{W} \equiv w \left(1 - F \left(\frac{1 - 2\lambda}{1 - \lambda} w \right) \right). \quad (10)$$

If $\bar{W} \geq c$, the follower will devise a project, but not otherwise. Depending on $F(\cdot)$ and λ , there may be no w such that the right-hand side of (10) exceeds c . For instance, if

$$F(\pi) = 1 - \exp \left(-\pi - \frac{1}{2} \right), \quad (11)$$

$c = 1/3$, and the leader is a pure profit-maximizer, then no solution exists ($E\{\pi\} = 1/2$ for this example). Welfare with a pure profit-maximizing leader would be zero in this example. Empathetic leadership can help: the first best is always achievable if $\lambda = 1/2$ by setting $w = c/(1 - F(0))$, so the follower has an incentive to invest, and because the right-hand side of (9) is 0, the implementation decision is efficient.

Even if the organization cannot optimize its leader's empathy level (i.e., set $\lambda = 1/2$), continuity implies that some levels of empathy are superior to no empathy. In some situations, even extreme empathy, $\lambda \rightarrow 1$, is superior to no empathy at all. A totally empathetic leader would always implement the project regardless of π or w . Setting $w = c$, the follower has the appropriate incentives to devise a project. For the example in which $F(\cdot)$ is defined by (11), expected net profit is $E\{\pi\} - c = 1/6 > 0$; the organization's expected net profit is greater with a totally empathetic leader than with a purely profit-maximizing leader.

Rotemberg and Saloner (1998) consider the importance of vision, particularly the extent to which an organization benefits from a leader with a contrarian vision.³⁸ Consider the following extension of the previous model.³⁹ Interpret π not as actual profits, but as a signal of expected profits if the project is undertaken. The objective (industry consensus) view is that the signal equals expected profits. The leader, however, is more optimistic and believes expected profits are $\pi + \Delta$, $\Delta \geq 0$. The leader is a risk-neutral profit-maximizer and undertakes the project if

$$\pi + \Delta - w \geq 0. \quad (12)$$

The follower will devise a project if and only if

$$w(1 - F(w - \Delta)) \geq c. \quad (13)$$

If $\Delta = c/(1 - F(0))$, then $w = \Delta$ makes (13) an equality. Moreover, when $w = \Delta$, (12) becomes the first-best rule for maximizing expected profit (objectively). Hence, a visionary

38. Van den Steen (2005) is a model in a similar vein. Van den Steen's work is discussed in Section 3.2.5.

39. Rotemberg and Saloner (1998) deal with how organizations choose among competing strategies and the value of managerial vision with respect to providing incentives to develop multiple strategies. The article's insights into leadership per se, however, are captured by the extension of Rotemberg and Saloner (1993) considered here.

leader with a Δ of $c/(1 - F(0))$ yields the first best (objectively). Continuity implies there is a range of Δ s that do better than a “visionless” leader (i.e., whose $\Delta = 0$). Indeed, if $F(\cdot)$ is given by (11) and $c = 1/3$, then an infinitely optimistic leader ($\Delta \rightarrow \infty$), who yields an expected net profit of $1/6$, is superior to a visionless leader, who yields no profit at all.

From the literature on relational contracts, these outcomes can be sustained given repeated play if a rational autocratic and visionless leader can develop a reputation for playing *as if* she had a $\lambda = 1/2$ or a $\Delta = c/(1 - F(0))$.⁴⁰ From a game-theoretic perspective, a leader with “style” is replicable by a leader who has no style but knows how to play optimally in a repeated setting.

Consequently, examples of successful leadership could fail to prove leadership style matters, but examples of unsuccessful leadership suggest it does matter. Plenty of smart people, who presumably know how to be strategic, have been undone by their poor leadership style. A salient example for economists would be Larry Summers’s effective ouster from the presidency of Harvard due to a problematic leadership style. Professor Summers’s brilliance and ability to think strategically are undisputed. Nevertheless, it would appear in his case that style trumped strategy.⁴¹ Bertrand and Schoar (2003) provide more systematic evidence that leadership style matters; specifically, they find significant and persistent differences in how different managers make decisions and that these differences correlate with individual attributes (e.g., age, education) that might influence managers’ outlooks and beliefs.

2.3.5. Overconfident Leaders

In the variant of Rotemberg and Saloner (1998) presented above, the parameter Δ represented vision. It could, just as readily, represent the degree to which the leader suffers from the cognitive bias of overoptimism. Another well-researched cognitive bias is overconfidence—believing you know more than you really do. Camerer and Lovallo (1999) present experimental evidence and Malmendier and Tate (2005) statistical evidence on the prevalence of overconfidence. Given overconfidence is a prevalent bias among managers (Malmendier and Tate), the obvious question is: Why hasn’t this bias been driven out by rationality? Could it, similar to the overoptimism bias in a Rotemberg and Saloner-like model, be organizationally useful?

Blanes i Vidal and Möller (2007) offer a model in which an overconfident leader can be superior to an unbiased one.⁴² A simplified version of their model is as follows. Initially, nature decides which of two projects, *A* or *B*, is the correct project. Assume the projects are equally

40. For more on relational contracts, see MacLeod (2007) and cites therein.

In an infinitely repeated game or one with an uncertain end, such a reputation is worth establishing if

$$\delta \int_0^\infty \pi dF(\pi) - \delta c - \frac{c}{1 - F(0)} \geq \delta V,$$

where δ is the discount factor and

$$V = \begin{cases} \int_w^\infty (\pi - w) dF(\pi), & w \text{ the smallest solution to (10) for } \lambda = 0 \\ 0, & \text{if (10) has no solution for } \lambda = 0. \end{cases}$$

41. It is not my intention to comment positively or negatively on Professor Summers’s tenure as Harvard’s president. It is, however, objectively true that a significant number of Harvard faculty were upset by his leadership style and that this was a factor behind his having to resign as Harvard’s president.

42. A recent working paper by Bolton et al. (2007) considers the advantage of an overconfident leader in a situation in which coordinating the followers’ actions is important.

likely to be the correct one. A public signal, $s_{\text{PUB}} \in \{A, B\}$, is then realized. Denote the probability that the signal is accurate by p .⁴³ Assume $1/2 < p < 1$. The leader receives a private signal, $s_{\text{PRI}} \in \{A, B\}$, that she cannot share with her single follower. Denote the objective probability that the private signal is accurate by q . Assume $1/2 < q < p$. Note the private signal is less precise than the public one. Once both signals are realized, the leader chooses the project to be undertaken. If she chooses the correct project, then the team produces $2e$, where e is the follower's effort. If she chooses the wrong project, then the team produces 0 regardless of e . As previously, contracts cannot be based on e , and the follower's utility is $w - e^2/2$, where w is his portion of the output. Assume an equal sharing rule between leader and follower. If the follower believes the probability of the leader's having selected the correct project to be b , then he chooses his effort to solve

$$\max_e be - \frac{e^2}{2}. \quad (14)$$

The solution to (14) is $e = b$.

Consider, initially, an objective (unbiased) leader. Because $p > q$, she should choose the project solely on the basis of the public signal. If $s_{\text{PUB}} = s_{\text{PRI}}$ and the follower could learn s_{PRI} , then

$$b = \frac{pq}{1 - p - q + 2pq} > p;$$

so the follower would work harder than if he knew only the public signal. Given that the leader always does better in expectation the harder the follower works, she has, similar to Hermalin (1998), an incentive to always claim her private signal agrees with the public signal. The follower, understanding this incentive, rationally disregards such announcements. The leader's private signal does, however, represent valuable information vis-à-vis the optimal amount of effort for the follower to expend. The leader's inability to communicate her signal credibly thus leads to a loss in team welfare relative to the first best. In this scenario, expected welfare is $W^u \equiv 3p^2/2$.

Now suppose the leader is overconfident: she believes the probability that her private signal is correct is $\hat{q} > p > q$. One can interpret this as her believing that she is better able to assess the market/situation/environment than she truly is. The value of $\hat{q}$ is common knowledge. Because $\hat{q} > p$, she bases her choice of signal on her private information and not the public signal.⁴⁴ Knowing this, the follower assesses the probability of the leader's chosen project being the correct project as

$$b_+ \equiv \frac{pq}{1 - p - q + 2pq}$$

if the chosen project agrees with the public signal and

$$b_- \equiv \frac{q(1 - p)}{p + q - 2pq}$$

43. That is, $p = P\{s_{\text{PUB}} = X \mid X \text{ is the correct project}\}$.

44. If you are worried that I just pulled a fast one, don't; I tidy things up in the next paragraph.

if the chosen project disagrees with the public signal. Observe that an overconfident leader credibly communicates her private signal, albeit at the cost of potentially acting on the wrong signal. Expected team welfare (using objective probabilities) is

$$W^o \equiv 2pqb_+ - (1 - q - p + 2pq)\frac{b_+^2}{2} + 2(1 - p)qb_- - (q + p - 2pq)\frac{b_-^2}{2}.$$

There exist values of p and q such that $W^o > W^u$; the team is better off with an overconfident leader than an objective leader for those values.⁴⁵

The preceding analysis presumes naïveté on the part of the leader; specifically, she chooses the project on the basis of her private signal without regard for how the follower will respond. If q is also common knowledge,⁴⁶ then the leader realizes $b_+ > b_-$, and she may therefore have an incentive to deviate from relying solely on her private signal when it disagrees with the public one. This incentive exists only if

$$\frac{\hat{q}(1 - p)}{p + \hat{q} - 2p\hat{q}} b_- < \left(1 - \frac{\hat{q}(1 - p)}{p + \hat{q} - 2p\hat{q}}\right) b_+. \quad (15)$$

Hence, the above equilibrium exists if (15) does not hold, which is to say

$$\hat{q} \geq \frac{p^3 + p^2q - 2p^3q}{1 - 3p + 3p^2 - q + 4pq - 4p^2q} \quad (16)$$

(the right-hand side of (16) < 1 given $p < 1$). For example, if $p = 0.85$, $q = 0.82$, and $\hat{q} = 0.95$, then the leader would rely solely on her private signal in equilibrium, and this would yield greater expected welfare than having an objective leader.

Although overconfidence can be an asset, it can also be disastrous given different parameter values (expected welfare, e.g., is reduced if $p = 0.85$, $q = 0.75$, and $\hat{q} = 0.95$), a point also recognized by Blanes i Vidal and Möller (2007). From Sophocles's *Oedipus Rex* to the political fallout from the Iraq war, literature and history are replete with examples of leaders brought low by their overconfidence (hubris). Literature and history, of course, are also replete with examples of bold leaders who triumphed against the odds. It may well be that overconfidence is neither a virtue nor a vice, but simply increases the variance of outcomes vis-à-vis those achieved by objectively correct leaders.

This last point can be illustrated from some work of mine in progress. Consider the simultaneous-play game shown in Figure 3. Two leaders are squaring off in a variation of a hawk-dove game. Assume the payoffs in the bold-bold cell arise as follows: In any conflict, one side triumphs and gains 1, and the other is crushed and loses 5. The objective probability of

45. For example, if $p = 0.85$, then $W^o \geq W^u$ for all $q \in (0.817, 0.85)$. The shortness of that interval is, in part, a function of the production function used to illustrate the model; other production functions can yield larger intervals.

46. Subtle issues arise if we assume that both q and $\hat{q}$ are common knowledge, and these issues are somewhat contentious in economics; see, for example, Gul (1998) and the response of Aumann (1998). I will, however, pass over these subtleties here.

		Column leader	
		Bold	Timid
Row leader	Bold	-2 -2	1 0
	Timid	0 1	0 0

Figure 3. A hawk-dove-like game.

		Less able leader	
		Bold	Timid
Abler leader	Bold	-1 -3	1 0
	Timid	0 1	0 0

Figure 4. The misperceived game.

being the triumphant side in such a conflict is $1/2$. In a world of objective leaders (i.e., who know the probability of triumph is $1/2$), the unique evolutionarily stable equilibrium is the mixed-strategy Nash equilibrium in which each leader is bold with probability $1/3$ and timid with probability $2/3$. Payoff variance is $2/3$.

Now suppose a proportion μ of all leaders hold the following objectively incorrect beliefs: (i) some leaders are more able than others; (ii) they themselves are such leaders; and (iii) when equally able leaders are in conflict, the probability of triumphing is $1/2$, but an abler leader against a less-able one triumphs with probability $2/3$. Such an overconfident leader thus believes if he plays against an abler leader, then the game is as shown in Figure 3; but it is as shown in Figure 4 if he plays against a less-able leader. Assume that μ is common knowledge, as are the beliefs of overconfident leaders and objective (unbiased) leaders.⁴⁷ Assume that when leaders are paired off to play the game, they do not know whether their opponent is overconfident or objective.

Let p_t be the probability that a type t leader is bold, $t \in \{o, u\}$ (overconfident or unbiased, respectively). The unique symmetric (in leader type) Nash equilibria are

$$p_o = \frac{1}{3\mu} \quad \text{and} \quad p_u = 0 \quad \text{if } \mu \geq \frac{1}{3},$$

$$p_o = 1 \quad \text{and} \quad p_u = \frac{1 - 3\mu}{3(1 - \mu)} \quad \text{if } \mu < \frac{1}{3}.$$

47. Again this assumption creates subtle issues. In this model they could be avoided when $\mu \geq 1/3$ by making the structure of the game common knowledge among the objective leaders, but having the overconfident leaders hold a fourth belief that less-able leaders are always timid.

Figure 5. Compound lottery. Given equilibrium values of p_o and p_u , probability of playing bold is $1/3$ and that of playing timid is $2/3$.

It is worth noting the equivalence of this game to one in which all leaders are unbiased, but they execute their mixed strategies according to the compound lottery shown in Figure 5. It follows that each type of leader has an equilibrium expected payoff of 0, so a leader neither suffers nor gains from being overconfident. It further follows that these equilibria are evolutionarily stable. In particular, overconfidence is neither evolutionarily advantaged nor disadvantaged. If σ_t^2 is the payoff variance for type t , it follows that

$$\sigma_o^2 = \begin{cases} \frac{2}{3\mu}, & \text{if } \mu \geq 1/3 \\ 2, & \text{if } \mu < 1/3 \end{cases} \quad \text{and} \quad \sigma_u^2 = \begin{cases} 0, & \text{if } \mu \geq 1/3 \\ \frac{2-6\mu}{3(1-\mu)}, & \text{if } \mu < 1/3 \end{cases}.$$

Observe $\sigma_o^2 > \sigma_u^2$ in both equilibria—payoffs are more volatile with an overconfident leader than an unbiased one, consistent with the idea that overconfident leaders have the most dramatic successes and the most catastrophic failures.

2.3.6. Is Leadership Illusory?

Overoptimism and overconfidence are cognitive biases suffered by leaders. A potential cognitive bias suffered by followers is the *fundamental attribution bias*—the well-documented tendency of people to ascribe outcomes to the attributes of the individual actors rather than to the situation they faced; effectively, to underweight the base rates of success or failure at a task when updating beliefs about an actor's ability from his or her success or failure at the task. Organizational behavior scholars have long postulated that followers will, consequently, unduly attribute the group's success or failures to its leaders, the so-called "illusion of leadership" (for citations to some of this literature, see Weber et al., 2001).

Weber et al. test this idea experimentally. They consider a teams problem with a weakest-link technology:

$$\text{team member } n\text{'s payoff} \equiv \begin{cases} \frac{5}{4}(\min\{e_1, \dots, e_N\} + 1) - e_n, & \text{if } \min\{e_1, \dots, e_N\} > 0 \\ 1, & \text{if } \min\{e_1, \dots, e_N\} = 0 \end{cases},$$

where, for each n , $e_n \in \{0, 1, 2, 3\}$. The game has four pure-strategy Nash equilibria, each characterized by all N team members playing the same e . The equilibria are Pareto ranked, with a higher- e equilibrium dominating a lower- e equilibrium. Earlier experimental evidence by Van Huyck et al. (1990) shows that large teams end up coordinating on the $e = 0$ equilibrium, while small teams can successfully coordinate on the $e = 3$ equilibrium.⁴⁸ In other words, cooperation is harder to sustain the larger the team. In Weber et al., one of the team members is made leader and the leader is allowed to make a speech exhorting her fellow team members to cooperate (i.e., play $e = 3$). Despite this, cooperation is far less common in large teams than in small teams, consistent with cooperation being harder to sustain in large teams. Through various methods, Weber et al. have team members indicate why their teams were successful (i.e., tended to cooperate) or unsuccessful. To a significant degree, team members ascribe the outcome to the ability of the leader; that is, they appear to be ignoring the effect of the situation (large versus small team) and overweighting the leader's leadership abilities.

Although insightful, this work is not without problems. First, in the Van Huyck et al. experiments, which had no leaders, large teams *never* coordinated. In the Weber et al. experiments, large teams are sometimes able to sustain coordination, suggesting that there is a role for leadership (or at least announcements). Second, the questionnaires given team members do not ask whether the size of the team contributed to success or failure. Hence, unless leadership ability were truly irrelevant to the outcome, it is not clear that one may conclude that the team members were assigning the wrong weights to the situation vis-à-vis leadership ability. Indeed, given the first point, it is not clear that team members were necessarily erring in attributing—at least in part—the outcome to the leader's ability.

To expound on these two points, consider a world in which ability, α , is drawn uniformly from $\{-1, 0, 1\}$. Assume there are two tasks, easy and difficult ($t \in \{E, D\}$). Let the probability of success conditional on task and ability be $p_t + \alpha\varepsilon$, where $0 < \varepsilon < p_D < p_E < 1 - \varepsilon$. Suppose people are surveyed after the task's outcome is realized and are asked what the most likely ability of the actor (leader) is. Bayes Rule requires $\hat{\alpha} = 1$ for success and $\hat{\alpha} = -1$ for failure. Given a large number M of such trials, approximately Mp_t successes should be observed for task t . If $p_E > 1/2 > p_D$, then the median rating of actors doing the easy task will be 1 and the median rating of those doing the difficult task will be -1 . The averages will be approximately $2p_E - 1 > 0$ and $2p_D - 1 < 0$, respectively. These values would give results analogous to those in Weber et al., but these results are perfectly consistent with unbiased attribution.⁴⁹

To be clear, however, this is not to say that the Weber et al. (2001) results can't be due to the fundamental attribution bias. The case for the fundamental attribution bias is strong in general, and there is no reason to think it, as well as biases like the hindsight bias, do not apply to followers' assessments of their leaders. The volatilities of established politicians' poll ratings

48. The actual game in Van Huyck et al. (1990) differs slightly in details, but that is immaterial for this discussion.

49. Weber et al. (2001) ask the team members to "rate the leader's overall leadership ability" on a nine-point scale, 1 = extremely poor; 9 = extremely good. (Note: in the reported tables, Weber et al. write "9 = average"; I believe, however, that must be a typographical error.) Medians for large teams are 3 or 4, depending on experimental design, and they are 5–7 for small teams. Means are similar but closer in value than medians, consistent with the hypothetical example in the text.

do not seem, for instance, readily reconcilable with rational Bayesian updating. However, as the above discussion shows, followers are not necessarily mistaken when they attribute at least some of the team's success or failure to their leader.

3. Corporate Culture

As the quotes in Section 1.2 demonstrate, corporate culture is not a precisely defined concept. It can be seen as encompassing the norms and customs of a firm, its informal and unwritten rules of behavior. As such, culture governs actions both in the firm and instructs members of the firm how to act with those outside the firm (e.g., suppliers or customers). Corporate culture is also defined to encompass the experiences, knowledge, and language shared by those belonging to the firm. Although shapeable by individuals, especially leaders, culture is more than an amalgam of current personalities in the firm; it is a property of the firm. Consequently, given normal personnel turnover, the culture will persist over time, evolving slowly if at all. Finally, although a firm's culture can be influenced by broader social mores and customs, it is nevertheless distinct from national or regional culture.⁵⁰

3.1. Assessment and Measurement of Corporate Culture

Given that corporate "culture is not just a concept but a family of concepts" and "like a Rorschach [test] means different things to different people" (O'Reilly and Chatman 1996: 159), it is not surprising that corporate culture has proved difficult to assess and measure. These difficulties, in turn, can create problems for a quantitative science such as economics.

In assessing and measuring corporate culture, a researcher could conceivably wish to know some or all of the following:

- What is the strength of the culture? How committed to it are people? How uniform is commitment across the ranks of the hierarchy? Across employee cohorts?
- What is the impact of the culture? How does it aid or hinder the firm?⁵¹
- How stable is the culture? Is it prone to decay? If so, at what rate?
- What resources does management expend on the maintenance of the culture?
- What resources would management need to expend to change the culture? How would it accomplish that task?

As detailed in Payne (2001) and Sparrow (2001), the principal measurement tools are surveys. Some surveys are conducted throughout the organization, and others (e.g., Kotter and

50. There is, however, a literature that considers the link between social customs and corporate culture. The influence of the broader society has been invoked, for example, to explain systematic differences in the corporate cultures of American and Japanese firms. See, e.g., Ferris and Wagner (1985), Okuno-Fujiwara (1994), Morita (2001), and Tackney (2001).

51. A certain suspicion must apply to any prediction that a strong corporate culture is always advantageous. If that were true, then how would one explain variation in the strength of culture across firms? Why wouldn't all weak culture firms become strong culture firms (or die)? Hermalin (2001: 243–248) discusses this issue in greater depth.

Heskett 1992) are sent only to top management. Sometimes, as in Kotter and Heskett, managers of one firm are asked questions about the culture of other firms as well as their own. For instance, people could be asked to rate a firm on the extent to which it is managed according to long-standing policies and practices, to rate it on whether it has a style or way of doing things, and so forth (see Payne). Sometimes people are asked directly to rate the strength of a firm's culture.

An indirect means of measuring the strength of a culture is to ascertain the degree of consensus on various attitudinal questions. Sometimes (see Payne 2001: 113) people are explicitly surveyed about the degree of consensus among people in the firm. The rationale behind these approaches is that a strong culture should lead to strong consensus in beliefs and attitudes.

Another indirect approach is to measure an organization's investment in correlates of strong culture (O'Reilly and Chatman 1996). From studies of organizations with notoriously high levels of indoctrination, such as religious cults, certain practices are known to lead to indoctrination or at least correlate with it. For instance, table 1 of O'Reilly and Chatman offers a list of such practices, such as "use multiple recruiting steps requiring escalating commitment on the part of the recruit," a practice used in religious recruitment. The rationale is that firms that employ strong indoctrination techniques will wind up with strong cultures.

Purely ethnographic methods have also been employed. Although such research can serve to enrich our understanding of corporate culture, it does not lend itself to quantitative conclusions, limiting its usefulness for any kind of statistical analysis.

In economics, where survey and ethnographic methods are rarely used, other approaches have been taken to the empirical study of corporate culture. An example is the study by Cronqvist et al. (2007), which posits that if cultures are influential and persistent, then firms' investment, financial, and operational policies should also be persistent; moreover, spinoffs should follow policies similar to their parents. The empirical evidence presented by Cronqvist et al. is consistent with these hypotheses.

3.2. The Economic Analysis of Corporate Culture

3.2.1. Coordination, Reputation, and Unforeseen Contingencies

Consider Figure 6, a "battle of the sexes" game between a senior and a junior person. An issue with such games is how do the players determine which of the game's three Nash equilibria is to be played? Absent some institution for selecting the equilibrium, there is no clear prediction of what the players will do. Experiments indicate, however, that the players will frequently fail

		Junior	
		A	B
Senior	A	2 3	0 0
	B	0 0	3 2

Figure 6. Coordination game between junior and senior personnel.

		Junior	
		A	B

	B	0 0	0 J

Figure 7. Family of coordination games between junior and senior personnel.

to coordinate (i.e., they will often get 0; see, e.g., Charness et al. 2007). It would therefore be welfare superior to have an institution that selected one of the two pure-strategy equilibria prior to play.

Kreps (1990) suggests that corporate culture is just such an institution. Suppose, for instance, it is understood, as matter of culture, that juniors are to defer to seniors. Consequently, juniors and seniors expect that the A-A equilibrium will be played, given it is best for the senior player.

3.2.1.1. Unforeseen Contingencies. Given that coordination on the A-A equilibrium could also be achieved by other means, including contractually, the usefulness of corporate culture is not immediately obvious. As Kreps (1990) suggests, its usefulness is more apparent if we imagine a world of unforeseen contingencies: Consider Figure 7. Provided $S > s > 0$ and $J > j > 0$, this figure generalizes the game of Figure 6. Imagine, now, that there are many such coordination games that junior and senior personnel will play. What A and B will be is not known ex ante, nor are the values of S , s , J , and j known. A player may not even know in advance if he will be the junior or senior player. In short, the details of all possible coordination games could be unforeseen contingencies. In such an environment, contracting could be impractical (although see the discussion at the end of Section 3.2.1.2).⁵² A cultural norm of deferring to seniors could serve as an efficient substitute for explicit contracting, ensuring that a Pareto efficient outcome is reached.

3.2.1.2. Corporate Reputation. A prevalent view is that a corporation's culture belongs to the corporation in the sense that it is robust to turnover in personnel. Building on Kreps (1990), consider the game in Figure 8: This is a game between a boss and an underling. The boss can treat the underling fairly or exploit him. The underling can trust the boss or not. The latter strategy partially protects the underling against exploitation, but is harmful to him if the boss plays fairly. Observe that exploit is a dominant strategy for the boss. In a one-shot game, she can, therefore, be expected to exploit. The underling's best response to being exploited is not to trust. Hence, the one-shot equilibrium outcome is the bottom-right cell. Both players would, however, be better off in the top-left cell.

52. Contracting includes a corporation's written rules, policies, and procedures, as well as explicit contracts between employees and the corporation.

		Underling	
		Trust	Not trust
Boss	Treat fairly	7 5 2	3
	Exploit	9 0 4	1

Figure 8. Trust game.

Suppose, conditional on survival to any given period, the game is repeated in (survives to) the next period with probability β .⁵³ For the moment, assume the boss and her underling live at least as long as the game is repeated. It is readily shown that if the per-period survival probability $\geq 40\%$ (i.e., $\beta \geq \frac{2}{5}$), then there is a subgame-perfect equilibrium in which the boss treats the underling fairly and he, in turn, trusts the boss to do so (for details, see Hermalin 2001).⁵⁴

In this model, the underling need not be a long-lived player. Period by period, he simply plays his best response to what the boss is supposed to do given the history of the game; he could, thus, live only one period *provided he, like the member of each generation, knows the history of the game to that point*. The boss, in contrast, does need to care about the future. She need not, however, be infinitely lived.⁵⁵ Specifically, suppose the current-period boss's compensation is an increasing function of the value of the firm, the sum of current payout plus expected future value (e.g., she has stock-based compensation or is an owner who cashes out). Suppose that each generation's underling expects his boss to treat him fairly if every boss in the firm's history has done so, but otherwise he expects to be exploited. The firm's expected future value is

$$V_F = \frac{7\beta}{1-\beta} \quad \text{or} \quad V_E = \frac{4\beta}{1-\beta},$$

depending, respectively, on whether bosses have treated underlings fairly or a boss has ever exploited an employee. Consider a firm in which bosses have so far treated their underlings fairly. This generation's boss will continue this tradition, provided her compensation from doing so exceeds her compensation from exploiting; that is, provided $7 + V_F \geq 9 + V_E$. A little algebra reveals that inequality holds provided $\beta \geq 2/5$. Observe that the reputation for treating employees fairly resides with the firm, not an individual. The corporation's culture can, thus, sustain desirable outcomes.

"Fair treatment" and "exploitation" are fairly amorphous concepts. Typically, whether behavior is fair is specific to the situation. Treating an employee harshly could be seen as fair if

53. Equivalently, the game is infinitely repeated with certainty, and β is the common discount factor.

54. Rob and Zemsky (2002) use another approach to modeling how social capital might be built in an organization. Rather than relying on the logic of repeated play, the authors assume the organization's personnel are endowed with a reciprocity norm. See Rob and Zemsky (2002) for details.

55. Cr  mer (1986) defines a model with a similar flavor. In that article, there is a team with N individuals, each of a different age cohort. An individual lives N periods. Except for the last period of his life, an individual has some incentive to cooperate if failure to cooperate today destroys future cooperation. Under certain conditions, cooperation is sustainable among the younger cohorts.

he is performing poorly, but not if he is performing well. Ex ante, it is difficult to foresee all the possible treatments that could be judged fair or unfair and, likewise, to enumerate all the situations in which they are fair or unfair. Again, the environment is plagued by unforeseen contingencies. What is fair and what is exploitation cannot be defined in advance; yet, under the rules of a given culture, ex post behavior can be judged to be fair or not. This is analogous with pornography regulation in the United States—material is legally obscene if it violates community standards, and whether it does is judged ex post by the criterion that people know obscene material when they see it.⁵⁶ Corporate culture matters in two ways: as reputation or tradition, and as the means of defining compliance with the reputation or tradition when it is infeasible to define future circumstances ex ante.

A concrete example will prove useful. A company seeks to lure a top employee from a rival. Before moving, the employee attempts to reach firm agreements with his new boss about the details of his employment. But situations can arise, which he failed to anticipate, in which he would want his new boss to take actions beneficial to him but costly to her. For instance, imagine he does not foresee that his current daycare arrangement will fall apart and that the best alternative arrangement will require him to leave work early. Although he's willing to make up the work, regularly leaving early imposes a cost on the boss (e.g., meetings are harder to schedule). The boss can bear that cost, she can demand he not leave early—although this means a worse daycare arrangement for his child—or she can exploit the employee's problem to hold him up by, then, renegotiating aspects of his contract. In short, this is the game of Figure 8: The employee can “trust”—go to a new firm knowing that he will be vulnerable—or “not trust”—stay put; likewise, the boss can be accommodating—let him adjust his schedule without penalty—or “exploit” him—force him to stay until five or otherwise give something up. The key point, however, is the following: Whereas the employee can't anticipate that he will want accommodation, he should realize he will be relying on his new boss to treat him fairly. His decision to switch employers would depend, in part, on his assessment of the reputation (corporate culture) of his potential new employer.

From the perspective of economic theory, however, this analysis is not without problems. Although specific contingencies could well be unforeseen, general types of contingencies—will he be treated fairly or not—should be foreseeable. Why can't the parties write a contract that says that the boss will treat the employee fairly? The obvious—but seriously incomplete—answer is that it would be difficult for a judge (jury, arbitrator, etc.) to determine whether treatment was fair. That is, a judge's assessment of how the employee was actually treated is subject to error. However, as Hermalin and Katz (1991), Edlin and Hermalin (2001), and Hermalin (2008) demonstrate, imprecise assessments do not preclude efficient contracting. As long as the judge's assessment is correlated with what the boss actually did, the parties can rely on this assessment as follows. They write a contract calling for the boss to treat the employee fairly, and after the boss has acted, they renegotiate the contract in anticipation of what might happen should they go to court. Under fairly general conditions (see, e.g., Edlin and Hermalin 2001), the parties can construct a contract that duplicates the outcome they would have enjoyed were the boss's

56. To paraphrase the standard for pornography set down by Supreme Court Justice Potter Stewart. Personally, the standard I've favored—which is not original to me—is pornographic material is material read with one hand.

action verifiable without error. That is, as a matter of contract theory, there is no need to rely on culture at all—the parties can instead rely on formal contracts.

In reality, the costs associated with negotiating, monitoring, and enforcing these contracts could make them a less desirable means of inducing fair treatment—reputation can be equally effective and cost less.⁵⁷ Note, however, the transaction costs associated with contracting need to be substantial in the following sense: the possibility of formal contracting can destroy the possibility of using reputation when the two are close substitutes. Reputations are more sustainable the greater the difference between the cooperative and the noncooperative payoffs. If noncooperation results in switching to contracts and contracting is a close substitute for cooperation, then this difference is small, and consequently, reputation could be unsustainable (for more on this point, see Schmidt and Schnitzer 1995).⁵⁸

3.2.2. Culture as Technology

One way to view culture is as a type of technology. That is, just as a firm may have certain processes by which it produces its goods or services, its culture could also play a role in the transformation of inputs into outputs. For instance, to the extent that understanding organizational norms avoids miscoordination and other mistakes, it could make the organization more productive, just as a superior production technology might.

One article that explores this view is Carillo and Gromb (1999). Consider the following, simplified version of their model. Workers are either productive in a culture or not. Whether they are or are not is an intrinsic characteristic, with a random worker's probability of being productive in any given culture equal to $p \in (0, 1)$ (and independent across cultures). Hence, over time, a firm is essentially trying to match workers to its culture (similar to some of the selection models discussed in Sections 3.2.4 and 3.2.5). Let R_t be what a worker productive under culture t produces. There are two cultures: A , which a firm is endowed with initially, and B , which it may subsequently have an opportunity to adopt. Culture B is superior insofar as

$$R_B > (2 - p)R_A; \quad (17)$$

however, its superiority is limited:

$$R_B < \frac{R_A}{p}. \quad (18)$$

In what follows, assume the firm's workforce is a continuum of measure one.

Just prior to the first period, when the firm has only culture A available (the possibility of B does not arrive until the next period), it affords workers who would otherwise not be productive under A an opportunity to possibly become productive. Specifically, it allows them to invest in human capital, so that the probability that such a worker is productive under A is a , where the value of a depends on how much is invested. The success of this investment is only known at the end of the first period (i.e., after observing a worker's output). Consequently, in the first

57. Although contracts (typically implicit or default) are not unheard of—there are plenty of employee lawsuits alleging unfair treatment.

58. See also Baker et al. (1994) and Kvaløy and Olsen (2009). Hermalin et al. (2012) make the point that sometimes reputations permit parties to write contracts that would be ineffectual in a one-shot setting.

period, the probability that a worker is productive is $p + (1 - p)a$. At the end of the first period, the firm fires all nonproductive workers. With probability $1 - s$, the firm has the opportunity to switch to culture B prior to the second period; if it does switch, then it tests its existing workers to see whether they will be productive under B , letting go those who will not be. It then hires replacements for any dismissed workers and produces in a second and final period under whichever culture it has. Workers at this stage cannot invest in human capital. Recall the probability that a worker is productive under B is p . Accounting for new hires, the probability that a random worker is productive under A is

$$p(2 - p) + a(1 - p)^2$$

Given (17) and (18), a firm would rationally switch cultures if $a = 0$, but not if $a = 1$. Hence, there is a value of $a \in (0, 1)$ such that the firm is indifferent between switching or not; let $\hat{a}$ denote that value.

If a period-one worker anticipates no switch in culture, he chooses a to maximize

$$wa - c(a), \quad (19)$$

where w is the wage premium for working for the firm in period 2 and $c(\cdot)$ is the differentiable cost of making the necessary investment in human capital; for convenience, assume $c'(0) = 0$ and $c'(1) > w$. If he anticipates the firm will switch if given the opportunity, he chooses a to maximize

$$w((1 - s)p + sa) - c(a). \quad (20)$$

Let a^* maximize (19) and a^{**} maximize (20). Given $s < 1$, $a^{**} < a^*$. Moreover, it follows that $da^{**}/ds > 0$. The parameter s can be thought of as the strength of the initial culture, A .

If $a^* > \hat{a}$, then there is an equilibrium in which those workers who need to invest choose a^* and the firm maintains culture A even if B is available. This equilibrium relies on workers believing their colleagues will invest more than $\hat{a}$. Given that workers will never invest less than a^{**} , this equilibrium is unique if $a^{**} > \hat{a}$. Conversely, if $a^* < \hat{a}$, the only equilibrium is one in which workers invest a^{**} . If $a^* \geq \hat{a} \geq a^{**}$, then two symmetric pure-strategy equilibria exist: one in which a^* is played and another in which a^{**} is played.

This analysis makes clear that the stronger its culture (i.e., the greater is s), the weakly better off the firm is. It is strictly better off from a marginal increase in s if $a^* < \hat{a}$. Even if $a^* > \hat{a}$, the firm could be strictly better off from an increase in s , depending on equilibrium selection or if that increase eliminates the inferior equilibrium. Consequently, the model offers an explanation for why strong cultures can be valuable. It also suggests that a firm with a strong but intrinsically inferior culture could nevertheless do well—even outperforming a firm with a intrinsically superior culture (e.g., in an equilibrium in which workers play $a^* > \hat{a}$, an A -culture firm in its second period would outperform an otherwise identical firm with a B culture in its first period).

Although an intriguing model, it is not without its limitations. One is the assumption that some individuals are endowed with the ability to automatically be productive in a particular

culture. If, instead, the parameter $p = 0$, then the assumed inability to learn culture B means that no firm would ever change from A ; strength of culture would be irrelevant. Conversely, if B can be learned, then, with a long enough horizon, it would be hard to see why the firm wouldn't always switch to B given the opportunity. Another issue is the interpretation of s as a measure of cultural strength: although the inability to conceive—or implement even if desired—another culture could be a measure of the strength of the incumbent culture, it is not clear that this fully encompasses what is meant by strength of culture. Finally, it is not always clear that a strong culture is desirable. Prebankruptcy General Motors, for instance, had a strong culture but arguably quite a dysfunctional one.

3.2.3. Culture as Convention

The discussion of Figures 6 and 7—the “defer-to-seniors norm”—illustrates what could be called the “culture-as-convention” view. One question, left unexplored by Kreps (1990), is where these coordinating conventions come from. Young (1993, 1998) has taken an adaptive-learning approach to the issue: Players adapt their play as a function of past experiences. In adaptive play, players randomly draw (recall) k observations from the past m periods of play. For a two-player game, each player treats the frequency of his opponent's actions in his k -sized sample as the mixed strategy his opponent will play in the current period; he, thus, plays his best response to that mixed strategy. It is readily seen, given this rule, that if the same pure-strategy equilibrium is played for m periods running, then it will be played forever after—play has converged on a convention.

What is the probability of getting a run of m instances of the same pure-strategy equilibrium? Young (1993, theorem 1) proves that if m is sufficiently greater than k , then adaptive play will converge almost surely to a pure-strategy equilibrium. Drawing from the discussion in Fudenberg and Levine (1998: 115), this result can be illustrated as follows. Let $m = 3$ and $k = 1$. Suppose the A-A equilibrium is played at time t , in the subsequent period both players sample the play of period t , and in the period thereafter neither player samples period $t - 1$. Then, in periods t , $t + 1$, and $t + 2$, the A-A equilibrium is played and is established as a convention. The probability of this occurring is $4/81$. A similar argument applies to the B-B equilibrium. Provided A-A or B-B are played infinitely often, such a run of either A-A or B-B will almost surely occur. The only question left is whether A-A or B-B are played infinitely often. The answer is yes, because it is impossible to have a run of three or more occurrences of A-B or B-A, and therefore, over any sample period there is a positive probability of the players both sampling the same action (i.e., both sample an A or both a B), thereby resulting in an A-A or B-B outcome.

Although clever, this approach has a few drawbacks. First, it implies culture is all random evolution and no intelligent design. No doubt, random evolution is the best model for biology, but it is doubtful it is the best model for organizations. There is no role for leadership or other influences. Second, cultures that emerge this way seem more fragile than real corporate cultures. If, for instance, the A-A convention emerged, it could be set aside the next day if the head of the corporation announced that henceforth the B-B convention held in the corporation—provided people believed enough people would follow this diktat, playing B would be everyone's best response and, thus, B-B the new convention. In reality, changing corporate culture is frequently seen as a difficult task (see, e.g., Selznick 1984; Schein 1992; and Kotter 1996).

A partial response to the second point is that going from a state of no convention to one with a convention can be Pareto improving, whereas as switching from one convention to another can create winners and losers. In a more elaborate model, the losers could seek to block the change in convention. Concretely, for the game in Figure 6, let σ_i be the probability that player i plays A in the absence of a convention. If $1/5 < \sigma_i < 4/5$ for both i , then either convention is Pareto superior to no convention and presumably would be supported by both players. But given an A-A (defer to seniors) convention, a move to a B-B convention would be opposed by seniors. Hence a more elaborate model could serve to explain both why conventions form and why, once formed, they are difficult to change. Exploration of this issue is an interesting area for future work.

3.2.4. Artificial Selection

If pure natural selection—random evolution—is not the best description of how cultures arise, perhaps artificial selection is a better one. Consider the following model, which is drawn from Hermalin's (2001) version of Lazear (1998). Consider the games shown in Figures 6 and 7. Suppose that there are two possible preferences (beliefs, mindsets, etc.), A and B. Of these, A is the preference that top management wishes to promote. Assume the organization in question has a continuum of individuals of measure one, $p(t)$ of whom prefer A at time t . At each moment in time, individuals are randomly paired. Let $s \in (0, 1)$ denote top management's effort to promote the adoption of A. Suppose this works to cause a proportion s of B-preferrers paired with A-preferrers to become A-preferrers. Consequently, $dp(t)/dt = sp(t)(1 - p(t))$. Suppose $p(0) = 1/2$; then

$$p(t) = \frac{e^{st}}{1 + e^{st}}.$$

Clearly, $\lim_{t \rightarrow \infty} p(t) = 1$ —given enough time, almost everyone will wish to play A.

Lazear (1998) posits that management seeks a homogeneous organization (e.g., all A-workers) and chooses (invests) s in such a way to maximize the returns from homogeneity less the cost of investing s . By what mechanisms does management set s ? Lazear (1998: 105) offers two answers:

- Let s be the probability that a B-worker who plays against an A-worker is fired and replaced with an A-worker. Investments in human resources that aid in routing out B-workers and identifying A-workers among potential replacements determine s .
- When noncoordination occurs (i.e., an A-worker meets a B-worker), the B-worker thinks "something went wrong here." With probability s , he then recalls the training seminar, the distributed literature, or a motivational speech telling him this is an A organization, which leads him to become an A-worker. The effectiveness of the training seminar, the salience of the literature, and the frequency of speeches determine s .

A third possibility is sanctions: A proportion s of A-workers who play against B-workers feels free to sanction the B-workers they play against with sufficient vehemence that the B-workers switch to being A-workers. Under this interpretation, the encouragement management gives A-workers to sanction B-workers or the severity they permit them to employ determines s .

3.2.5. Culture as Self-Selection

The idea, noted in the previous section, that an organization might select like-minded individuals is an example of a more general view of corporate culture as the outcome of processes that lead to like-minded individuals joining or being selected for the same organization.⁵⁹ There is a long tradition in economics of models that predict that people will cluster into homogeneous groupings (e.g., Schelling 1971; Young 2001), and such modeling would seem readily applicable to organizations.

Van den Steen (2005, 2010c) offers one way homogeneous organizations could emerge. Individuals hold differing priors about what is the best technology, strategy, or course of action for a firm to adopt. When individual efforts are complementary and each individual is motivated, in part, by her private assessment of the likelihood of success, then individuals do better, in their expectation, to cluster into organizations of like-minded folks.

Van den Steen's ideas can be partially illustrated as follows. Each firm has two individuals. Firm profit, which is equally divided between the individuals, is $2\theta \min\{e_1, e_2\}$, where θ is a productivity parameter of uncertain value. Let $\hat{\theta}_n$ be individual n 's expected value for θ , and assume that all such beliefs are common knowledge.⁶⁰ Individual n 's expected utility given her beliefs is

$$\hat{\theta}_n \min\{e_n, e_{-n}\} - \frac{e_n^2}{2}.$$

Her best response function is, therefore,

$$BR_n(e_{-n}) = \begin{cases} e_{-n}, & \text{if } \hat{\theta}_n \geq e_{-n} \\ \hat{\theta}_n, & \text{if } \hat{\theta}_n < e_{-n} \end{cases}.$$

It follows that the second-best equilibrium is $e_1 = e_2 = \min\{\hat{\theta}_1, \hat{\theta}_2\}$. If $\hat{\theta}_2 > \hat{\theta}_1$, then individual 2 is unhappy insofar as she believes the firm is squandering $(\hat{\theta}_2 - \hat{\theta}_1)^2$ of potential surplus in expectation.

Suppose there are $K \geq 2$ technologies indexed by k . A k -individual is one who believes that if her firm adopts technology k , its expected θ is $\bar{\theta}$; but that if it adopts another technology, its expected θ is $\underline{\theta} < \bar{\theta}$. Given the previous paragraph's analysis, a k -individual prefers both to work for a firm using the k technology and to have a co-worker who is also a k -individual. Suppose, for simplicity, that there are the same even number of k - and k' -individuals for any k and k' . In equilibrium, each firm will be homogeneous with respect to beliefs about the correct technology to utilize. An outside observer, noting this homogeneity, might ascribe it to indoctrination by the firms, when, in fact, it simply reflects the desire of like-minded individuals to group with one another.

59. See Chatman (1991), O'Reilly and Chatman (1996), and Cronqvist et al. (2007) for empirical evidence supporting this view.

60. Again, this assumption raises subtle issues concerning the overall consistency of beliefs. See footnote 46.

Is this intrafirm homogeneity a good thing? To answer this, suppose that the probability that a k -individual is correct is, objectively, $1/K$. Per-firm expected surplus is, therefore,

$$\frac{1}{K}\bar{\theta}^2 + \frac{K-1}{K}(2\underline{\theta}\bar{\theta} - \bar{\theta}^2), \quad (21)$$

given firms with workers holding homogeneous beliefs, that is, in the self-selection equilibrium that would emerge absent any interference. In contrast, if firms were compelled to hire workers holding different beliefs, with equal numbers of firms adopting each of the K technologies, then per-firm expected surplus would be

$$\frac{1}{K}(2\underline{\theta}\bar{\theta} - \underline{\theta}^2) + \frac{K-1}{K}\underline{\theta}^2. \quad (22)$$

Expression (22) less (21) is

$$\frac{K-2}{K}(\bar{\theta} - \underline{\theta})^2 \geq 0. \quad (23)$$

Hence, unless $K = 2$, the population's expected surplus is greater with heterogeneous workplaces than with homogeneous ones.

What should be made of this result? Note, first, that by limiting attention to weakest-link production, the free-riding problem that is endemic to teams problems has been avoided. Were there a teams problem—workers undersupply effort vis-à-vis the first best—then devices that increase their incentives (e.g., working for a firm where they believe $\theta = \bar{\theta}$) could be welfare improving. However, this result is broadly consistent with empirical work on corporate culture (see, e.g., Sørensen 2002). This work suggests that strong culture—homogeneous—firms do less well when there is uncertainty about the environment (e.g., appropriate technology) than do heterogeneous firms. In other words, there is evidence to suggest that the greater is K —here, equivalent to a measure of environmental uncertainty—the worse strong culture firms will do.⁶¹

In addition, the analysis above presumes that there is no explicit coordination between the individuals. In particular, neither individual is the boss of the other. Most organizations are, however, hierarchical; hence, there is the prospect that one member of the pair has some authority over the other. Van den Steen (2010a,b) explores the effect of authority in settings similar to the one considered above. For instance, following somewhat in the lines of Van den Steen (2010a), suppose that one person in the pair (she) is the boss and can, at personal cost $c > 0$, compel the other person (he) to choose whatever effort she wishes. Suppose the boss believes $\hat{\theta}_B = \bar{\theta}$ and she knows the other person, the worker, believes $\hat{\theta}_W = \underline{\theta}$. From the above analysis, the boss will compel the worker to choose effort equal to $\bar{\theta}$ if

$$\frac{1}{2}(\bar{\theta} - \underline{\theta})^2 > c.$$

61. Another, quasi-biological, explanation for this finding could be that firms are like species. As in biology, the less intraspecies genetic variation (the greater the homogeneity of the employees in terms of knowledge, experience, world view, etc.), the greater a species' risk of decline or extinction should the environment change.

Assume that condition holds. Suppose the two individuals are equally likely to be right in their beliefs. It follows from (23) that there is no expected gain from compulsion, so the expenditure of c is a complete waste in expectation. Of course, if the organization were homogeneous in terms of beliefs, then the boss would have no reason to expend c . Hence, in this simple model, it follows that homogeneity is superior to heterogeneity when one takes into account control costs. More generally, heterogeneity leads to control costs, as those with authority seek to get underlings with different beliefs to line up behind what they believe. If these costs are large, then organizations with greater homogeneity of beliefs (stronger cultures) can outperform those with greater heterogeneity of beliefs (weaker cultures) even when there would otherwise be advantages to “genetic variation.”

3.2.6. Shared Knowledge, Language, and Custom

The previous models effectively define corporate culture largely in terms of shared norms (e.g., play A) or shared beliefs. Another aspect of corporate culture is shared knowledge—knowledge of procedures, pertinent facts, goals and objectives, and social structure and personalities.⁶² Such shared knowledge is beneficial to a firm insofar as it prevents people from working at cross-purposes, reinventing the wheel, and going up the same blind alleys. It also streamlines communications, because some knowledge can be presumed and not spoken. Of course, if the flip side of shared knowledge is shared ignorance, then there can be a downside, because such firms could be more vulnerable to changes in their environments.

Crémer (1993) and Crémer et al. (2007) consider an aspect of how shared knowledge streamlines communications. Specifically, they look at the value of jargons and technical language in an organization.⁶³ Organizations and trades tend to develop their own vocabularies, which are often impenetrable by outsiders. For example, The University of California at Berkeley faculty know the meaning of the “words” apee-em, beecce, elleness, and youcop, whereas outsiders typically do not. As an economist, your vocabulary includes ellem, emmar, Pigouvian, and Walrasian.

Crémer (1993) explains the value of language as a coding that saves on transmission costs. Sending a name requires fewer bits than sending a description of what is named. “Penguin,” for instance, uses fewer bits than “flightless black-and-white aquatic bird from the southern hemisphere.” Of course, at some point, people in an organization have to be taught the definition of names, which entails an upfront cost. If an organization needs to refer to something often enough, the savings on future transmissions makes it profitable to make the upfront expenditure on teaching its name. Infrequently referred-to things are left unnamed.

Crémer et al. (2007) consider efficient coding when there is a limit on how much can be learned. A simplified version of their model will serve to illustrate their main point. Suppose that people can learn only two words, w_1 and w_2 . Suppose there are three possible states, x_1 , x_2 , and x_3 , that people in an organization might wish to communicate. One word, say w_1 , can be assigned one state and the other word can be assigned two states. Hence, the vocabulary

62. Note, though, the overlap with norms and reputations, ingredients of the previous models.

63. Some of their ideas build on Arrow (1974). Other work examining the role of language in economics is Lazear (1999), Rubinstein (2000), and Dewatripont and Tirole (2005). Garicano (2000) looks at the organization of knowledge within organizations.

could be $w_1 \Rightarrow x_1$ and $w_2 \Rightarrow x_2 \vee x_3$. An individual who hears w_2 needs to expend $c > 0$ to determine whether the sender means to refer to state x_2 or x_3 . Is this an efficient coding? To answer, we need to know the frequency of the states. Let f_n be the relative frequency of x_n . If $f_1 > \max\{f_2, f_3\}$, then this vocabulary minimizes expected communication cost, which is $(1 - f_1)c$; otherwise, if $f_1 < \max\{f_2, f_3\}$, another vocabulary would be more efficient. In general, the precise term—the word that refers to one state—should refer to the most frequent state and the broader term—the word that refers to two states—should refer to the less-frequent states. As Cr  mer et al. show, this logic extends to more words and more states; in an optimal code, broader words describe less-frequent states.

As normative models of coding, the logic of this work is irrefutable. As positive models, however, they are less convincing. It is clear from any book on the subject (e.g., McWhorter 2001; Deutscher 2005) that languages evolve in an unplanned manner. One of the drivers of this evolution is a tendency of speakers (and, to an extent, writers) to economize for their private benefit (see Deutscher 2005: 73–114). That it is a private benefit is illustrated when 2nite u get txt msg from ur teen—she will spend less time typing it than if she were to spell out every word, but it will take you longer to decipher it than if she would. However, if u get enuf txt msgs, then you will become as adept at reading them as standard English, so total communication time (yours and your daughter’s) will clearly fall. In this sense, then, Cr  mer (1993) reflects an aspect of reality: senders economize for private reasons; receivers, if they interact repeatedly with the same senders, as in an organization, become adept at understanding the senders’ shorthand lingo and terse messaging. Total communication cost—in terms of time—is reduced.

An idea that has not received attention is how culture permits the creation of jargon. If the message sender believes she shares knowledge with the receiver, then she is more likely to believe her linguistic economizings will be understood by the receiver. For instance, consider the sentence, “The dean of ‘elleness’ is likely to be the new provost.” Even if you do not immediately know what “elleness” means, your immersion in the culture of academia allows you to deduce its meaning: (i) deans head colleges; (ii) elleness must be a college; (iii) “elleness” resembles the abbreviation “L&S”; (iv) in academia, particularly in reference to colleges, “L” often abbreviates “letters” and “S” “science” or “sciences”; (v) therefore, the sentence means the dean of the College of Letters and Science(s) is expected to be the next provost. In other words, much of our vocabulary is learned through the context in which we hear new words, and thus, whether jargon or neologisms spread depends on whether listeners grasp the context of conversations (i.e., their level of acculturation).

Economizing is not the only force that influences the evolution of language. Another important influence is the tendency of people to employ metaphors and similes (Deutscher 2005: especially 144–170). Metaphors and similes rely on shared knowledge. Suppose, for example, that Robin is known to be forgetful. When another person forgets something, a third person might quip, “You’re acting like Robin.” As that quip becomes stale, it may evolve and be economized (Deutscher 2005: 115–143), becoming “that’s a Robin” or “he Robined that meeting.” Through this process, the in-house verb meaning to forget could end up “to Robin.” There are two points to this example: (i) observe that in-house slang and jargon can often arise not to streamline communications—“you’re forgetful” is shorter than “you’re acting like Robin”—but out of the universal tendency to use metaphors and similes, and (ii) such slang and jargon are at least as much a product of the culture as they are definers of the culture. In fact, slang and jargon

could arise from people's desire to prove they are plugged into the culture (e.g., know Robin's reputation).⁶⁴ A related point is that the use of slang and jargon could serve to maintain group integrity, to help distinguish in-group from out-group, and this could be its purpose as much as streamlining communication (on the use of customs to distinguish in-group from out-group see, e.g., Harris 1978).

Weber and Camerer (2003) present an experimental study of culture formation, specifically, of jargon. In the experiment, each subject privately views a fixed and common set of 16 pictures showing office environments. The pictures are distinct but share common elements. Pairs of subjects played together as "firms." In each round of the experiment, the subject serving as a firm's "manager" for that round had, through the descriptions she offered, to get her partner, the "employee," to select eight of the 16 pictures in an order specific to that round. For example, imagining the 16 pictures as being indexed in a fixed manner, the manager might be required in a given round to get her employee to pick, in order, 5, 2, 6, 4, 3, 1, 14, and 12. The subjects' payoff per round was a function of how fast they completed the task. Because they received more the faster they completed the task, the pressure to economize on language was especially strong.

Consistent with the ideas in Cr  mer (1993), subjects develop names for the pictures. An example of such evolution is the following:

one pair of subjects began by referring to a particular picture as: "The one with three people: two men and one woman. The woman is sitting on the left. They're all looking at two computers that look like they have some PowerPoint graphs or charts. The two men are wearing ties and the woman has short, blond hair. . . ." After several rounds, this [pair's] description of this picture was condensed to simply "PowerPoint." [Weber and Camerer 2003: 408]

Also consistent with the idea that language becomes idiosyncratic to firms, another pair named this picture "guy hunching" and yet another "woman sitting, smiling." Note, however, in contrast to a model of fully rational language or coding, the names could have been shorter (e.g., "charts," "hunch(er)," "woman who sits, smiles," respectively). In addition, there is evidence of metaphors and similes: one pair named a picture "Uday Rao" because of the similarity between a figure in that picture and a well-known professor of that name.

3.3. The Directive versus Internalization Debate

One question in the study of corporate culture is whether individuals adhere to the prevalent culture because it is rational for them to do so (e.g., it is a Nash equilibrium; as in Kreps 1990) or because they truly believe in the culture and adherence is almost instinctual (e.g., somewhat as in Van den Steen 2010c). This is sometimes referred to as the "directive versus internalization debate."

64. Sometimes the jargon outlasts its cause: we use the "cc" line in our emails, even though no carbon paper is involved; a committee on which I serve makes much use of the red and burgundy books, although neither has been a physical book with a colored cover since well before any member of the committee began his or her service; and so forth.

Not surprisingly, given neoclassical economics' reliance on the rational-actor paradigm, most economic work on culture falls into the directive camp (e.g., Cr  mer 1986, 1993; Kreps 1990; Young 1993, 1998). Even when the actors are not fully rational, fail to foresee contingencies, or engage in adaptive learning, their motive to adhere to the culture is strategic rather than intrinsic.⁶⁵ The work of Van den Steen and, depending on interpretation, Lazear (1998) are exceptions: some beliefs and behavior are intrinsic.

One might imagine that evidence of adherence to norms that are irrational would provide the internalization side with compelling evidence. Fair play in dictator and ultimatum games (for discussions, see Rabin 1993, 1998) would suggest that people have internalized a fairness norm. Yet, as Sugden (1985) notes in his critique of Jones (1984), in real-life, nonexperimental settings, one often observes sanctioning mechanisms lurking in the background when there is conformism to norms. Evidence from biology is also less than clear-cut: on the one hand, chimpanzees seem to abide by hierarchical norms, yet on the other, they also scheme in various ways against them (de Waal 1998). As noted earlier, some view the evolutionary advantage of a large hominoid brain in terms of its usefulness for strategizing against your social group (Sapolsky 2005).

A personal experience may help convince you that witnessing norm violation can create a visceral reaction: In the early 1990s, Berkeley was plagued(?) by people walking about naked in public. The first time I saw a naked woman walking down the street toward me, the sense of shock was palpable—I felt as if I'd been hit in the chest.⁶⁶ A visceral reaction or acting in an emotionally hot state can lead to actions that the actor would consider irrational in an emotionally cool state.⁶⁷ Consequently, such reactions could lead people to carry out sanctions against norm violaters that are not in their rational self-interest, even in a repeated-game setting.

To be speculative, a possible synthesis of the directive versus internalization debate is that norm adherence or violation is directive (strategic), but sanctioning norm violaters is internalized. Evolutionarily, it would seem advantageous to be committed to punish those who harm you (i.e., violate norms), as this serves as an effective deterrent against others, but to be flexible yourself as to whether you adhere to norms, as this allows you an opportunity to gain advantage (e.g., seize a mating opportunity even if you aren't the dominant male). Like any reductionist argument, exceptions exist. It is difficult to explain tipping at restaurants we will never visit again or not stealing when detection is impossible without some sense that adherence to (some) norms is internalized. Conversely, long-term (strategic) considerations often allow us to calm ourselves and forgive norm transgressors.

4. Conclusion

Throughout this chapter, I have sought to flag areas that strike me as ripe for future work. In addition to those, let me conclude by listing a few more.

65. The same schism exists in the leadership literature: Hermalin (1998) and its extensions are rational-actor models, whereas Rotemberg and Saloner (1993, 1998), Huck and Rey-Biel (2006), and Blanes i Vidal and M  ller (2007) presume some degree of norm internalization.

66. Although it may reflect poorly on me, the reaction was definitely shock and not arousal.

67. Some economic work on the role of emotions in decisionmaking includes Loewenstein (1996, 2000), MacLeod (1996), Loewenstein and O'Donoghue (2005), and Hermalin and Isen (2008).

- *The interaction between leadership and corporate culture.* In particular, how do leaders shape culture? Is a strong leader essential or detrimental to a strong culture? Does a strong culture make a leader more or less effective (does *asabiyyah* apply in corporations)?
- *The time path of cultures.* What are the evolutionary forces that lead cultures to change? Are cultures self-sustaining? Do they erode absent intervention?
- *The emergence of leaders.* How do would-be leaders compete to become the leader? How do followers choose among competing leaders? When do leadership battles lead to organizational schisms?
- *The interaction between leaders and followers' affective states.* How, for instance, do leaders boost morale and affect the emotional states of their followers?
- *The role of emotions in organizations.* How do emotions govern norm adherence and the sanctioning of norm violation? To what extent do cultures rely on and exploit emotional needs?

Even if this chapter fails to inspire you to engage in such work, it should enrich your understanding of organizations by illustrating the power and importance of the informal aspects of organization, such as leadership and corporate culture. Leadership is critical if managers and officers are to be effective in their jobs. Corporate culture is a vital component in the control of organizations and with respect to organizational efficiency.

Personnel Economics

Edward P. Lazear and Paul Oyer

1. Introduction

Personnel economics is the application of economic and mathematical approaches to traditional topics in the study of human resource management. This includes such topics as compensation, turnover, and incentives that are inherently economic, as well as those that do not at first appear to be economic topics (e.g., norms, teamwork, worker empowerment, and peer relationships). Using the tools from advances in game theory, information economics, econometrics, and other areas of economics, personnel economics has come a long way over the past few decades. It now produces a large share of the labor economics literature, has earned its own code in the *Journal of Economic Literature* classification system (M5), and has its own working group in the National Bureau of Economic Research. In this chapter, we review how this literature has developed and discuss some avenues for fruitful future research.

Personnel economics provides both positive and normative analyses of human resource practices and methods. On the positive (or descriptive) side, we study a range of questions. When do firms choose to use one form of compensation over another? When are teams important? How do firms find the right workers? When are certain benefits or stock grants given to workers? The list extends to any decision an employer has to make with respect to its dealings with employees. That is, personnel economics attempts to describe how human resource practices can best address an employer's goals, subject to the constraint that employee actions will be affected by those practices.

Perhaps because the subject was taken up by business school economists, whose job it is to teach managers what to do, personnel economics has not shied away from being somewhat prescriptive. Several MBA textbooks and numerous MBA classes that are either focused on personnel economics or cover it as part of a broader subject deliver research findings to current

We thank the editors of this volume, Robert Gibbons and John Roberts; James Malcomson; Bentley MacLeod; Scott Schaefer; Michael Waldman; Jan Zábojník; and participants in the *Handbook of Organizational Economics* 2006 conference for comments.

and future managers.¹ In many ways, the basic outlines and topics of this chapter are similar to the syllabi for the MBA classes we teach at Stanford (though the details are very different). Given the importance of human resources to many organizations' success and the fact that labor accounts for the majority of business costs, bringing research findings to managers can have an important effect.

In this review, we introduce the key topics of personnel economics. We also focus on some relatively new findings that have emerged since prior reviews of some or all of the personnel economics literature, such as Gibbons and Waldman (1999), Lazear (1999, 2000b), Malcomson (1999), Murphy (1999), and Prendergast (1999). Throughout the discussion and in the conclusion, we suggest open questions where future research can make valuable contributions to the literature.

Personnel economics research has focused on five aspects of employment relationships: incentives, matching firms with workers, compensation, skill development, and the organization of work. Though some research focuses on only one of these, much of the literature touches on multiple aspects of jobs. For example, incentives have an effect on which workers accept positions, and the organization of the workplace depends on the skills a firm develops (or selects for). Nonetheless, these five areas of employment relationships allow for a broad categorization of research in personnel economics. So we explore each of these in turn, reviewing the main theories, empirical tests of those theories, and the open questions in each area.

Before proceeding, it is worth briefly noting what personnel economics is *not*. Personnel economics is a branch of labor economics, but there is a great deal of labor economics that is not personnel economics. Studies that do not consider interactions between a firm and its workers or that do not explicitly or implicitly consider a firm trying to maximize some objective (usually profits) are not personnel economics. Many findings in labor economics are important conceptual or empirical inputs to, but not part of, personnel economics. For example, labor economists estimate Mincer-ian earnings functions of the returns to experience and the return to schooling, and they estimate labor supply functions. Although these equilibrium outcomes are very important issues to firms designing personnel policies, they are not strategic choices of the firm. Similarly, most personnel economics is not policy oriented. Personnel economics models typically focus on welfare within a given employment relationship rather than on the overall social welfare function. In the absence of a market failure, firms' best interests will be the same as those of the economy as a whole. Although there are some exceptions (e.g., policy and personnel economics influence one another in the study of workplace discrimination), the main contributions of personnel economics to social welfare are in research advances and helping managers to run their businesses more efficiently rather than in influencing policymakers' decisions.

2. Incentives

Firms and employees naturally have opposing interests in that employee effort typically leads to benefits to the firm and costs to the employee. However, there can be gains from trade if the value to employers is enough to compensate workers for the cost of their effort. Encouraging employee effort is a central issue in personnel economics and, as with much of economics, has

1. A recent paper by Bloom and Van Reenen (2007) suggests that managers can benefit from using modern managerial practices, including some specific practices studied in personnel economics.

led to a large literature on incentives. When effort is contractible, providing efficient incentives is trivial. But in the more realistic case where there is hidden action (moral hazard), one of the keys to successful personnel practices is to design incentives for employees.

When effort is not contractible, one potential way (though not the only way) to obtain the socially efficient level of worker effort is to pay the worker the full value of output—that is, sell the firm to the worker. The firm could set a base salary to meet the worker's participation constraint and let the worker keep all the marginal fruits of his effort. The base salary will need to be negative—that is, the worker will pay the firm for the right to work there—for the firm to find the employment arrangement profitable. In other words, moral hazard problems can be solved by making employees the residual claimants on their effort. If individuals own all their output, they will efficiently match the marginal benefits of their effort to the marginal cost.

There are employment arrangements that involve selling the firm to the worker (e.g., taxi drivers who rent cabs for a shift and keep all fares), but these jobs are exceptions. Why does this simple model fail for the vast majority of workers who have positive base wages and piece rates of less than one (and usually zero)? There are many reasons, but they generally relate to the facts that worker output (i.e., measures of the worker's productivity) is imperfectly related to inputs (i.e., the worker's effort), that firms cannot always credibly commit to reward effort *ex post*, and that individuals are typically more risk averse than employers.

2.1. The Trade-off between Risk and Incentives

Most theoretical principal-agent models assume that output is an increasing function of effort and that it is also influenced by some unobservable random shock.² The employee's utility is decreasing and concave in effort (i.e., her disutility of effort is positive and convex). Because she is risk averse, utility is increasing and concave in income. The complication, which makes it impossible to simply pay the agent for her inputs, is that the principal can only observe the output measure, so this is the only variable on which compensation contracts can be based. If the two parties could write enforceable contracts based on effort, the problem would be simple. The risk-neutral firm would simply pay for effort, and the agent would be completely insured.

The problem for the principal is to set the compensation scheme to maximize profit subject to incentive compatibility and participation constraints. A key implication is that there is now a trade-off between insurance and incentives. Because workers do not like risk, the firm must dampen the relation of wages to output. If compensation is based largely on output, the firm may have to provide substantial risk compensation. But if compensation is not based on output, workers will put forth little effort. The second-best solution, though the "best" compromise, forces the worker to bear risk and provides the firm with an inefficient amount of effort.

This model has two key predictions. First, the stronger the incentives are, the harder the employee will work. As we discuss below, there is ample empirical evidence to suggest that this relationship holds in most employment relationships. Second, there is a trade-off between risk and incentives. Everything else equal, in settings where factors beyond the employee's control

2. See Prendergast (1999) for a somewhat more detailed description of moral hazard theory. See Johnson (1950) and Cheung (1969) for important early compensation analyses from the agricultural economics literature and Ross (1973), Mirrlees (1974), Stiglitz (1975), Bergson (1978), and Holmström (1979) for early modern treatments of the moral hazard problem.

have a relatively large effect on output, incentives will be weaker. As we also discuss below, the empirical evidence on this linkage is decidedly mixed (probably at least partially due to an inability to make “everything else equal”).

2.1.1. *Distortions in Performance Measures*

Imperfections in performance measurement can lead firms to limit the use of incentives, even when employees are risk neutral. In addition to exogenous shocks to output measures, the usefulness of a performance measure may also be limited by employees having private information or by their ability to influence the measure without actually advancing the principal's goals.

Gibbons (1987) considers the case where only the worker knows the difficulty of the job and only the worker knows his true action. Under these circumstances, Gibbons shows that workers will restrict output (i.e., there will be a “ratchet effect”) when the firm cannot commit not to use information it learns about the difficulty of the task. He argues that this effect contributed to the decline of piece rate systems, which were extensively used at the end of the nineteenth century.

Another class of models considers the implications of employees who can affect the output measure differently from their effect on actual output. Lazear (1986a) briefly discussed the implications for incentives and performance measurement when workers can increase quantity at the expense of quality. Baker (1992) provides a more general model of a firm that wants to maximize some noncontractible objective (call it V). The firm can write compensation contracts based on P , which is imperfectly correlated with V . The employee has private information about how her actions affect both P and V . The firm wants to provide incentives so that the employee will exert more effort, but it has to trade this off against the possibility that the employee may exert effort when that effort has a large effect on P but not on V . That is, the firm has to worry about the fact that incentives drive efficient effort and gaming at the same time.

Holmström and Milgrom (1991) explore the limits of measurement from a slightly different perspective. They derive a multitasking model where an employee engages in two tasks that affect actual output and measured output differently. Incentive contracts may drive the employee to underinvest or overinvest in one or both tasks. They discuss how this process may explain the limits of incentive pay for teachers. Although incentives may lead teachers to work harder, they may also focus their effort on teaching rote skills that are rewarded on standardized tests at the expense of teaching logical reasoning and other skills, where the payoff is not easily measured in the short term.³ As we discuss below, these models are generally consistent with several empirical studies showing unintended responses to incentives.⁴

2.1.2. *Subjective Measures of Performance*

Given the limits of objective performance measures, what alternatives do firms have for motivating workers? The answer for most employees is various incentives based on subjective measures

3. Lazear (2006) lays out how the performance measures should be designed and how much information about them should be given to employees when employees engage in multiple tasks.

4. One case study that shows direct evidence of the importance of multitask issues is Brickley and Zimmerman (2001). They show that teacher ratings rose and research output fell at the University of Rochester's Simon School of Business, New York, after the administration increased the relative importance of teaching in its reward structure.

of performance. That is, the performance of most employees is monitored by some supervisor(s) who develops a reasonably accurate, but nonverifiable, signal of how good a job that employee does. Good performance can then be rewarded through a variety of mechanisms, including increases in base salary, subjectively determined bonus payments, or promotions.

Bull (1987), MacLeod and Malcomson (1989), and Baker et al. (1994) model the use of subjective performance evaluation. They analyze the optimal mix of incentives based on imperfect objective measures and perfect (but unverifiable) subjective measures. These models highlight the trade-off between strong incentives from well-designed subjective measures and the fact that employees have to trust firms to follow through on the inherently implicit contracts involved in any nonverifiable performance measure. For example, many Wall Street firms distribute year-end bonuses to employees based on largely subjective measures of the individuals' contributions. The shareholders of those firms would gain in the short term by announcing that nobody had earned any bonus in a given year, but the firm would find it hard to motivate employees in the future.

As the pioneering career concerns models of Fama (1980) and Holmström (1999) discuss, immediate pay for performance is not necessary if current performance affects an employee's reputation and future compensation.⁵ Gibbons and Murphy (1992), building on these models, analyze employees that exert effort both in response to explicit incentives and in the hopes of improving employers' beliefs about their abilities. Firms do not need to provide strong current-period incentives for young workers, who have more reason to be motivated by future promotions and opportunities. They find some support for the model in the way CEO compensation varies with age and experience. Chevalier and Ellison (1999), who study mutual fund managers, find further support for age-based variation in the need for objective incentives.

In addition to the limits that stem from using implicit contracts for enforcement, subjective performance evaluation also is limited by differences between actual and measured performance. There are interesting models of at least three ways that subjective assessments can differ from actual productivity. First, employees can take actions that affect their supervisors' assessments. This issue has been studied in a series of papers on "influence activity," starting with Milgrom and Roberts (1988). The key idea is that employees will try to influence their bosses' decisions in their favor (and not necessarily in the interests of the firm) if their pay does not properly reflect their productivity. Firms face a trade-off between taking advantage of the manager's information and letting the manager manipulate decisions in her own best interests. For decisions that do not affect the distribution of benefits within the firm, this presents no problem. But when decisions have distributional implications, the firm may want to commit not to use information provided by agents. For example, the firm may commit to promote according to seniority rather than based on subjective assessments of performance. Meyer et al. (1992) and Schaefer (1998) show how the firm can benefit from a crisis (i.e., very bad alternatives for agents) to reduce influence activity and align the interests of employees and the firm.⁶

5. See Prendergast (1999) and Gibbons and Waldman (1999) for more detail on career concerns models.

6. Also see Fairburn and Malcomson (2001), who develop an integrated model of incentives and promotions when managers can engage in influence activity. They argue that managers with sufficient monetary incentives will be resistant to influence activity when making promotion decisions, which both makes promotion-based incentives stronger and more efficiently matches workers to appropriate jobs.

Second, Prendergast and Topel (1996) consider a manager who favors some workers over others. That is, the manager affects the payoffs of the employees, and the distribution of employee payoffs, in turn, affects the utility of the manager. The firm has to trade off the informational advantage of the manager regarding the employees' true performance, the taste for the manager to have more discretion, and the distortion to incentives caused by favoritism. In order to avoid the ill effects of favoritism, the firm reduces overall incentives and relies on imperfect (but noncorruptible) objective performance measures.

Finally, MacLeod (2003) considers the optimal contract when the manager and employee have different opinions about the employee's performance. He shows how the optimal implicit contract will vary with the degree of correlation between the manager's assessment of the employee's performance and the employee's self-assessment. The model predicts the tendency of managers to bunch or compress employee's ratings. MacLeod (2003) also studies the effects of favoritism, allowing for a more general set of contracts than Prendergast and Topel (1996) study. He shows that favoritism reduces the incentives of employees who are discriminated against, leading pay to suffer due to discrimination and lower effort. This result has the interesting implication that, holding performance constant, measured differences in wages will understate the importance of manager bias, because it will ignore the effect on the employees' incentives.

These models of subjective performance evaluation and implicit contracts have made important contributions to personnel economics and our understanding of compensation structure. However, even though these models are consistent with anecdotal examples and case studies, they have not been backed up by a great deal of rigorous empirical corroboration. Hayes and Schaefer (2000) provide compelling (though indirect) evidence on the importance of implicit contracts and subjective performance evaluation of executives. They argue that a board of directors that uses subjective evaluation will reward executives in the current period for actions that will affect objective measures of performance in future periods. They then show that there is an important empirical relationship between current pay and future performance and that this relationship is stronger at firms where they would expect subjective performance measures to be relatively advantageous for providing efficient incentives.

2.1.3. Relative Performance Evaluation

Some performance measures, whether objective or subjective, can be improved by making them depend on an employee's relative performance rather than on some absolute standard. Relative performance evaluation (RPE) can be used in two different ways. First, firms can use the performance of a peer group of competitors to filter out shocks that are common to the whole peer group. This helps the firm to lower the risk (and the associated compensation premium) imposed on individual employees. As Antle and Smith (1986) and Gibbons and Murphy (1990) discuss, this idea has the empirical implication that pay will be increasing in the employee's own performance but decreasing in the average performance of the reference group. As we discuss in Section 4.4, at least in the case of CEOs (whose performance and that of a peer group are easily observed), there is surprisingly little evidence that firms filter out common shocks of a peer group.

A second form of RPE is to use fixed rewards for a fixed group of people, where the distribution of rewards is based on the order of the participants' performance. This form of reward system, generally known as a tournament, can vary from a group of people competing for a single

promotion (e.g., to CEO) to a large set of prizes that diminish in value as a person's relative performance diminishes (e.g., at a golf tournament or in the memorable real estate sales tournament in the film drama *Glengarry Glen Ross*).

Tournament theory, as modeled by Lazear and Rosen (1981), models promotions as a relative game. The compensation at one level of the firm, in addition to motivating individuals at that level, motivates those at lower levels. There are three basic principles of tournament theory. First, prizes are fixed in advance and depend on relative rather than absolute performance. Second, larger spreads in wages at different levels of the hierarchy motivate those at lower levels to put forth more effort. Third, there is an optimal spread. Although a greater spread increases effort, at some point the additional wages necessary to compensate workers for the increased effort are larger than the additional output generated.

An important variable in the Lazear and Rosen (1981) model is the amount of noise—that is, the degree to which luck affects the probability of winning. When there is more noise (so that luck becomes relatively more important and effort relatively less important), workers will try less hard to win, because effort has a reduced effect on whether they win. In production environments that are very uncertain, large raises must be given to offset the tendency by workers to reduce effort. Similarly, the number of slots available affects effort. If a firm has 100 vice presidents (VPs) and only one slot for president, most VPs will give up trying to become president, thinking that the chance of promotion is too slim. At the other extreme, if there were 100 VP slots and 95 president slots, so that each VP knew that she would almost surely be promoted to president, VPs would become complacent.

The firm can use the size of the spread between pay at various levels to manage effort. When luck is unimportant, the wage spread will be small. But when luck is important, the firm needs to increase the spread to boost effort. This may help explain differences in salary structure across countries or across industries. The model of Lazear and Rosen (1981) implies that riskier industries (where this is interpreted as risk that affects individual output) should have larger wage spreads than less risky industries to induce workers to put forth the appropriate amount of effort.⁷

These basic ideas of tournament theory have been extended in numerous ways. For example, while Lazear and Rosen (1981) focus on relative performance strictly as a means of generating incentives, Green and Stokey (1983) highlight the potential usefulness of tournaments in removing common shocks from risky performance measures. They show how individual incentive contracts compare to tournaments based on variation in how common the shocks to agent output are, how easily the firm can observe these shocks, and how many employees participate in the tournament. Nalebuff and Stiglitz (1983) allow for risk-averse employees, allow the number of participants in the contest to vary, and allow for both rewards and penalties. They derive a large set of results regarding when tournaments will be more efficient than incentive schemes that are not based on relative performance and how the optimal incentive system will vary with the number of participants, environmental uncertainty, and other factors. Rosen (1986b) extends basic tournament theory to a multiple-round elimination ladder and shows that, to keep incentives strong, prizes must be concentrated among a select few participants.

7. This prediction also comes from incentive models where agents are risk averse.

Dye (1984) and Lazear (1989) consider how the potential for collusion, sabotage, or other forms of noncooperative behavior in tournaments counter the incentive value of a large spread in rewards. Chan (1996) considers how firms should balance the incentive value of internal promotion tournaments against the value of retaining the option to hire an outsider when a senior opening occurs. He suggests that giving insiders a handicap in the tournament may help mitigate the possibility of influence activity or sabotage.

Patterns of pay and promotions in firms and in other contest contexts fit the predictions of tournament theory. DeVaro (2006) uses a sample of recent hires and their initial promotions to fit a structural model of tournaments. He shows the importance of relative, rather than absolute, performance in determining promotions. Knoeber and Thurman (1994) provide empirical evidence consistent with several specific predictions of tournament theory in the context of rewards for producers of broiler chickens. They show, for example, that spreads between prize values affect output. Drago and Garvey (1998), using a survey of Australian firms, show that individuals are less cooperative with other employees and work harder when promotion incentives are strong. Ehrenberg and Bognanno (1990) show that golfers are affected by prize spreads in tournaments. Finally, Bull et al. (1987) perform laboratory experiments (so that “effort” is chosen and stated rather than experienced) on how people respond to contests with piece rates and tournaments. The results of their experiments are generally supportive of tournament theory, though they find that less able people expend more effort than the theory would predict.

2.1.4. Alternative to Incentives I—Monitoring

An alternative to financial incentives is to simply monitor workers. If a supervisor can keep close watch over employees, she can ensure that the employee takes the best action. However, monitoring is typically imperfect, which led to the idea of efficiency wages. Shapiro and Stiglitz (1984) suggest that a firm will pay workers a wage premium when it cannot perfectly monitor effort. Workers, facing a choice between earning this wage premium if they work hard and facing a probabilistic chance of being caught and fired if they shirk, choose to work hard.

Efficiency wage theory implies a negative relationship between monitoring intensity and wages.⁸ The empirical evidence in favor of this prediction is mixed at best.⁹ This may be because the conditions that make efficiency wages optimal for individual employers may not exist at a large subset of firms in the economy. That is, there could well be many firms that can monitor very effectively or use output-based incentives, while other firms (such as the one studied by Cappelli and Chauvin 1991) use efficiency wages.

A recent study by Nagin et al. (2002), although not directly testing the relevance of efficiency wage theory, finds empirical support for the underlying relationship between employee productivity and the probability of catching employees that do not act in the firm’s best inter-

8. The monitoring/pay relationship is the primary implication for the personnel economics literature. But Shapiro and Stiglitz (1984) actually focus on the fact that efficiency wages also lead to equilibrium unemployment. Bulow and Summers (1986) also model equilibrium efficiency wages and focus on equilibrium unemployment. They discuss how the reaction to Ford Motor Company’s \$5 day for assembly line workers, introduced in 1914, is consistent with efficiency wage theory.

9. See Malcomson (1999) and Gibbons and Waldman (1999) for further discussion of the empirical relevance of efficiency wage theory.

ests. They run a field experiment at a telephone solicitation company where employees spend their workdays calling people to ask for donations to charitable organizations. They find that the rate at which workers “cheat” by trying to get paid for donations people did not actually make varies inversely with the rate at which managers audit donations. When the probability of getting caught goes up, workers cheat less.¹⁰ However, based on a survey of the telephone solicitors, Nagin et al. (2002) conclude there is little evidence to support another key idea in efficiency wage models—that those workers who value a job most will react most strongly to monitoring.

2.1.5. *Alternative to Incentives II—Intrinsic Rewards*

One way to save on both the costs of incentives and those of monitoring is to rely on the intrinsic value workers get from doing their jobs well. If firms pick workers carefully and create the right work environment, won't their employees be productive? In other words, standard moral hazard models assume that all productive effort is distasteful to the employee. But perhaps this assumption is not reasonable.

All else being equal, people who are intrinsically motivated to do certain types of jobs (or, put another way, those who simply enjoy certain jobs) will find work with firms that let them do those jobs.¹¹ If the labor market is reasonably competitive, then no matter how much workers enjoy the job, the firm will still have to pay them to do it, because employers will bid wages up to the person's marginal product of labor. But if people like their jobs enough, why would firms ever need to provide incentives or monitor workers?

The answer to this question, and the limit to intrinsic motivation, is not that people are not intrinsically motivated or that they do not like their jobs (though this is surely true in many cases). Rather, it is that the efficient outcome in most employment relationships is for the employee to dislike her job on the margin. Put another way, the key assumption in moral hazard models is not that all effort is distasteful. The key assumption is that the marginal disutility of effort is convex.

Many employees are intrinsically motivated to expend at least some effort at their jobs. However, at some point between zero and twenty-four hours of work in a given day, the marginal cost of an additional hour of work becomes positive. If a somewhat intrinsically motivated worker had no incentives or monitoring, she would do some work but would stop at some point. Assuming the person is still productive at the effort level where marginal work becomes costly, it is efficient to induce her to work more. It makes sense for her to work until the marginal disutility of her effort hits the marginal value to the firm.

This argument in no way implies that intrinsic motivation is not important. In fact, as our discussion of selection and matching below makes clear, firms should work hard to find workers who are motivated so as to decrease their own costs of compensation. But it does suggest that, on the margin, agency theory and other economic principles about motivation and incentives apply even when workers like their jobs.

10. Duflo et al. (2012) show that monitoring works in increasing teacher attendance in India. In their case, the employees do not have to infer the monitoring rate.

11. See Prendergast (2007) for a model of how different forms of intrinsic motivation should affect the matching of people to employers.

Although this very simple discussion of intrinsic motivation gets at the key economic issue regarding intrinsic motivation, it misses some potentially important and subtle effects having to do with the context of intrinsic motivation. Firms may affect employees' intrinsic rewards with the signals they send. Bénabou and Tirole (2003) formalize this idea and argue that a traditional economic model can be reconciled with many of the findings by psychologists about the demotivating effects of incentives.¹² They set up a model where both the employee and the firm have private information. The employee has better information about his abilities and his own interests, while the firm has better information about the attractiveness of the task. The contract offered by the firm affects the employee's beliefs about the task or the firm's beliefs regarding the employee. Under certain conditions, incentives can have negative effects on the employee.

2.2. Responses to Incentives—Empirical Studies

In a variety of situations where economists have been able to study the effects of incentives in relatively controlled settings, employees respond to incentives. However, although incentives work, several studies have shown some of the unintended consequences created by employee incentives. That is, the distortions predicted by some theoretical work appear to be important empirically. Some of these studies, because they focus on individual firms, could be capturing mistakes. Others, which show systematic and long-term costs of incentive schemes, suggest that incentives cannot be implemented perfectly but that the costs are worth bearing.

In this section, we review the empirical work on incentives. We first review several studies that establish that employees respond to incentives. We then discuss studies that show the importance of distortions in incentive schemes. There are several important empirical papers that consider how incentives operate in group settings. We defer the discussion of these studies to Section 6, where we discuss the organization of work.

Lazear's (2000a) study of the Safelite Glass Company provides a case study of the effect of incentives on both effort and worker selection. Safelite switched from paying windshield glass installers an hourly wage to paying them a piece rate per windshield installed. Because Safelite implemented the new pay scheme at different times at different locations, Lazear (2000a) could isolate the effect of the pay scheme while controlling for other companywide changes. In addition, because he was able to observe many new workers under both pay schemes and could control for on-the-job learning (i.e., tenure effects), he could separate the degree to which any change in productivity was due to changes in individual worker behavior and to changes in the types of workers that Safelite was able to attract. He finds that the piece rate system increased productivity at Safelite by about 44%. About half of this increase was the pure productivity effect. That is, the typical windshield installer that worked at Safelite under both pay schemes increased his productivity by about 22% upon the implementation of the piece rate scheme. The rest of the increase in productivity came about because the piece rate scheme led to self-selection of more-productive workers joining Safelite (and the self-selection of less-productive employees leaving the company).

12. For a review of many of these papers, see Deci et al. (1999). As we discuss below, in contrast to these suggestions of incentives demotivating workers, empirical studies by economists have generally found that explicit incentives increase productivity (though not always profits).

Shearer (2004) studies how piece rates affect the productivity of tree planters in British Columbia. Working in cooperation with the company that employs the tree planters, Shearer was able to implement a true experiment where a treatment group was randomly assigned to be paid a piece rate while a control group was paid an hourly wage. Thus, he cannot estimate a selection effect of piece rates but ensures the validity of a causal interpretation of the incentive effect that he measures. Shearer (2004) finds that workers paid through a piece rate are approximately 20% more productive than those paid by the hour, which is nearly identical to the effect in Lazear (2000a).

Bandiera et al. (2007) consider how the implementation of an incentive pay system affects the productivity of managers of fruit pickers on a U.K. farm. The pickers themselves are on a piece rate system at all times, but the farm made an unannounced switch to incentive pay for managers in the middle of one season. Bandiera et al. (2007) show that the average picker's productivity increased by 21% when his manager's pay was related to his productivity. They go on to show that much of this increase is due to the managers focusing their effort more carefully on those pickers for whom it will have the largest marginal effect on productivity, but that at least half is due to the managers being more discriminating about which workers they select.¹³

Freeman and Kleiner (2005) provide a useful reminder that while incentive pay generally increases productivity, it does not necessarily increase profits. They study a footwear manufacturer that switched from piece rate pay to an hourly wage as part of an attempt to cut costs and change its manufacturing processes. The firm implemented numerous other changes at the time of the change in compensation system, so it is difficult to isolate the exact effect of the change in pay scheme on productivity. But Freeman and Kleiner (2005) do find a significant reduction in productivity, and an increase in profits when piece rates were removed.¹⁴

These studies all show that incentives can be a powerful managerial tool for affecting individuals' behavior. Asch (1990) shows the same thing but highlights the more problematic side of incentives. She studies U.S. Navy recruiters who were measured, and in some cases paid, based on their ability to enlist sailors. To the extent that productivity affected compensation for the recruiters, it was based on whether they met annual quotas. Therefore, recruiter incentives were low if they either had already reached their quotas or if it became apparent that they would not reach them. In addition, due to discounting, the return to recruiter effort grew as the end of the measurement period approached. Asch (1990) shows that recruiting success was higher near the end of the year as the end of the measurement cycle approached. So even though incentives "worked," they did not work consistently. It is difficult to determine whether this inconsistency had any negative ramifications for the Navy.

Courty and Marschke (2004) examine the response of another set of government workers—managers of job training centers—to nonlinear incentives. However, in this case the incentives are indirect: performance affects the budget of the job training office and not the employees' compensation. Courty and Marschke (2004) show that managers act so as to increase the expected amount of incentive payouts near the end of each measurement period, but that their

13. Other studies showing evidence that incentives affect employee behavior but not allowing ready interpretation of the "incentive effect" include Groves et al. (1994), Fernie and Metcalf (1999), and Gaynor et al. (2004).

14. Note, however, that this profit effect could reverse in the long run if employees become more productive in the future due to current effort. See Friedman and Kelman (2008), who show that short-term financial incentives in British hospitals had long-run effects on productivity.

actions generate real costs in terms of lowering the quality of overall training. The incentives may lead to benefits in terms of overall quality, but it seems likely that these benefits could be captured without the costs imposed by the focus on year-end results.

The analyses by Asch (1990) and Courty and Marschke (2004) suggest that incentives can have a costly and inefficient side to them. However, because these studies are each based on a single institution (and one that is not subject to competition), it is feasible that they are simply studies of mistakes. Over time and facing competition, perhaps the Navy and the job training incentive systems would be changed or driven out of existence. However, there are broader (though less direct) studies of unintended consequences of incentives suggesting that firms choose to live with some of these consequences for the sake of capturing other benefits.

Oyer (1998), for example, analyzes the effects of the tendency of firms to plan their budgets and their incentive systems around a fiscal year. Executives and salespeople typically have contracts with a nonlinear relationship between pay and performance. Salespeople often have annual quotas, for example, and many executives receive certain bonus payments only if they surpass some target. This provides these employees with incentive to try to exert some discretion over when certain results are achieved. For example, a salesperson who is rushing to meet a quota near the end of the year may offer a customer a big (but unnecessary) price break if the customer orders immediately. He shows that, controlling for the calendar seasonality of a firm's industry, firms tend to sell more (and at lower margins) near the end of fiscal years than they do in the middle of the year. They also tend to sell less early in the year, suggesting that salespeople and/or executives "borrow" from the next year to meet the current year's quota.¹⁵ Larkin (2007), using data from a large software company, finds that salespeople's reaction to their incentive contracts cost the firm 6–8% of potential revenue.

The specific example studied by Larkin (2007), as well as the broader pattern identified by Oyer (1998), raises the interesting question of why these nonlinear contracts are so prevalent, given that they create inconsistencies in the production process and cut profit margins at the end of the year. However, given that these fiscal-year effects have been so common for so long, it appears there must be some benefit from these contracts that outweighs the apparent costs.

Chevalier and Ellison (1997) show that nonlinearities also lead to persistent distortions for mutual fund managers, though these nonlinearities are not chosen by firms.¹⁶ Specifically, they show that there is a nonlinear relationship between mutual fund investment returns over a calendar year and investment inflows into those funds. As a result, near the end of the year, some mutual fund managers have an incentive to change the level of risk in their funds. They show that such changes in risk do occur, suggesting that mutual fund managers choose their portfolios' risk with more than just maximizing return in mind. Again, given that this distortion has been taking place in a competitive market for a long time, it appears that the costs imposed by this behavior of mutual fund managers are outweighed by some benefits.¹⁷

15. See Healy (1985) and Murphy (2000) for further evidence that there is a relationship between executive contracts and timing of performance within fiscal years.

16. Also see Brown et al. (1996), who reach similar conclusions about mutual fund managers.

17. For other examples of problematic responses to incentives and measurement, see Dranove et al. (2003) and Jacob and Levitt (2003).

2.3. Empirical Relevance of the Risk/Incentive Trade-Off

In a series of papers over the past decade, Canice Prendergast has explored the trade-off between risk and incentives discussed above. First, in a review of the incentives literature at that time (Prendergast 1999), he argued that the empirical evidence was mixed on the risk/incentives trade-off.¹⁸ Then, in a series of papers, Prendergast (2000, 2002a,b) more carefully lays out the evidence on the risk/incentive trade-off and offers several explanations for why the risk/incentive trade-off may be difficult to find in the data even if the underlying idea is correct.

In Prendergast (2002a), risky environments are likely to be those where a manager's private information is more valuable. A firm will be willing to pay the additional costs to compensate a manager for additional risk to make sure the manager uses his private information profitably. In other words, the marginal value of the manager's effort is increasing in environmental risk such that the natural trade-off between risk and the cost of incentives may be overwhelmed by a positive relationship between risk and the benefits of incentives.¹⁹ Initial attempts to test Prendergast's model have been generally supportive (see Adams 2005; DeVaro and Kurtulus 2010), though they are limited by the difficulty of finding exogenous variation in the delegation of decision rights.

Prendergast (2002b) presents a model of subjective assessments and shows that either favoritism or costs to the manager of making assessments can lead firms to find incentives more valuable when risk is higher. Prendergast (2000) argues that if the costs of monitoring effort directly are correlated with risk, then firms may use more incentives in riskier environments, because the requisite risk premium is smaller than the cost of the additional resources that would be required to directly monitor the agent's actions.

Oyer (2004) offers an alternative reason risk and the value of incentive contracts can be positively correlated, even when the pay scheme is not meant to affect the agent's actions. He develops a model where the employee's reservation wage and the firm's value or profits are correlated with each other because they are both affected by macroeconomic shocks. The firm ties the employee's pay to the firm's success to lower contracting and renegotiation costs if a shock affects the employee's outside opportunities. In environments where shocks (and therefore, risk) are greater, the firm will tie more pay to firm performance to more closely match compensation to the employee's outside opportunities. However, if the environment gets too risky, the firm will abandon performance-based compensation and renegotiate wages when conditions change. This suggests that the incidence of "incentives" will be negatively related to risk but the amount of incentive will increase with rising risk.

Prendergast (1999: 21) summarized the research on the risk/incentive trade-off as of the time he wrote by stating, "there is some evidence that contracts are designed to optimally trade off risk against incentives" and "it would not appear that on the margin, the risk measures that have been considered are the true constraining factors on the provision of incentives." These conclusions

18. See Aggarwal and Samwick (1999a) and Jin (2002) for recent evidence that the trade-off holds for American CEOs.

19. Zábajník (1996) draws similar implications in a model where a portion of market risk is related to the manager's marginal product and is revealed to the manager before she chooses her effort, though Zábajník does not model the decision rights of the manager.

are still appropriate. But in the past several years, some of the extensions to the basic moral hazard model reviewed above have uncovered possible reasons empirical researchers find the risk/incentive trade-off to be so elusive. The challenge in the years ahead is to design empirical strategies and measures that can confirm or refute these newer models, as well as the basic moral hazard model.

3. Matching Firms and Workers

Matching firms with workers would be an easy process if labor were a commodity like some other inputs. However, labor is probably the most heterogeneous of all inputs in production functions. This is true on both sides of the market—the value of a given worker is likely to vary dramatically across potential employers, and the disutility of effort associated with work will vary for a typical worker across the firms she might work for. Matching the right firms to the right workers (as well as matching workers to the most appropriate jobs within the firms) creates economic value of a magnitude that few other economic processes can.

Given the importance of job market matching, it is not surprising that economists have been studying the selection process since well before there was a field known as personnel economics. Important theoretical contributions have come in two varieties—game-theoretic models of asymmetric information and models of efficient matching with symmetric learning about worker productivity.

3.1. Learning Models

Suppose individual i 's output y in period t , if employed at firm j , can be written as

$$y_{ijt} = \alpha_i + \mu_{ij} + \epsilon_{ijt},$$

where α is the innate ability of worker i , μ is the “match” productivity of the worker i and firm j combination, and ϵ is a productivity shock. Suppose all three variables on the right-hand side of the equation are random variables with mean zero and variance σ_α , σ_μ , and σ_ϵ , respectively.

Consider the case where $\sigma_\alpha = \sigma_\mu = 0$. In this case, each individual is identical and labor is a commodity. Efficiency is independent of how workers are matched to firms. If this case were a reasonable representation of the world, then the field of personnel economics would not study selection of workers.

Now consider the somewhat more interesting example where $\sigma_\mu = 0$, but $\sigma_\alpha > 0$. In this case, workers differ in their productivity, but their productivity is independent of where they work. Again, selection is uninteresting in this environment as long as information about an individual's value of σ is symmetric between firms and the worker.²⁰

Now consider the more interesting example where $\sigma_\mu > 0$. In this case, which is the core of the matching model in Jovanovic (1979), a worker's expected productivity in any given period

20. While selection issues are not important in models with symmetric learning about general ability (i.e., ability that is equally useful to all employers), these models have interesting implications for compensation. See Section 4.1.

depends on where she works. Then it is important, in terms of economic efficiency, to maximize the firm/worker match quality μ . Though exactly who captures the value of this match quality will differ, depending on the competitive environments in the labor and production markets, the total size of the economy will increase in average match quality. In the absence of any cost of changing jobs, workers would switch jobs several times early in their careers in search of the best match. But, given some search or other transaction cost in job switching, workers will switch jobs only if the expected gains to doing so are large enough.

There are two key empirical implications of matching models, both of which are also consistent with models of firm-specific human capital. First, turnover rates will decrease with job tenure (i.e., the longer a person stays in a job, the less likely she is to leave the job in any given period). Farber (1994) and others confirm that this pattern generally holds. Second, as long as it takes at least a little time for the worker and firm to learn the value of their match, wages will increase with job tenure. This implication holds in most specifications, but there has been some controversy as to whether it is true when the wage model to be estimated is properly specified. Abraham and Farber (1987), Altonji and Shakotko (1987), and Neal (1995) all argue that the wage/tenure relationship does not hold when properly controlling for other proxies of match quality. Topel (1991), using a different method, argues that the causal effect of tenure on wages is quite high, which is consistent with firm-specific human capital being important.

The relative importance of matching and firm-specific human capital is still somewhat of an open question. Although the patterns in the data sometimes appear consistent with both models, the managerial implications of these models are drastically different. If σ_μ is very high, so that match quality varies, employers should invest carefully in screening and selection. But if match quality does not vary and firm-specific human capital is an important driver of productivity, firms should focus on training and other human capital development.

Note that the matching literature is vague about what underlies the value μ of a match. Two recent models explore this. Lazear (2009) models a world where all skill is completely general, but employers value mixes of skills differently. Hayes et al. (2006) emphasize the value of co-worker specific match quality. Employees are more valuable at some firms than others, because they work more productively with the employees at some firms. Although both these ideas can help get to the root of matching, they do not help with distinguishing matching from firm-specific human capital. The mix of skills and/or relationships with co-workers can be developed after taking a job, which would make them a form of firm-specific human capital rather than *ex ante* match quality.²¹

Two recent papers that look more directly at the importance of matching are Woodcock (2008) and Andersson et al. (2009). Andersson et al. (2009) examine the matching of the most-talented software engineers to the firms with the highest returns to talent, while Woodcock (2008) analyzes the importance of individual skill, firm effects, and match-specific productivity on wages. Empirical research along these lines, which has become more feasible as rich employer-employee datasets have become available, could shed some light on how the matching process

21. Backes-Gellner et al. (2011) test Lazear's model using German data on employer-provided training. Their results suggest that the skills mix idea is enhanced by on-the-job training, though this conclusion does not exclude the possibility that employers select employees that already have (or show the ability to acquire) the range of skills the firms need.

takes place and how much value it creates.²² In addition, research at single firms or small groups of firms that analyzes job applicants, those offered jobs who do not accept, and those who accept positions might inform research and practice in selection and matching.

3.2. Asymmetric Information Models

While matching models focus on firms and workers that are equally well informed, other models consider how employees match to firms when one party is better informed. An important example of how asymmetric information can be critical in the labor market is when a person knows her ability but a firm has only a noisy estimate. If all workers were honest, firms could simply ask job applicants about their ability and make hiring decisions based on what the applicants say. Less qualified applicants have considerable incentive to exaggerate their qualifications, so firms must find another way to extract this information.

Two solutions to this problem have been suggested. In the pioneering work of Spence (1973), employers use costly signals to infer the ability of applicants. The cost to an individual of obtaining an education is inversely related to her ability (and, therefore, her productivity as an employee). Signaling will only solve selection problems when acquiring the signal is sufficiently costly and when the cost of acquiring it is inversely related to the person's ability. However, signaling is an inefficient solution to the selection process, because the cost of acquiring the signal is a deadweight loss. Another way to separate people of differing skill is to use self-selection (see Salop and Salop 1976). If some portion of compensation or other parts of the employment relationship differ in their value to prospective employees, and if these differences in value are related to productivity, then more productive employees will self-select into an organization. Self-selection has the advantage of not wasting the resources involved in acquiring a signal, but it relies on employers being able to find a condition of employment that will separate people based on ability.

Lazear (1986a) models how incentive schemes can be useful for signaling and self-selection. Suppose that potential workers know their abilities but employers do not. If productivity differences cannot be measured on the job, then all employees will be paid the average workers' productivity. But suppose an employer can measure an individual's productivity at some cost. Lazear (1986a) assumes that all employers in the marketplace observe the person's productivity when one employer measures it, so the firm will only undertake this measurement if the employee pays for it (presumably through lower compensation). Once productivity is measured, employee wages are bid up to their individual productivity level. If measurement is costless, then the system fully unravels and everyone is paid exactly their productivity. But if measurement is costly enough, then those with relatively low productivity are not willing to pay to be separated from those with the lowest productivity. As a result, some firms pay a fixed salary for all workers and attract those of relatively low ability. Other firms set up compensation systems related to output and measure workers. This simple framework may explain why salespeople are paid commissions, which is output-based pay, whereas most high-level service workers are paid salaries.

22. Oyer and Schaefer (2010) also use a newly available data source—directories of employees from law firms' web sites—to study the match between firms and workers.

In the latter case, it is more costly to obtain a decent measure of output, so more pooling occurs and pay relies on proxies for input.

Now consider a different type of asymmetric information model that can lead to inefficiencies in the labor market. Suppose each employee has ability a_i as in the prior discussion and firms cannot observe an individual's ability before hiring her. However, suppose the firm obtains a precise estimate of the person's ability shortly after hiring her. Then, as Greenwald (1986) shows in an extension of the early work by Akerlof (1970), under certain conditions, employee mobility (especially among higher ability workers) will be impaired.²³ Firms use their informational advantage to retain high-ability workers when they receive outside offers while not responding to outside offers made to mediocre performers (known as "lemons" in the paper). Fearing this information disadvantage will lead them to the winner's curse and overpaid lemons, firms are reluctant to make offers and workers will not change firms.

In some labor markets, this may not be an issue. For example, the productivity of professional athletes (and academic economists) is readily observable to other teams (universities), and the markets for these professionals' services are quite liquid with significant volume of trade. However, in other markets, ability is not as easily observed by outsiders and this observability need not be completely exogenous. Several models have advanced Akerlof (1970) and Greenwald (1986) by analyzing how employers can best take advantage of their inside knowledge of their workers' abilities. For example, Waldman (1984) considers strategic assignment of employees to jobs within a firm when outside firms take these assignments as signals of employees' ability. He shows that employees may not be assigned to the jobs where they would be most productive and that pay will depend on job assignment rather than strictly on ability.

Milgrom and Oster (1987) extend this idea by considering two classes of workers—a regular group and a disadvantaged group. If it is easier to hide the disadvantaged group than the regular one, then firms will not promote or pay the skilled members of the disadvantaged group as much as they pay other skilled workers. This tendency leads to persistent discrimination (i.e., lower wages and underrepresentation in senior positions) against the disadvantaged workers and less investment in human capital by members of this group. Bernhardt (1995) also assumes that incumbent firms can exploit an informational advantage regarding employee ability and that this advantage may vary across certain classes of workers. He develops a model that is consistent with several stylized facts of some labor markets. The model also predicts the so-called "Peter Principle" where some managers are promoted to positions that are no longer appropriate for their skill levels.²⁴

Although layoffs, or even voluntary turnover, may reveal a "lemons" problem in some cases, Gibbons and Katz (1991) point out that this will not be the case when a firm fails. They predict that, because of the inferences drawn by employers, the reemployment wages of a worker at a plant that closes will be higher than the wages of a worker who is laid off from a continuing operation. They find some empirical evidence to support this prediction, though follow-up

23. Lazear (1986c) also formalizes the adverse selection issue in the employment setting by putting the problem in the context of efficient turnover and auctions.

24. For alternative explanations of the Peter Principle, see Lazear (2004a), who shows that on average, early success is at least partially good luck and Fairburn and Malcomson (2001), who indicate that risk-averse managers may inefficiently promote underlings to provide them with more incentive.

studies have argued that their results are fragile (see Song 2007 and other work cited there). Nonetheless, the insight that there might be more stigma attached to losing a job at a downsizing firm than at one that is closing an operation has become widely used in the labor economics literature.²⁵

The asymmetric information literature has been quite successful at developing realistic models that match some basic stylized facts. Until recently, the models have not been tested or estimated carefully because of a lack of empirical proxies for some key parameters in these models. However, several recent empirical papers have emerged, using a variety of strategies to test for asymmetric learning. DeVaro and Waldman (2012) find evidence consistent with asymmetric learning being an important factor in one large firm's pay and promotion practices. Zhang (2007) and Kahn (2008), using the National Longitudinal Survey of Youth, find evidence that asymmetric learning is important in the broader labor market, whereas Schonberg's (2007) analysis of the same data suggests this is only true for more skilled workers.

3.3. Firing and Displacement

In addition to selecting workers when they hire them, firms have the opportunity to change their selection of workers at any time by layoffs. If firms could freely adjust wages to an employee's marginal product, then worker displacement would not be an issue, because workers would make efficient voluntary decisions about when to leave. However, because of wage compression within firms, norms against nominal wage reductions, and other factors, workers often do not voluntarily quit when firms would like them to.

Most worker displacement is simply the result of some significant negative shock to a firm or its industry or is the result of an individual proving to be significantly less productive than the firm anticipated. This type of turnover does not generate particularly interesting insights into how firms manage their human resource systems, so we do not cover it in detail here. It is worth noting, however, that displacement typically has negative and economically significant consequences for workers stemming from loss of firm-specific human capital (or match-specific productivity), stigma of losing a job, or other factors. See Farber (2005) and Kletzer (1998) for reviews of the frequency and effects of job loss in the United States and Hallock (2006) for a discussion of the layoff process.

One way that displacement affects the way firms run their personnel systems is through limits that are placed on firm's ability to dismiss workers. A firm making decisions about who to hire and whether to hire may act differently if it loses the option of correcting bad hiring decisions through dismissal. Consider a firm weighing the possibility of taking on a particular candidate. The firm trades off the expected costs and benefits of hiring that person versus its next-best option (which may be an alternative candidate or it may be to not hire at all). The firm will typically have an imperfect estimate of the benefits an employee will bring the firm, because it does not know the person's ability (or match) exactly and the firm's business environment could change in a way that affects the potential employee's marginal product.

25. This stigma of some layoffs is similar to the signal sent by not getting outside offers discussed in Lazear (1986c).

Consider a firm that is choosing between candidates A and B. Normalize the person's expected marginal product of labor in a given period (and, therefore, their reservation wage) to 0. But suppose that candidate A produces 0 for sure, candidate B produces either z or $-z$ (each with 50% probability), and output-contingent contracts are not feasible. Assuming everyone is risk neutral and the person is hired for only one period, a firm would be indifferent between the two candidates. However, if the employment match can last multiple periods, then under certain conditions and all else being equal, the firm will prefer type-B workers for their option value. In equilibrium, type-B workers will earn a wage premium and only certain types of firms will want these workers. Lazear (1998) develops a model along these lines, where he explores the market equilibrium when workers have option value.²⁶ The option value of risky workers will be highest in contexts where workers are somehow tied to their firms and where it is relatively easy for employers to dispose of workers that turn out to be unproductive.

In many cases, firms face barriers to dismissing workers stemming from legal or other institutional (e.g., union) reasons. This makes the cost of employing workers higher, lowering labor demand, and it can lead to some combination of lower wages and lower employment.²⁷ In addition to lowering overall labor demand, firing costs can reverse the logic of preferring risky workers for their option value, because substantial negative realizations relative to expected productivity can be very costly. That is, a firm that cannot lower wages substantially will want to fire a type-B worker that turns out to have productivity of $-z$. If firing costs are substantial enough, then the costs of hiring an unproductive type-B worker can outweigh the option value of having a productive type-B worker. Oyer and Schaefer (2002) model how equilibrium wages and employment will change for different types of workers when these workers differ in the observability of their abilities or productivity. They argue that increases in firing costs that are constant across workers should increase the wage premium to seniority, because employers have more precise estimates of the ability of workers with more experience. They find support for this model empirically, using labor market and civil rights litigation data around the time of an increase in employer liability for discrimination in displacement.

In addition to affecting the riskiness of workers a firm would want to hire, firing costs also affect the types of workers that a firm will displace. If the costs of firing a worker increase, a firm will be willing to live with a less productive worker, because the benefits of firing the previously marginal worker will no longer outweigh the costs. Thus, those workers whom a firm fires when firing costs are high will be, on average, of lower ability than the ones it fires when firing costs are low. Empirical support for this idea has been found using variation in firing costs generated by three different institutional settings: U.S. Civil Rights legislation, institutional barriers to worker displacement in Europe, and firing restrictions imposed by state courts and legislatures. Oyer and Schaefer (2000) find evidence consistent with this idea by using variation in firing costs by race. Extending this logic one step, the stigma that Gibbons and Katz (1991) argue

26. See Bollinger and Hotchkiss (2003) for an analysis of risky hires in professional baseball. Lazear (1998) may also apply to academic labor markets, because moving costs tie professors to their institutions while the tenure system allows schools to displace less experienced workers relatively easily.

27. As Lazear (1990) points out, perfectly efficient labor markets could undo the negative consequences of firing costs. However, as Lazear (1990), Dertouzos and Karoly (1992), DeLeire (2000), Acemoglu and Angrist (2001), and Autor et al. (2006) show, there is substantial evidence that firing costs increase unemployment.

will go along with displacement should be greater when firing costs are greater. Canziani and Petrongolo (2001) formalize this idea and find empirical support using data from Spain around the time of easing of firing restrictions in the mid-1980s. Kugler and Saint-Paul (2004) develop a similar model, focusing on the choice of firms to hire workers who are unemployed or working at other firms. Using variations in firing restrictions across U.S. states, they find that the “lemons” effect increases with firing costs.

4. Compensation

4.1. The Level of Compensation

How much will firms pay their employees? In the absence of incentive issues and any firm-specific productivity, compensation will be just enough to keep employees from leaving the firm (as long as the firm does not lose money). In equilibrium, this amount will be equal to the expected marginal product of the employee’s labor. But how do firms and employees determine an employee’s marginal product? How do they know what is a reasonable amount to pay? For some employees with a lot of experience, firms and workers have a pretty good idea of what a reasonable wage is. But when an employee enters the labor market, firms have to rely on observable features, such as the person’s education, performance during interviews, and performance on tests. Over time, firms and employees learn more about the employee’s skill and tailor jobs and his pay accordingly.²⁸

Farber and Gibbons (1996) model this learning process. Consider a person entering the labor market. The firm that hires him expects his productivity (y_{it}) to be

$$y_{it} = F(\alpha_i, X_{it}),$$

where α_i is the innate ability of worker i , and X is a set of characteristics that are observable to the firm (e.g., education). Because neither the firm nor the individual know the exact value of α , initial wages are based largely on X . However, over time, the firm observes a set of noisy signals about y_{it} and updates its estimate of α . Farber and Gibbons (1996) derive empirical implications of employer learning on the measured correlation between pay and X , as well as how pay is related to characteristics firms cannot observe at the time of hiring. Using data from the National Longitudinal Survey of Youth, they find empirical results that are broadly consistent with employer learning playing a large role in the development of wages over careers.²⁹ Altonji and Pierret (2001) develop this idea further and point out that, until the learning process is fairly developed, employers are statistically discriminating on the basis of the observable X characteristics. A key point in these models is that the level of pay will more closely approximate the worker’s marginal product as the firm and worker learn about the worker’s true ability.

Competitive labor markets do not require that workers earn their expected marginal products in any given period. Firms may set implicit contracts across multiple periods as a means of facilitating long-term relationships, providing incentives or more efficiently sharing risk. Lazear

28. See Waldman (2010) for a more detailed survey of careers in organizations.

29. Gibbons et al. (2005) and Lluís (2005) extend this learning model and the empirical analysis in Farber and Gibbons (1996) by noting that employees may have differing productivity in different ranks within a firm. Firms and workers learn about workers’ innate skills, as well as which rank best fits their skills, over time.

(1979) focuses on the long-term relationship and incentives ideas. He notes that a firm can provide incentives through fixed wages if the firm pays the worker less than his marginal product early in his career and more than his marginal product later. After a person has been at the firm for a while, he has incentives to perform well and avoid being fired to enjoy the rents he has been promised later. Because this ties the worker to the firm, it may also encourage development of firm-specific human capital. Older workers are overpaid in this model and need to be induced to leave the firm either through a mandatory retirement policy or an appropriate pension scheme.

Harris and Holmström (1982) model wage dynamics over careers when employees are risk averse and when firms and workers learn symmetrically about workers' ability. In their model, workers are insured against negative shocks to their realizations on ability. In equilibrium, individuals never have wage decreases and wages increase faster than productivity. Frank (1984) offers an alternative explanation for why workers may not be paid their marginal products and why wages are generally thought to be more compressed than productivity. He argues that, if workers care about their pay relative to their peers within the firm, high-ability workers will be willing to take a wage discount for the value they get from being near the top of the pay scale.

A look inside firms shows that actual wage dynamics are driven largely by the jobs people hold. That is, individual jobs have a fairly narrow band of possible wages. The learning process that leads to people settling into the appropriate compensation scheme over time appears to be largely about finding the right job for the person rather than finding the right pay for different people doing similar jobs. This can be seen in the firms studied by Lazear (1992), Baker et al. (1994), and several more recent studies (see Waldman, this volume, for more details).

4.2. The Mix of Compensation

Money isn't everything, but everything can be expressed in terms of its monetary equivalent. That is, in most markets, consumers pay some amount of cash in return for a good or a service. In some labor markets, such as temporary help or "under-the-table" work, transactions take this form. But most people sell labor services in exchange for a range of cash and other compensations. Interpreted broadly, the other compensations can include standard noncash benefits, such as health care, retirement benefits, and employer-sponsored child care as well as amenities, such as a large or nicely decorated office, low risk of injury or death, or a job that consists of largely interesting tasks. If all firms had the same cost structure, all employees had the same preferences, and employees could buy any amenities or benefits from other sources for the same prices the employer would pay to procure them, then labor would be traded for money and individuals would buy their own basket of benefits to best suit their needs.

However, because of institutional features (e.g., tax incentives) or economies of scale, firms often have a comparative advantage in providing benefits or amenities relative to workers. In addition, some firms are better at providing benefits than other firms, and individuals vary in terms of how they value benefits. For example, a restaurant can more cost effectively provide meals to its employees than a firm that manufactures ball bearings, and some people place a higher value on food provided by their employers than do other people.³⁰

30. For alternative justifications of certain benefits, see Rajan and Wulf (2006), Marino and Zábojník (2008), and Oyer (2008). They consider the relationship among benefits, employees' cost of effort, and productivity.

These forms of differentiation lead to two important conclusions. First, it is often efficient for firms to provide a compensation package that mixes cash with other things.³¹ Second, the total economic value of employment relationships can be enhanced by matching workers who value a given benefit or amenity with firms that have a comparative advantage in providing that benefit. That is, one of the determinants of the match-specific surplus discussed in Section 3.1 is the degree to which a firm efficiently provides amenities valued by its employees.

The classic work by Rosen (1974) laid out the theoretical foundations for this job differentiation, and Rosen (1986a) provides an intuitive discussion of how this model leads to the theory of compensating differentials in labor markets. Rosen (1974) shows how market equilibrium prices allow inferences about the monetary value of some characteristic. For example, suppose that we want to determine the monetary equivalent value of interesting work in a firm. Define X as the proportion of tasks in a given job that are new to the employee. Suppose that data were available on wages and the proportion of tasks on a job that were new per day. Consider the following regression:

$$\text{Wage on job } j = a + bX.$$

The coefficient b reveals the value that the market places on having flexibility on the job. The coefficient reflects the market value and not necessarily the tastes of any one individual. Employees who value new tasks relatively highly can earn rents by taking jobs at firms that offer many new tasks, and firms that can provide new tasks to workers at relatively low cost can earn rents by providing a relatively high proportion of new tasks. Rosen (1974, 1986a) discusses the conditions under which the market price reflects individual tastes, firm technologies, or neither.

There is an empirical literature that attempts to examine the relation of wages to nonmonetary benefits and to determine the “price” of various benefits and amenities.³² These analyses are very challenging, however, because of the effects of unobserved ability. Consider two people who are observationally equivalent (same age, education, etc.), but one has more skill that is observable to employers and unobservable to an econometrician. The more highly skilled employee will be able to command higher total compensation. However, because of regressive taxes on cash compensation and the fact that income effects will generally make the marginal utility of workplace amenities (relative to cash compensation) higher for more highly paid workers, such workers will take some of their additional compensation in the form of workplace amenities. As a result, Ehrenberg (1980) found that pensions and wages were positively correlated (when there should be a trade-off between the two), and numerous studies have shown that wages are positively related to benefits.³³ This does not mean that hedonic wage theory or the concept of

31. Employer-provided health care and pensions account for a large share of the cost of employee benefits, as well as of economics research on benefits. Gruber (2000) reviews the huge literature on employer health insurance. The large literature on pensions focuses on the various types of pensions offered and how they affect retirement behavior. See surveys by Lazear (1986b) and Lumsdaine and Mitchell (1999).

32. See Antos and Rosen (1975), Thaler and Rosen (1976), Brown (1980), and Woodbury (1983) for early examples of this literature.

33. Hamermesh (1999) and Pierce (2001) highlight an interesting implication of the income effects of benefits. They show that changes in wage inequality in the United States in recent decades understate the total increase in compensation inequality, as benefits have become relatively more generous for highly paid workers.

compensating wage differentials is wrong. It just means that measuring the market price of these differentials is difficult.

There are at least three potential ways that future research can get around the challenges presented by unobserved ability. First, if there are variables that are correlated with whether a person receives a benefit at work but not otherwise related to that person's earning potential, then instrumental variables can be used to identify the salary/benefit trade-off. Olson (2002) uses this approach to estimate that married women will accept a 20% salary reduction in return for health insurance, using their husbands' union status and firm size as an instrument for whether the women have employer-provided health insurance. Although this approach can be useful when looking at health insurance, the value of other benefits is unlikely to be high enough to allow for precise estimation of the salary/benefit trade-off. Second, detailed information on multiple job offers made to the same person can provide estimates of trade-offs, assuming the value of the employee is roughly equal to the various employers. Stern (2004) takes this approach by surveying scientists about the compensation and research components of their job offers. His estimates suggest scientists are willing to accept substantial wage decreases to engage in on-the-job research. However, highlighting a potential weakness of this approach, his estimates are imprecise, because his sample size is small and respondents' recall of job offer details is likely to include substantial measurement error. Third, given that benefits are such an important part of human resource policies, a large firm might be willing to work with economists to design experiments that randomize across workers by location. Large firms that have many locations and are known for providing generous benefits (e.g., Starbucks or Whole Foods Markets) are promising candidates. Laboratory experiments may also be helpful for learning about how people view benefits relative to cash, but the short-term and relatively low-stakes nature of that environment is likely to be an important limitation.

4.3. Equity Ownership

Over the past few decades, stock and stock options have grown as compensation tools. This trend probably reflects several factors, including attempts to increase worker incentives and the fact that, as economic growth has made workers wealthier, employee risk aversion may have gotten lower. Think about a middle manager at a large firm. If this person were truly risk neutral, he would be indifferent between taking his compensation in the form of cash or in terms of company stock. The stock would have the benefit of aligning his incentives with those of other shareholders. However, given that this manager's efforts have only a trivial value on stock holdings, it would be difficult to generate incentives unless the firm issued him huge amounts of stock (as in Holmström 1982). In this case, risk costs would certainly become important. So why do firms grant stock to employees?

One possible answer is to retain employees, as in the Oyer (2004) model we discuss below. Another possible answer is to attract the right employees. There may be several "sorting" benefits of making equity compensation part of the employment agreement, even in the absence of incentives. The manager who has many stock options and a low base salary does not earn much unless the company does well. Thus, a manager who is willing to take a job under these circumstances reveals that he believes in the company. This information may be valuable to

investors, whose information about the true value of the company is not as good as that of managers. See Salop and Salop (1976) and Lazear (2004b).

Similarly, equity compensation, like any other noncash benefits, may be used when a firm can provide it at relatively low expense and the employees value it. That is, firms can use equity-based pay to lower compensation costs by attracting employees that are particularly optimistic about the firm's prospects. A slightly different, but closely related, idea is that if workers who are optimistic about a firm are also the most productive (perhaps because of enthusiasm or an understanding of the firm's environment), then equity-based pay would just lead to the type of self-selection in Salop and Salop (1976) that we discussed above. See Oyer and Schaefer (2005) and Bergman and Jenter (2007) for theoretical and empirical analyses of this idea in the context of broad-based stock option plans.

Although attraction and retention may be important reasons to grant equity to employees, perhaps the most important justification for equity-based pay is to generate incentives. This explanation is likely to apply in small firms or among very high-level managers at large firms. These employees can have an important impact on the firm's value, and the incentive effects of ownership can outweigh the inefficiency in asking these employees to bear the risk of factors beyond their control that affect firm value.

4.4. Executive Compensation

One set of workers that has been widely studied, with much of this work falling in the arena of personnel economists, is top executives. There are several reasons executives have received more than their share of attention in the personnel economics literature.³⁴ First, executives (and especially CEOs) receive a great deal of compensation. The average CEO of a large American company now makes several million dollars per year, and the growth rate over the past few decades has been much faster than for compensation more generally. Second, due to disclosure regulations, publicly traded firms have to provide information about both executive compensation and company performance. This information allows empirical economists to create large datasets of individuals' pay and "performance" (where performance is a firm's stock return or measures based on a firm's or division's accounting statements). For these reasons, CEOs and other executives have been widely studied.

Murphy (1999) documents the rise in executive-related academic work and provides a summary of this literature. We refer readers interested in details on the institutional features, the level and structure, and the politics of executive pay to Murphy's review.

However, we highlight a few stylized facts from the executive compensation literature that relate directly to personnel economics. First of all, as one might expect, given the large effect CEOs can have on firms' outcomes and the relatively easy availability of performance measures, CEOs have high levels of incentive-based pay. Much of it is based on explicit incentives, such as performance-contingent bonuses and equity ownership. A smaller, but important, amount of incentives comes in the form of subjective or implicit incentives, including adjustments to salary and bonuses not tied to objective metrics. These incentives vary in ways that most theories predict, with stronger incentives at firms where the marginal product of the CEO is likely to be higher (e.g., larger firms, those with more capital, and unregulated firms).

34. This is certainly true on a per-worker basis and is probably still true on a per-compensation-dollar basis.

Murphy (1999) also shows that executive turnover is somewhat based on firm performance, but that the relationship is not as strong as one might expect and, at least as of the time of his writing, had weakened over time. In addition, he shows that there is a surprising lack of RPE in executive pay. Executives are rewarded (penalized) for good (bad) macroeconomic conditions, though it would seem easy for firms to filter this uncontrollable risk out of pay/performance contracts.

Murphy's (1999) survey ends with suggestions for future research. He asked why RPE is rare.³⁵ Numerous explanations have been suggested since Murphy posed the question. First, in trying to justify the lack of RPE for executives, Garvey and Milbourn (2003, 2006) have provided both supply (i.e., executive-driven) and demand (firm-driven) explanations. They argue that there is RPE for some executives, but that the average effect is small, because there are many cases where RPE is not used. In Garvey and Milbourn (2003), they argue that RPE is unnecessary once an executive attains sufficient wealth. Once his assets that are not part of current compensation are large enough, he can completely undo any position in the firm's stock in his private portfolio such that the use of RPE is irrelevant. Consistent with this idea, they find that younger and less wealthy CEOs, who are less likely to have sufficient assets to unwind compensation contracts imposed by the firm, are more likely to be subject to RPE. Garvey and Milbourn (2006) suggest that CEOs will try to influence boards of directors to limit RPE when the market is performing well. They then show empirically that CEOs are more likely to have their pay indexed during bad times than during favorable markets.

Aggarwal and Samwick (1999b), influenced by an idea proposed in Fershtman and Judd (1987), suggest that RPE will be counterproductive when products are strategic substitutes (as in differentiated Bertrand markets) and when market competition is imperfect. Pay based on relative output will lead managers to be too aggressive in product market competition. They find empirical support for this idea by showing that the typical level of RPE is higher when product market competition is more intense.

Oyer (2004) models a case where adjusting compensation contracts is costly and employees' reservation wages are correlated with their firms' performance. Firms provide at least some compensation in the form of equity ownership, because this will give workers a raise when there is greater demand for their services and a pay cut when labor demand is lower. Options or shares in the firm's stock can therefore serve two purposes: providing incentives and adjusting pay to market rates. RPE is useful for incentive purposes, but firms would not want to insulate employees from marketwide conditions when equity compensation is used for the other purpose.

Yet another possible explanation for the lack of RPE is that the marginal return to effort may be correlated with the state of the market. Suppose the firm's value Π is an additively separable function of the CEO's effort e , macroeconomic conditions θ , and an idiosyncratic shock ϵ , so we can write $\Pi = v_1 e + v_2 \theta + \epsilon$. Then it is clearly optimal to filter out the macroeconomic effects. But if the marginal product of effort v_1 is correlated with the macroeconomic conditions θ , then the optimal contract will be an increasing function of θ .

35. See Bertrand and Mullainathan (2001) for details on the lack of RPE in executive compensation. Note that Murphy (1999) also posed the question of why executive pay has increased so much in recent decades. Several explanations have been put forward. However, because these explanations are largely a debate about corporate governance rather than personnel policies, we do not address that issue here.

Just as we might expect CEO pay to use RPE, we might also expect relative outcomes to affect CEO dismissals. Barro and Barro (1990), who focused on bank CEOs, found that pay is not related to relative outcomes but turnover is. Two more recent and broader studies, however, show that CEO turnover is affected by both overall market conditions and relative performance of individual firms. Jenter and Kanaan (2011) and Kaplan and Minton (2008) both show that CEO turnover is higher when the firm's industry performs poorly and when the firm underperforms the industry.

5. Skill Development

The analysis and discussion to this point have been naïve in assuming the person's ability and match-specific productivity as given. In reality, people develop skill over time both before and after joining a given firm, and this skill development affects productivity. As Becker (1964) laid out in his classic study of human capital, people can develop general skill that is equally useful to multiple employers (and, therefore, becomes part of what we called "ability," or α , in Section 3.1) or that is more useful to one employer than to any other (and, therefore, becomes part of the match-specific component μ in Section 3.1).³⁶

Becker (1964) argued that the efficient way to divide the investment costs of skill is for firms to pay for firm-specific human capital acquisition of workers and for workers to pay for their own general human capital. Any other means of splitting human capital investments costs will lead to the potential for the firm or the worker to hold up the other party after sinking the cost of a relationship-specific investment.

This allocation of human capital investment clearly applies in most situations and, in particular, when the investment is large. For example, almost all people pay the cost of their own secondary, college, and graduate education. There are exceptions, such as firms that sponsor their employees earning MBAs, but these arrangements often come with a contractual commitment not to leave the firm for some set period. Similarly, firms generally pay employees the going wage during training periods and early in job tenure while the employee is largely acquiring the skill and knowledge necessary to be productive in a given firm.³⁷

Recently, some papers have argued that Becker's optimal allocation of human capital investments does not appear to be applied in certain situations and have tried to explain why. There are situations that are fairly clear examples of firms paying for the acquisition of workers' general human capital. For example, Stanford University offers free computer training in a variety of programs to all employees, sometimes including programs not related to a person's current job. Employees who take advantage of this suffer no compensation ramifications and are allowed to attend training while being paid. A series of recent papers has attempted to explain

36. One important idea related to human capital is the extent to which incentives to acquire general and firm-specific human capital are related to promotions, careers within organizations, and even optimal organizational form. See Kahn and Huberman (1988) on firm-specific human capital and up-or-out contracts, Waldman (1990) on general human capital and up-or-out contracts, Prendergast (1993) on the relationship between promotion and firm-specific human capital, and Levin and Tadelis (2005) on partnerships in high-skill industries.

37. Note that it is often difficult to determine whether a firm or a worker have paid for the acquisition of skill, because generally we do not have complete information on both the compensation arrangements in a given job and what those arrangements would be in the absence of skill acquisition.

why situations may arise where firms find it in their best interest to pay for employees' acquisition of general human capital. Most of these papers focus on the same informational advantage of incumbent firms modeled by Greenwald (1986) and discussed above.

An example is Autor (2001), who focuses on a specific example that clearly violates Becker's model. Manpower Associates is a large U.S.-based temporary help services firm. This firm offers potential "temps" free computer training. The training provides skill in common computer programs, is completely free to the person, and is not coupled with any obligation to work for Manpower. A person can take this class and then go down the street to another temp agency or any other employer and use her new computer skills.

Why would Manpower offer such a program? Building on ideas in Katz and Ziderman (1990), Autor (2001) argues that the process of training gives the firm asymmetric information about the ability of the temporary worker. The firm then can use that information to match temps to assignments in a way that creates rents, at least until the person has been out on enough assignments that another temporary agency can infer her ability and where to assign her. He argues that this information advantage may be made even more valuable when free training helps a temporary help agency attract higher quality workers. He develops a model of the agency's acquisition and exploitation of private information, arguing that it will lead to particular relationships between market wages, training, and the degree of local temporary labor market competition. He then uses data from a Bureau of Labor Statistics survey of temporary service suppliers and finds evidence that is consistent with the model's predictions. For example, firms that offer free training offer slightly lower wages, but this gap gets smaller in more competitive markets.

Acemoglu and Pischke (1998) offer a related explanation for firms making investments in general human capital, based on the information structure in Greenwald (1986). In their model, firms have some level of monopsony power over workers and can capture some of the rents associated with acquisition of general human capital. Because workers do not capture the full value of general human capital investments, they will underinvest in these skills. Some firms may therefore find it profitable to sponsor this training. They find evidence consistent with the predictions of their model using a test, in the spirit of Gibbons and Katz (1991), that looks at the relative wages of German apprentices who stay at the firm that trains them, those who quit and move to another firm, and those who quit for an exogenous reason (random selection into the military).

In another study, Acemoglu and Pischke (1999) show that, even in the absence of information asymmetry, firms may sponsor general training if wages in the labor market are compressed relative to workers' marginal products. This compression, which they argue can arise from search costs or other transaction costs or from institutional factors (e.g., unions and minimum wages), may differ across labor market settings, leading firms in some markets to be relatively likely to sponsor human capital investments.

Another justification for firms making investments in worker general human capital is that it may provide incentives for the employee to stay at the firm while in training. Manchester (2008) analyzes data from a single nonprofit institution's training programs and from a cross-section of firms. She finds that training is related to increased employee retention.

The work by Autor, by Acemoglu and Pischke, and, to a lesser extent, by Manchester focuses on general training of relatively low-skilled workers. There are interesting examples of

firm-provided general human capital for higher skilled workers, often including cases where the training is highly visible to outside employers. For example, both of us (the authors) previously held positions at business schools that offered part-time MBA programs for people with full-time jobs. Most of these students were sponsored by their employers and were not paid less than people doing similar jobs (though some firms required workers to partially repay these investments if they leave before a specified time). Future research focused on advanced training and degree programs might provide useful insights into optimal human capital investment for highly skilled workers.

6. Organization of Work

To this point, we have acted as though a firm picks a single worker to do a well-defined set of tasks. However, in reality, firms are made up of a group of diverse people doing different sets of tasks. In this section, we briefly look at how firms decide who does what, who works with whom, and who works for whom.

6.1. Job Design

Most firms beyond some minimum size set up organization charts that show individual jobs designed to do some set of tasks. Several studies of individual companies, including Lazear (1992), Baker et al. (1994), and Gibbs and Hendricks (2004), show how firms divide jobs into well-defined pay grades. Given this importance of jobs, how do firms divide tasks into jobs? There has been very little empirical analysis of this question because of the difficulty in measuring, categorizing, and describing the tasks workers perform in a day. In addition, the way tasks are combined into jobs is often driven by obvious cross-task complementarities (e.g., teaching and research for professors or sales and service for copy machine providers). However, there have been numerous theories emphasizing how incentives, an employer's desire to learn about employees, the firm's production function, and other factors may affect job design.

Prendergast (1995) models the interaction of human capital, incentives, and job design. If performing tasks provides human capital, managers will hoard tasks and overextend themselves. Prendergast's paper and related ones on incentives and job design consider who will determine what tasks should be performed, as well as how to bundle tasks into jobs. For example, Zábojník (2002) shows that firms may want to let workers decide what to do even when the manager has superior information, if worker liquidity constraints limit the available incentive contracts. Olsen and Torsvik (2000) add a dynamic element to this issue. They show that the ability of the firm to learn about the difficulty of the tasks workers engage in will induce the firm to give workers more discretion over tasks and weaker incentives. Specifically, this learning process will mute the positive correlation between discretion and incentives predicted by static models. Crémer (1986) also analyzes job design in a dynamic context. He focuses on the relationship between job design and career concerns when firms want to promote cooperation among employees.

Holmström and Milgrom (1991) note that firms may want to bundle tasks with similar degrees of measurability, so that workers do not ignore tasks that are difficult to measure. Itoh (1994) and Schöttner (2007) show that the implications of multitask considerations for task assignment differ depending on the circumstances. Itoh (1994) notes that, when individual task

outcomes cannot be measured, firms will make workers generalists by bundling all tasks into one job, while Schöttner (2007) shows that the ability to write relational contracts will mitigate some of the potential concerns of assigning multiple tasks to a single job.

The models just discussed generally explain why firms may have different jobs even if workers are homogeneous. But, even if these are the reasons that firms differentiate jobs, an important consideration in jobs will be assigning heterogeneous workers to jobs that match their skills. Rosen (1978) focuses on worker heterogeneity in his model of matching firms and workers based on the tasks firms need done and the comparative advantage of workers in performing each of these tasks. (For a review of assignment models, see Sattinger 1993.) In many ways, this model matches firms to workers based on tasks the same way that Rosen (1986a) models the matching of firms and workers based on employee preferences. A similar model underlies the analysis in Gibbons et al. (2005), which highlights the importance of assigning workers to their most productive sectors. Gibbons and Waldman (2006), however, develop a model where workers develop task-specific human capital, so that a person's job assignment has important effects on how her career develops.³⁸ The lack of good empirical proxies for how firms assign tasks to jobs makes it difficult to assess the relative importance of these models that emphasize optimal matching of heterogeneous workers to tasks and the homogenous worker models discussed above, but it seems likely that these matching concerns are first-order determinants of job design.

6.2. Teams, Worker Interaction, and Human Resource Practices

Successful human resource management is not simply a matter of giving each individual proper incentive to engage in work in isolation. If it were, there would be no need for the firm. Perhaps the greatest value of the firm is that it provides a mechanism for people to work together and take advantage of complementarities in their skills and interests. The evidence that there can be gains from assembling workers into teams or groups has to be done at a firm-by-firm level because of the need for data on productivity and team structure. As a result, much of this work falls into the category of "insider econometrics." Ichniowski and Shaw (this volume) review this method. We briefly discuss a few papers related to the issue of group incentives.

Hamilton et al. (2003) study a garment manufacturer that switched from an individual piece rate system to group-based piece rates. Workers were given some discretion over when they made the switch. Though the most productive workers had the most to lose financially from the switch, they tended to be early adopters. Productivity went up (and stayed higher) overall, suggesting that collaboration was valuable at this company. The gains were greater for more heterogeneous teams, and abler team members had a bigger influence on others' productivity than did less able team members. Not all manufacturers get such positive results from the switch to teams, however. King (1998) provides anecdotal evidence of a much different (and much less successful) transition to teams at Levi's.

Boning et al. (2007) look at the effects of team production in the steel industry. Most firms in their sample pay some sort of group-based incentive, but only some organize their workers

38. Also see Garicano and Rossi-Hansberg (2006) on dividing tasks based on skill level, though they do not focus on within-firm task allocation.

into cooperative teams. They find that productivity is higher at firms that use teams and that this effect is especially large where the product and production process are more complicated. Incentive pay is also associated with higher productivity at these firms.³⁹

What are the sources of these group-based productivity benefits? In some cases, groups allow people to solve problems better and to take advantage of different skills. Gant et al. (2002, 2003), again focusing on the steel industry, show that interactions among a larger set of workers are associated with higher levels of production.

Mas and Moretti (2009) show how supermarket clerks are affected by the productivity of other clerks working at the same time. They find that high-productivity clerks increase the productivity of peers. Like Hamilton et al. (2003), they find larger productivity gains when groups of workers are more diverse in skill. Mas and Moretti (2009) also find evidence suggesting social pressure is important, because productive checkers have larger effects on peers who can see them while they work. Similarly, Ichino and Maggi (2000) show that absenteeism and misconduct has an effect on peers in an Italian bank.

In addition to these field studies, Falk and Ichino (2006) find noteworthy peer effects in an experimental environment. Subjects were given a mundane task (stuffing envelopes) and no financial incentive. Average worker productivity was higher when each person worked in the same room as another person than when people worked in isolation. The least productive workers were the most affected by working in a group, so the increase in their output more than made up for the decrease in output of the most productive workers. The results of all these studies taken together suggest that, at least in many environments, people prefer working in groups to working in isolation, people working in groups feel some pressure to keep up with the efforts of those around them, and/or the most productive workers pressure others into working harder.

As the theoretical work of Milgrom and Roberts (1990) and Kandel and Lazear (1992) suggests, the effectiveness of team-based systems is likely to vary from firm to firm because of complementarities across human resource practices. That is, team-based productivity may be more important when firms invest in selecting employees carefully, training people in the system, and other practices. Testing this idea empirically is challenging, however, because measuring productivity is difficult, and human resource practices are adopted endogenously. Several studies (see, e.g., Black and Lynch 2001; Cappelli and Neumark 2001; Bloom and Van Reenen 2007) have shown that the adoption of various workplace practices tends to be done simultaneously, suggesting complementarity between the practices. They are also associated with and likely cause increased productivity in the firms in which they are adopted. However, it is difficult to make any causal statements about these relationships.

Ichniowski et al. (1997) allay this concern to some degree by looking at productivity of individual steel production lines around the time of adoption of modern human resource practices. They show that these practices increase productivity in these factories and that the marginal effect of each practice is increasing in the adoption of other practices.

39. Incentives are group-based in these steel mills. However, even when people work in groups, firms may want to use individual incentive pay to keep workers from colluding (either against the firm or against other workers). Bandiera et al. (2009) show that managers on a fruit picking farm allocate workers more efficiently when the managers are given incentive pay. Some of this productivity improvement comes at the expense of the managers' friends, who receive worse assignments under the incentive pay plan.

6.3. Hierarchies

Most people work in a hierarchy with several levels of reporting responsibility. There are many contributing factors to this standard institutional arrangement, and we do not investigate it in any great detail here, because it is the focus of Garicano and Van Zandt (this volume).

As we noted in some detail above, one benefit of hierarchies is that they provide incentives. Hierarchies can also be a substitute for incentives, however, in that they can provide a mechanism for monitoring employees directly. Lucas (1978), formalizing ideas in Manne (1965) and elsewhere, develops a model where some people are simply endowed with superior management skills. These skills can be interpreted as monitoring, decisionmaking, motivating, or any other skill that would be more valuable for a manager than for other employees.

Rosen (1982) distinguishes between the managerial tasks of making choices about what to produce, strategy, and the like ("management") and ensuring that employees carry out these decisions ("supervision"). To best utilize superior management skills, it would be efficient to grow firms ever larger. However, there are diseconomies of scale in supervision, so optimal firm size trades off these two factors. Rosen's (1982) model can explain skewed firm size within an industry and skewed compensation within a firm.

Garicano (2000) models hierarchies as a means of matching problems to those in an organization that can most efficiently solve them. There would be no need to use a hierarchical structure for this issue if everyone knew who was capable of solving which problems. But when there are costs of communicating this knowledge, expertise organized by levels efficiently assigns the right person to the right problem. Hierarchies are arranged with the highest skilled person at the top, the next-highest skilled people at the next level, and so on to the lowest skilled workers at the bottom. Each new problem enters the firm at the lowest level and gets bumped up the hierarchy until it reaches the person who can solve it. Given the increasing importance of services and knowledge workers, this idea of knowledge-based hierarchies has become more important. See Garicano and Van Zandt (this volume) for discussion of recent related work.

7. Conclusion

We have described a great deal of progress in the personnel economics literature. This research has helped explain how firms operate and has helped shape business education curricula in recent years. So it seems sensible to ask, where do we go from here? There is plenty of room for more work, especially empirical work, in all the areas we have discussed. But it seems likely that the highest returns will come from careful analyses of the selection, sorting, and matching processes. How do firms find the right workers? How important is it that firms find the right workers for their particular context? Business school curricula and the business press are filled with many case studies of firms that highlight finding people who match their specific needs (Southwest Airlines, SAS Institute, and Whole Foods Market are prominent examples). How do these and other companies generate economic value by finding the right people?

Another question worth further pursuit is how employees value different fringe benefits. As employees become wealthier and as technology breaks down the work/leisure divide, firms are likely to find noncash compensation more strategically useful. Some types of on-the-job skill development that we discussed can also be thought of as noncash benefits. Why do firms train

employees in computer skills and send them to executive education training? Is it to increase their productivity, to reward them, or to signal something to or about them?

In addition to these broad areas, we have also noted some specific questions presented by recent work that are worth pursuing. What explains the lack of evidence to support the risk/incentive trade-off predicted by moral hazard models? Are American executives overpaid? How would we ever know? Other questions will emerge as external and institutional features evolve. For example, if the returns to skill continue to increase, how will firms manage the reorganization process as they pay for greater skill while trying to economize on low-skill jobs? What problems, if any, will result if internal pay differentials grow too large?

Two empirical methods have become useful in answering these and other questions, and we expect them to continue to grow in influence in personnel economics. First, studies of single firms, often involving a field experiment, can provide precise analysis of the effects of various human resource policies. This approach has proven effective in studying incentives, team-based production, and the role of jobs, despite the lack of generalizability of these studies. Well-crafted future studies (and perhaps experiments) can broaden the value of this method to selection, the wage/benefit trade-off, the use of subjective performance evaluation, training, and other areas.

The other method is the exploitation of employer-employee datasets, which have become much more prevalent in recent years.⁴⁰ These data can provide rich time series detail about firms' pay structure, growth, employee tenure, and so on. The lack of detail on firms' human resource practices makes it challenging to frame an economic question in a manner that can be addressed across the whole dataset. But careful modeling and/or focusing on certain industries or types of workers often helps make the exercise manageable.

Personnel economics has come a long way in the past few decades. We have learned a great deal about the underlying economics of human resource policies. But through the methods and ideas we have just mentioned, as well as others we have overlooked or that have not yet been discovered, we believe there will be much more learned in the next few decades.

Theory and Evidence in Internal Labor Markets

Michael Waldman

1. Introduction

During the past 30 years economics has made great progress in moving beyond treating the firm as a “black box” and understanding various aspects of its internal operation. One area, in particular, where substantial progress has been made is that of internal labor markets.¹ In this chapter I do not broadly survey the now-extensive literature on this topic (for broad surveys, see Gibbons 1998; Gibbons and Waldman 1999a; Lazear 1999; Lazear and Oyer, this volume) but rather focus on connections between theory and evidence in this literature. In particular, pursuing a theme first explored in Gibbons and Waldman (1999a), I explore the extent to which patterns of empirical evidence can be used to choose among competing theories.

Most of the early literature on internal labor markets was theoretical, and these papers typically fall under one of two main approaches. One approach was to identify and model a fundamental factor concerning the operation of internal labor markets. Important works here include Becker (1962, 1964) on human capital, Holmström (1979, 1982) and Shavell (1979) on agency theory, and Rosen (1982) on the allocation of workers across a job ladder. Clearly these are important contributions. But mostly these papers were not focused on the extent to which the models developed are able to capture important empirical relationships.

I thank Jed DeVaro; Suman Ghosh; Jin Li; Hodaka Morita; Bryan Ricchetti; Jan Zábojník; the volume editors, Bob Gibbons and John Roberts; and participants at the meeting of the NBER Working Group in Organizational Economics devoted to reviewing early drafts of chapters from this handbook at Stanford for helpful comments. I especially thank Bob Gibbons for numerous conversations that have helped develop my thinking on this subject, and Jin Li and Hodaka Morita for help in reviewing the literature.

1. Doeringer and Piore (1971) originally employed the term “internal labor market” to refer to the human resource practices of a firm (or part of a firm) that employs ports of entry, promotion from within, wages attached to jobs, and job ladders. Their analysis focused mostly on blue-collar settings and was mostly descriptive rather than based on statistical analysis. Consistent with more recent literature, I use the term to refer to various issues concerning a firm’s labor force when the labor force exhibits long-term attachments to the firm. With this usage the term can be used to describe either blue- or white-collar settings. Alternative terminology would be to refer to “personnel economics” or “careers in organizations” rather than “internal labor markets.”

The second approach was more closely tied to the empirical evidence in that the focus was typically on providing an explanation for an important empirical phenomenon. Important papers here include Lazear's (1979) model of mandatory retirement; Lazear and Rosen's (1981) seminal model of labor-market tournaments that provides an explanation for large wage increases associated with promotion; and Waldman (1984a), which explores the signaling role of promotions and provides a competing explanation for large wage increases upon promotion.

But as the literature has matured, two related questions have become central. First, when there are competing theories for a phenomenon, which one best captures the correct real-world explanation? For example, both tournament theory and promotions serving as signals provide explanations for why promotions are typically associated with large wage increases. How should we choose between these theories, or possibly, what would lead us to conclude both are at work? Second, empirical phenomena should not be viewed in isolation. If, for example, tournament theory is the correct explanation for large wage increases at promotion, then this has implications for the correct explanation for other internal labor market phenomena. In other words, many of these phenomena are inherently intertwined, so there should be a single model or a set of related models that explain related phenomena rather than a completely different model for each fact.

More recent literature makes progress on these issues in one of two ways. First, on the empirical side, rather than focusing on a single fact or phenomenon, many papers present a pattern of evidence on related issues. Early papers in this category are the Medoff and Abraham (1980, 1981) papers on performance evaluations and wages. More recent important papers include Baker et al. (1994a,b) on wage and promotion dynamics and the Ichniowski et al. (1997) investigation of human resource practices.

Second, some more recent theoretical studies focus on whether the model is consistent with patterns in the empirical evidence rather than with a single fact or empirical phenomenon. Examples of papers in this category are Milgrom and Roberts (1990), Bernhardt (1995), and Gibbons and Waldman (1999b, 2006). Milgrom and Roberts (1990) show how complementarity across work practices can explain various standard findings concerning innovative work practices, while Bernhardt (1995) and Gibbons and Waldman (1999b, 2006) provide models that explain various findings concerning wage and promotion dynamics inside firms.

This survey focuses on this agenda. That is, it focuses on how patterns of evidence can be used to choose among plausible alternative theoretical approaches, where (not surprisingly) sometimes the evidence points toward a combination of theories being the right answer. I also try to highlight the open questions. Given the focus of the chapter, rather than providing a comprehensive survey of the internal labor market literature, I consider specific topics where the literature is sufficiently mature that focusing on patterns of evidence and theories that can address these patterns is a worthwhile exercise.

The three specific topics I consider are wage and promotion dynamics, human resource practices, and international differences. Sections 2 and 3 consider the literature on wage and promotion dynamics. Section 2 surveys empirical evidence, including basic empirical findings, the role of schooling, and the role of performance evaluations. Section 3 then discusses four candidate models for explaining the evidence and also provides an overview and synthesis. Sections 4 and 5 consider the literature on human resource practices. Section 4 begins with a description of the different types of evidence available and then proceeds to survey the evidence

concerning the effects of adoption and patterns of adoption of innovative human resource practices. Section 5 discusses relevant theories. Section 6 considers international differences in internal labor market operation, where most of these differences are closely linked to differences in human resource practices. Here most of the focus is on U.S.-Japanese differences and the various theoretical models that have been put forth to explain these differences. Section 7 concludes.

2. Empirical Evidence on Wage and Promotion Dynamics

This section starts with a discussion of basic empirical findings and then follows with discussions of the role of schooling and performance evaluations. Some evidence concerning wage and promotion dynamics is found in tests of specific theoretical models. Much of this evidence is discussed in Section 3, which focuses on theory.

2.1. Basic Empirical Findings

Although most findings in this section appear in Baker et al. (1994a,b), most of the focus is on findings with support both there and elsewhere. Other important papers in this literature include Lazear (1992), McLaughlin (1994), McCue (1996), and Podolny and Baron (1997). Note that some of these studies are similar to the Baker et al. study in that the data are drawn from a single firm's personnel records, whereas others analyze data drawn from broader cross-sections. Also, like Baker et al., some studies focus on white-collar workers, whereas others consider both blue- and white-collar workers. For each finding I provide a list of papers that find supporting evidence (and where appropriate papers that find contradictory evidence), but because of the rapid growth in this literature I do not attempt to provide an exhaustive list for each finding.²

The first finding is that real wage decreases are not rare, but nominal wage decreases and demotions are. That real wage decreases are not rare is found in Baker et al. (1994a,b), McLaughlin (1994), and Card and Hyslop (1997). Baker et al. find that real wage decreases are more frequent in high-inflation environments, which suggests a lag in the wage-adjustment process, but some real wage decreases are seen even with low inflation. The same papers find evidence of a low rate of nominal wage decreases. In terms of demotions, in addition to Baker et al., some studies—including Seltzer and Merrett (2000) and Treble et al. (2001)—find that demotions are rare. A few exceptions, however, find a significant rate of demotions, including the Dohmen et al. (2004) study of Fokker Aircraft's decline and Lin's (2005) study of low-level salespersons in a Taiwanese firm.

A second finding with significant support is serial correlation in promotion rates; that is, a worker promoted quickly from, say, level one to level two will on average earn promotion to level three more quickly. This is sometimes referred to as a fast track. Support for this phenomenon is found in Rosenbaum (1984), Baker et al. (1994a,b), and Podolny and Baron (1997). Belzil and Bognanno (2010) use a structural estimation approach to investigate what drives fast tracks.

2. One recent paper specifically worth mentioning is Kauhanen and Napari (2011), which finds empirical results similar to those found in Baker et al. (1994a,b) but which investigates a large linked employer-employee dataset.

They find that fast tracks are mostly driven by individual heterogeneity rather than by early promotions increasing the probability of a subsequent promotion. In other words, their findings suggest that fast tracks are mostly driven by workers with certain characteristics having a high probability of earning multiple promotions, as opposed to an early promotion having a direct causal effect on the likelihood that the worker receives a subsequent promotion.³

A third finding is serial correlation in wage changes. Here the evidence is mixed. Evidence in favor of the finding appears in papers focused on relatively homogeneous samples such as the Baker et al. analysis of the managerial workforce of a single firm, the Lillard and Weiss (1979) study of American scientists, and Hause's (1980) study of young Swedish males. Such studies as Abowd and Card (1989), Topel (1991), and Topel and Ward (1992) look at heterogeneous samples, such as the Panel Study of Income Dynamics (PSID), and do not find the result. One exception is Baker (1997), which finds serial correlation in wage changes using the PSID. A possible reason that paper finds different results is that it considers a larger panel than the other studies and also uses different econometric tests.

Another finding, this one with strong support, is that promotions are associated with large wage increases. This has been found in numerous studies, including Lazear (1992), Baker et al. (1994a,b), and McCue (1996). There is also strong evidence, however, that wage increases at promotion are small relative to the difference between average wages across adjacent job levels. This result is found in Murphy (1985), Main et al. (1993), and Baker et al. (1994a,b). Evidence in Murphy (1985) nicely illustrates the finding. In a study of large U.S. manufacturing firms Murphy found that (1) the average real increase for vice presidents promoted to president was 21% and (2) the average salary plus bonus for presidents was 60% higher than for vice presidents. Although at first these findings may seem contradictory, as discussed in more detail later, they are actually easy to reconcile, given that on average wage changes are positive in periods where no promotions occur.

The last two findings have less support in the literature, possibly because these issues have been less studied than the previous ones. The first is that large wage increases early at a job level predict subsequent promotions. Baker et al. (1994a,b) demonstrate this result; related evidence is found in McCue (1996). The last finding is that wages exhibit cohort effects; that is, a cohort's average wage as it ages is related to the average starting wage even after controlling for composition differences across cohorts. This is found in Baker et al. (1994a,b) and, more recently, in Oyer (2006), Kahn (2010), and Oreopoulos et al. (2012), which look at economywide or industry-level cohort wages. Also, related findings appear in Beaudry and DiNardo (1991), which is discussed in more detail in Section 3.1.2.

2.2. The Role of Schooling

This section discusses empirical findings that specifically relate to the role of schooling in wage and promotion dynamics. The first result, which I take as noncontroversial so I do not list papers that find it, is that schooling positively affects the starting wage. Certainly, if this were

3. In contrast, Ariga et al. (1999) consider fast tracks in a large Japanese firm and find in that case fast tracks are not primarily driven by individual heterogeneity. See also Clemens (2010).

not the case, many of us would likely be unemployed, because the demand for undergraduate and graduate teaching would be significantly reduced.

A second finding is that schooling is positively related to promotion probabilities. Supporting evidence can be found in Baker et al. (1994a,b), McCue (1996), Lluís (2005), and Lin (2006), although McCue's study, which focuses on the PSID, finds a statistically significant relationship only for white men. Lluís (2005) also shows a related finding. As will be discussed in the next section, one explanation for why schooling is positively related to promotion probabilities is schooling is positively related to worker ability, and worker ability is positively related to promotion probabilities. Thus, controlling for worker ability should weaken the positive relationship between schooling and promotion probability. Lluís finds such a result. Specifically, when she includes a lagged value of each worker's wage growth, which should be a noisy measure of ability, the positive relationship between schooling and promotion probabilities becomes weaker.

A third finding with strong support is that schooling is positively related to wage level even after controlling for experience and job assignment (Medoff and Abraham 1980, 1981; Baker et al. 1994a,b). In each case the authors run Mincerian regressions that include job level and find that schooling is positively related to wage level even after controlling for experience and job level.

A final finding, where the evidence is mixed, concerns schooling and the returns to experience. Farber and Gibbons (1996), using data from the National Longitudinal Survey of Youth, regress the wage level on various variables, including schooling, experience, experience squared, a test score unobserved by employers, and various interaction terms. When they include controls for changes in the return to education over time they find that extra schooling does not change the return to experience.⁴ In contrast, Rubinstein and Weiss (2007) use three datasets—the Current Population Survey short panel, the PSID, and the National Longitudinal Survey of Youth—directly to consider how earnings growth over various career intervals is related to schooling. They find strong evidence that schooling is positively related to the return to experience. Also, in a study using the Current Population Survey, Habermalz (2006) allows for nonlinearities and finds results consistent with schooling being positively related to the return to experience.⁵

2.3. The Role of Performance Evaluations

The final issue I consider is the role of performance evaluations. Few papers have considered this topic, so many of the results are taken from Medoff and Abraham (1980, 1981). These authors' main focus was on a discrepancy between the way wages depend on labor market experience and firm tenure and the way performance evaluations depend on these two factors. Specifically, they find that within a job wages are strongly positively related to labor market experience and

4. An alternative approach is to use a logarithmic wage specification explored in a large literature starting with Mincer (1974) (for surveys, see Willis 1986; Card 1999). A standard finding in this literature is that log wage is positively related to schooling, which suggests that the absolute return to experience increases with schooling. But in his original study Mincer also adds an experience-schooling interaction and finds a significant negative coefficient. This findings throws some doubt on whether the return to experience is truly increasing with education level.

5. Gibbons and Waldman (2006) argue that the finding of Farber and Gibbons (1996) that the return to experience is not increasing with education may be due to the limited time period studied.

firm tenure, whereas performance evaluations are either unrelated or slightly negatively related to these variables. In interpreting their results they question the idea that much of wage growth is the result of accumulation of human capital, but as I discuss in Section 3.4.1, there are other possibilities.

A related finding is that the magnitude of the negative relationship between performance evaluations and labor market experience depends on the manner in which the test is conducted. Specifically, the negative relationship between performance evaluations and labor market experience is larger in absolute value in cross-sectional analyses than in longitudinal analyses on the same dataset (Medoff and Abraham 1980, 1981; Gibbs 1995). This finding suggests that some of the negative relationship found in cross-sectional analyses is due to the sorting of workers across jobs and firms over time stemming from promotions and exits as workers age.

Another set of findings is that high performance evaluations today predict good future outcomes. For example, Medoff and Abraham (1980, 1981), Dohmen (2004), and DeVaro and Waldman (2012) find that performance evaluations are positively related to future promotions and future wage increases. Also, as is discussed in more detail in Section 3.3.2, DeVaro and Waldman find that, holding performance fixed, the probability of achieving a promotion varies with education level.

A final point here about the Medoff and Abraham interpretation of their results is that it is important to consider what performance evaluations actually measure. If such evaluations are a completely unbiased measure of productivity, then these authors' interpretation of their main findings would almost have to be correct. But that this is the case is not clear cut. It is quite possible that workers are evaluated relative to a specific set of peers, where the comparison group changes over time as workers age and move up the job ladder. As is discussed in more detail in Section 3.4.1, if this is the case, then other possibilities arise concerning what may be driving the main findings of Medoff and Abraham (1980, 1981).

3. Four Candidate Models

This section discusses four theoretical approaches that can be used to address the empirical facts presented in Section 2: (1) symmetric learning and insurance, (2) the tournament approach, (3) promotions as signals, and (4) symmetric learning with human capital accumulation and job assignment.⁶ The end of the section provides an overview and synthesis.

3.1. Symmetric Learning and Insurance

This section discusses Harris and Holmström's (1982) model of symmetric learning and insurance (see also Freeman 1977). As is made clear below, this model does well at capturing various

6. There are other theoretical approaches one might consider. These include delayed compensation (e.g., Becker and Stigler 1974; Lazear 1979, 1981), the efficiency wage argument (e.g., Calvo 1979, 1985; Shapiro and Stiglitz 1984), influence costs (e.g., Milgrom 1988; Milgrom and Roberts 1988), knowledge hierarchies (e.g., Garicano 2000, Garicano and Hubbard 2005; Garicano and Rossi-Hansberg 2006), social preferences in the workplace (e.g., Frank 1984, 1985; Cabrales et al. 2008), and incentives created by the need for repeated human capital investment (e.g., Kwon 2006). I focus on the four theoretical approaches that I believe are the strongest candidates for explaining the evidence.

facts concerning wage dynamics, but because of a lack of a hierarchical structure, it does poorly in terms of capturing facts that relate to promotions.

3.1.1. *Basic Description*

In the Harris and Holmström model workers vary in terms of their abilities, but within a schooling group (or some other attribute easily observable at the time of labor market entry) they look observationally equivalent upon entering the labor market. As time passes firms observe workers' outputs and update their beliefs concerning workers' abilities. Because of a stochastic component in the production function, this learning is gradual; because output realizations are public, all firms have the same belief concerning a worker's expected ability in each period.

The other main aspect of the model concerns the contracting environment. Because workers are risk averse and firms are risk neutral, firms would like to insure workers against uncertainty concerning how beliefs about worker ability evolve over time. Harris and Holmström (1982) assume long-term contracting is feasible but also suppose realistically that a worker cannot commit not to leave his or her current employer to accept a higher wage elsewhere.

Equilibrium contracts consist of a downward rigid wage, but the wage may increase over time depending on subsequent output realizations. The downward rigid wage provides partial insurance, where full insurance is not feasible, because workers cannot commit not to leave later for a higher wage elsewhere. Further, at any point in time a worker's wage equals the worker's expected output minus an insurance premium the worker pays for the downward rigidity, where the size of the premium is negatively related to both worker age and the precision of beliefs concerning worker ability. The insurance premium falls with age, because the expected cost of offering a wage floor is lower when there are fewer future periods in which the wage floor might exceed subsequent values of expected worker productivity. Similarly, it falls with the precision of beliefs about worker ability, because the expected cost of a wage floor is lower when future expected productivity is anticipated to vary little.

3.1.2. *Theoretical Extensions and Empirical Tests*

A related theoretical analysis appears in Weiss (1984). In that analysis realized productivity in any period is stochastic, and expected productivity grows stochastically as workers age, where expected future productivity depends positively on previous productivity. As do Harris and Holmström (1982), Weiss considers the role of insurance contracts. Further, similar to Harris and Holmström's conclusions, Weiss finds that under specific assumptions concerning mobility costs and access to capital markets, the result is a downward rigid wage where wage increases occur if the stochastic process eventually results in sufficiently high expected productivity.

There have been a few empirical tests of the theory. Beaudry and DiNardo (1991) first extend the theory to consider the importance of past labor market conditions on current wages. They find that a worker's current wage should be a positive function of the best labor market conditions experienced since the worker was hired. This prediction contrasts with the spot-contracting prediction that only current labor market conditions should matter. They test the prediction using data from the Current Population Survey and the PSID and find supportive evidence. More recently, Grant (2003) investigates the same prediction using the National Longitudinal Surveys, Clemens et al. (2009) investigate the prediction using data from a single firm that experienced wide swings in demand, and Schmieder and von Wachter (2009) focus on

related tests using the Displaced Worker Survey. All three papers find evidence that supports the theory. In contrast, Devereux and Hart (2007) find no support for the prediction using British data.

A different test is investigated in Chiappori et al. (1999). They first extend the model to show that late beginners do better than early starters. That is, holding fixed the wage at date t , the wage at $t + 1$ is negatively correlated with the wage at $t - 1$, so higher recent wage growth on average translates into higher subsequent wage growth. The authors then find supporting evidence using managerial data from a large French state-owned firm. That they find supporting evidence is not surprising, because the prediction is similar to serial correlation in wage increases, which, as discussed earlier, has been found in a number of studies. In addition, one drawback of this test, which is discussed by Chiappori et al., is that there is an alternative explanation. The same prediction follows if wages equal expected productivity and changes in productivity growth are positively correlated over time as in, for example, Gibbons and Waldman (1999b, 2006).

3.1.3. *Pros and Cons*

There are several positives concerning this theory. First, it explains the Medoff and Abraham (1980, 1981) finding that wages on average rise with experience even though performance evaluations do not. That is, assume performance evaluations not increasing with labor market experience means average productivity does not increase with experience. Then the Harris and Holmström (1982) analysis exactly captures this Medoff and Abraham finding. In their model expected productivity is independent of labor market experience. Yet the average wage increases with experience because of the downward rigidity of wages and because, as discussed, high output realizations push the average wage up over time and the insurance premium falls with experience.

Second, the model is consistent with a number of findings concerning earnings growth not discussed in the previous section but which are found in the literature. For example, the model captures Mincer's (1974) findings that within a schooling group the variance of earnings increases with labor market experience and that within schooling-experience groups the distribution of wages tends to be positively skewed. Third, as discussed above, a few papers have developed tests of the theory, and those tests have in general been supportive.

However, there are also some drawbacks. Probably the most important is that the evidence is not consistent with the model's main prediction. In the Harris and Holmström setting wages are downward rigid, where the prediction is real wage rigidity and not nominal rigidity. But substantial evidence discussed in Section 2 shows that the proportion of real wage decreases is substantial. The other main problem is that, because of its lack of a hierarchical structure or at least alternative job assignments, the model does not address the various empirical findings concerning promotions discussed in Section 2.

3.2. The Tournament Approach

Here I discuss the tournament approach to internal labor market compensation. This literature began with the seminal analysis of Lazear and Rosen (1981), which was the first major theoretical study to focus on the important role of promotions in worker compensation. Most of the

discussion focuses on Lazear and Rosen's analysis, although I do discuss a few later papers. As also discussed, there is clear empirical support for the main ideas underlying tournament theory, but in general this literature has not explored the extent to which the theory can explain many of the empirical findings concerning wage and promotion dynamics discussed above.

3.2.1. Basic Description

Lazear and Rosen (1981) consider a setting characterized by two risk-neutral identical workers, where worker output is a function of effort and a stochastic term. In their world effort is not directly observable, so a firm cannot base compensation on the effort choices of its workers. Instead the firm establishes a tournament. It commits to prizes for the winner and the loser, where the winner is the worker who produces more and the two prizes are independent of the difference between the outputs and the absolute levels of the outputs.

Lazear and Rosen show that the difference between the prizes (i.e., the spread) serves as an incentive for effort, where a larger spread means higher equilibrium effort. In turn, the equilibrium spread is the one that generates efficient effort levels. That is, because effort is costly for workers, too much effort is not desirable due to the higher wages a higher effort level requires, so the firm chooses a spread that equates the marginal disutility of effort with the extra productivity associated with effort. Lazear and Rosen interpret their results as providing an explanation for the large compensation increases associated with promotions. In this interpretation promotions and the associated higher compensation serve as prizes, and lower level workers exert effort because doing so increases the probability of receiving these prizes.

Lazear and Rosen (1981) also discuss and analyze the circumstances in which labor market tournaments are preferable to alternative ways of motivating workers when effort is not directly observable. They first show that given risk neutrality, tournaments and piece rates both yield first-best outcomes. They then argue that because the information requirements for conducting tournaments are less than for paying piece rates—the tournament only requires an ordinal ranking of the workers—tournaments may be preferred, as they are less costly to conduct. Lazear and Rosen also consider what happens when workers are risk averse and argue that in some circumstances tournaments will be preferred to piece rates. I come back to this issue below.

3.2.2. Theoretical Extensions and Empirical Tests

A large literature extends Lazear and Rosen's (1981) analysis. Such papers as Green and Stokey (1983) and Nalebuff and Stiglitz (1983) focus on a comparison between the efficiency or profitability of employing tournaments versus contracting directly on output. As was true of Lazear and Rosen's analysis of risk aversion, these two papers do not focus on optimal contracts. In contrast, Mookherjee (1984) shows that under risk aversion the optimal contract typically dominates the optimal tournament. This again raises the question of why tournaments are employed. In addition to Lazear and Rosen's answer, which concerns savings on information costs, Malcomson (1984) argues that tournaments may be employed because individual performance is not verifiable, so individual contracting is difficult to enforce.

Other papers model a tournament that consists of several rounds or contests. Clearly, real-world promotion tournaments do not consist of a single contest, but rather promotion to a higher level job is typically soon followed by competition for a subsequent promotion. Rosen

(1986) models a tournament along this line (see also Meyer 1992). In Rosen's model pairs of workers compete against each other in a round, and then the winners proceed to the next round, where there is again competition between pairs of workers. The tournament ends when a single winner remains. Under the strong assumption that worker effort is constant across rounds, Rosen shows that the wage structure is convex. Specifically, he shows that the wage increase associated with winning the last round of the tournament is larger than the increases associated with winning earlier rounds.⁷ The paper thus provides an explanation for why wage increases associated with being promoted to the top levels of firms seem to be especially large, as found, for example, in Murphy (1985) and Baker et al. (1994a,b).⁸

There is also a substantial literature focused on testing the implications of tournament theory. Various papers—including Ehrenberg and Bognanno (1990a,b), who study professional golf tournaments; Becker and Huselid (1992), who study auto racing; and Audas et al. (2004), who study promotions at a large British financial sector employer—find evidence consistent with effort being positively related to the spread. Although of interest, I find this set of findings weak in terms of how strongly they support traditional tournament theory. These tests provide evidence that the individuals in the tournament behave in a fashion consistent with utility maximization (i.e., effort increases when the winning prize is higher). This does not tell us anything about whether, as is true in classic tournament theory, firms commit to optimal prizes in advance of the actual promotion decision.

Another set of papers focus on predictions concerning firm behavior derived from extensions of the basic Lazear and Rosen (1981) model. The first prediction is that the spread or wage increase due to promotion should be positively related to the number of workers at the job level from which the promoted worker is drawn. The logic of this prediction is that, holding the spread fixed, increasing the number of workers competing for a promotion typically reduces equilibrium effort levels, so in response the firm increases the spread.⁹ Main et al. (1993), Eriksson (1999), and Bognanno (2001) find supporting evidence, whereas O'Reilly et al. (1988) do not.

A second firm-side prediction is the convexity of the wage structure derived in Rosen's (1986) analysis discussed above. Support for this prediction is found in Lambert et al. (1993) and Eriksson (1999). I find the general support for these two firm-side predictions more persuasive than the support for the worker effort prediction discussed above. The worker effort prediction seems not so closely tied to tournament theory, whereas the firm-side predictions are derived from classic tournament theory's assumption that firms commit to promotion prizes with incentives in mind. However, there are potential alternative explanations. First, as discussed in footnote 17, the idea that the wage increase due to promotion is related to the number of workers at the job from which the promoted worker is drawn can be explained using the promotion-as-signal

7. See Prendergast (1999) for an interesting discussion of what drives this result in Rosen's (1986) analysis.

8. Other important theoretical extensions of the basic tournament model include Lazear's (1989) model of sabotage and wage compression (see also Garvey and Swan 1992; Drago and Garvey 1998; Carpenter et al. 2010) and models that show that tournaments can lead firms to favor insiders over outsiders when deciding whom to promote (see Malcomson 1984; Chan 1996, 2006; Waldman 2003).

9. See Prendergast (1999) for a more detailed discussion of the logic of this prediction.

hypothesis. Second, convexity of the wage structure could be due to various factors, such as income effects resulting in higher wage increases on promotion to higher ranks. The logic is that, because of income effects, at these higher ranks higher wages are needed to induce effort.¹⁰

More recently, DeVaro (2006a,b) uses a structural estimation approach to consider simultaneously worker-effort and firm-side predictions of tournament theory. DeVaro looks at a sample of skilled workers taken from a cross-section of establishments. Using a structural estimation approach that treats promotions, wage spreads, and performance as endogenous, he finds support for both types of predictions. Specifically, he finds results consistent with firms choosing spreads optimally and worker effort being higher when spreads are larger.

3.2.3. *Pros and Cons*

There are clearly strong positives associated with tournament theory. Probably the most important is the plausibility of the central ideas captured by the argument. Clearly, the possibility of promotion does serve as an incentive for worker effort in real-world firms, and it would be surprising if in thinking about promotion practices firms did not consider the ramifications for worker effort. Further, the approach provides a very plausible explanation for a well-documented internal labor market finding. That is, a quite plausible explanation for large wage increases at promotion is that the large wage increases are used to provide incentives for effort.

The other main positive is that most studies that have tested implications of tournament theory have found supportive evidence. As discussed above, there is substantial evidence that as the model predicts, holding average wages fixed, worker effort is positively related to the spread between winning and losing. Also, studies generally find that compensation varies within and across firms in ways consistent with theoretical predictions. Specifically, evidence supports the prediction that the spread is a positive function of the number of lower level employees and also that there should be a convex relationship between compensation and job level.

The main disadvantage of the tournament approach is that the theory has not been developed in ways that make clear the extent to which the approach can capture various internal labor market findings, such as early wage increases at one job level predicting subsequent promotions, wage increases upon promotion being small relative to wage differences across adjacent levels, and cohort effects being important. But that such findings have not been addressed to date does not mean that some enriched tournament model is not capable of capturing these findings.¹¹

Another drawback is that there are certain aspects of standard tournament theory that seem unrealistic. For example, the idea that firms commit to “prizes” that are independent of the attributes and performance of the winner seems inconsistent with empirical evidence in such papers as Baker et al. (1994a,b), where a newly promoted worker’s wage seems to depend

10. Recently, Oyer (2007) tests a third firm-side prediction. As mentioned in footnote 8, several extensions of the basic tournament model predict firms favor insiders over outsiders in promotion decisions. Oyer tests this prediction by looking at tenure decisions in economics departments and finds supporting evidence. Specifically, outside the world’s top-ten departments, those hired into tenured positions from the outside are more productive on average than those promoted from within. Note, however, this finding could also be explained by asymmetric learning (e.g., Greenwald 1979, 1986) and by influence activities (e.g., Milgrom 1988; Milgrom and Roberts 1988).

11. See Krakel and Schöttner (2008) for a recent paper that moves in this direction by incorporating the possibility of bonus payments into a tournament model.

both on worker attributes and performance. Similarly, the Lazear and Rosen (1981) approach incorporates the market in a very limited way. That is, in initially attracting workers the firm must offer wages that translate into an expected utility at least as high as some reservation value, but there are no similar participation constraints after promotion decisions take place. This also seems inconsistent with Baker et al. (1994a,b) and similar papers, where workers enter and leave at all levels of the job ladder. As discussed further in Section 3.5, possibly the answer to these drawbacks is that there are labor market tournaments, but they take a somewhat different form than initially modeled by Lazear and Rosen.

3.3. Promotions as Signals

Another important approach for investigating the wage and promotion dynamics of internal labor markets is the promotion-as-signal hypothesis, as first modeled in Waldman (1984a) and later extended in Bernhardt (1995). This approach captures a number of empirical findings in the internal labor market literature, although most standard theoretical models in this literature are inconsistent with some important findings in the empirical literature.

3.3.1. Basic Description

Waldman (1984a) puts forth the basic argument. That paper considers a model characterized by asymmetric as opposed to symmetric learning. When workers enter the labor market their ability levels are initially unknown and there is learning. The difference is that only a worker's current employer directly observes ability, while other firms learn about worker ability by observing the actions of the current employer. In Waldman's analysis the key action is the promotion decision.

In Waldman's two-period model workers vary in their innate ability levels but look identical upon labor market entry. Firms are characterized by two jobs—a low-level job where the return to ability is low and a high-level job where it is high. In the first period all workers are assigned to the low-level job, and then at the end of the period a worker's initial employer learns the worker's ability level. In the second period high-ability workers are then promoted to the high-level job, where one of the key results is that fewer workers are promoted than is first-best efficient. The reason is that a promotion serves as a signal that worker ability is high, so after a promotion other firms bid more for the worker's services. Thus, the current employer must pay a promoted worker more to stop the worker from being bid away, but this causes firms to only promote workers who are significantly more productive in the high-level job.¹²

Bernhardt (1995) extends this analysis. The main differences are that in Bernhardt's model workers are in the labor market for more than two periods, there is a richer process of human capital accumulation, and workers vary in terms of their publicly observed schooling levels. What happens is that as a cohort ages workers are promoted in bunches, where the highest ability workers are promoted first and then the next highest, and so forth. Further, as in Waldman's

12. One difference between tournament theory and the arguments discussed here and in Section 3.4 is that in tournament theory a promotion does not result in a change in the set of tasks performed, whereas in these other arguments it does. The only relevant empirical work I am familiar with is Pergamit and Veum (1999). In their study of young workers approximately 70% of promoted workers were given additional responsibilities in their current job or position or were moved to a new job or position.

analysis, because of signaling, promotions are associated with large wage increases and fewer workers are promoted than in the first best.

In addition to showing that the main results found in Waldman (1984a) continue to hold in a richer model, Bernhardt also derives a number of new and interesting findings. For example, Bernhardt finds that firms favor more highly educated workers in the promotion process. That is, holding true productivity fixed, workers with more education are promoted first. This arises because even in the absence of a promotion, workers with more education are paid a higher wage, so the signaling role of promotion is smaller for these workers. Bernhardt also shows how his model can explain serial correlation in promotion rates (i.e., promotion fast tracks).

3.3.2. *Theoretical Extensions and Related Empirical Tests*

There have been many theoretical extensions of this framework and a more limited number of empirical tests. The most important extension appears in Zábojník and Bernhardt (2001).¹³ That paper connects the promotion-as-signal idea to the tournament approach (see also Gibbs 1995; Ghosh and Waldman 2010; Zábojník 2010). In the traditional labor market tournament model the firm imposes the promotion tournament to create incentives. In the Zábojník and Bernhardt model the tournament instead arises from asymmetric learning and the resulting signaling aspect of promotions. That is, rather than firms committing to a prize associated with promotion, prizes arise because promotions serve as signals, and large wage increases are needed to stop promoted workers from being bid away. In addition to showing how the labor market tournament approach and the promotion-as-signal approach can be reconciled, Zábojník and Bernhardt show that their model explains various findings in the firm-size-wage-effects literature and the interindustry-wage-differences literature.¹⁴

On the empirical side there have been a number of tests of asymmetric learning in labor markets but only one that focuses on the promotion-as-signal hypothesis. The classic test of asymmetric learning in labor markets is found in Gibbons and Katz (1991), which builds on Greenwald's (1979, 1986) analysis of adverse selection in labor market turnover. Gibbons and Katz argue that laid-off workers should have lower ability on average than those fired in a plant closing, because adverse selection means laid-off workers are drawn from the low end of the ability distribution, whereas workers fired in a plant closing are drawn from the whole distribution.¹⁵ Based on this logic, they derive three testable implications: (1) predisplacement wages should be uncorrelated with the cause of the displacement, (2) postdisplacement wages should

13. Related theory papers include Milgrom and Oster (1987), Ricart i Costa (1988), MacLeod and Malcomson (1988), Waldman (1990), Bernhardt and Scoones (1993), Owan (2004), and Golan (2005, 2009). Also, see Ishida (2004a,b) for interesting analyses that focus on the interaction between education as a signal and promotion as a signal.

14. The Zábojník and Bernhardt (2001) argument also serves as an explanation for the puzzle first identified in Baker et al. (1988): why are promotions used as incentive devices given this creates inefficiencies since the incentive and allocation roles of promotion will sometimes be in conflict? An alternative explanation for this puzzle is found in Fairburn and Malcomson (2001), which is based on the idea that bonus-based incentives are subject to the negative effects of influence activities.

15. To be precise, the Gibbons and Katz (1991) argument allows for both adverse selection as in Greenwald's (1979, 1986) analysis and for the possibility that layoffs serve as a signal like in the promotion-as-signal hypothesis.

be lower for laid-off workers than for those fired in a plant closing, and (3) postdisplacement unemployment duration should be higher for laid-off workers than for those fired in a plant closing. Using data from the Current Population Survey Gibbons and Katz find evidence that supports all three predictions.

There have been numerous follow-up studies, and the evidence is mixed concerning whether the Gibbons and Katz (1991) results are in fact due to asymmetric learning. Acemoglu and Pischke (1998), which is discussed in more detail in Section 6.2, extend the theoretical framework to consider incentives for firms to provide their workers with general human capital and then show supporting evidence using German data. But some studies that have investigated the Gibbons and Katz results argue that their results are explained by something other than asymmetric learning. For example, Krashinsky (2002) argues that the results are due to laid-off workers being displaced from larger establishments that pay higher predisplacement wages, and Song (2007) makes a similar case and also argues that recall bias is important (see also Doiron 1995; Stevens 1997; Grund 1999; and Hu and Taber 2011).

More recently, several papers have developed other predictions of asymmetric learning, and these papers mostly find supporting evidence. Specifically, Schonberg (2007) finds evidence consistent with asymmetric learning for university graduates but not for high school graduates and dropouts,¹⁶ and Kahn (2008), Zhang (2008), and Pinkston (2009) all find general support for asymmetric learning across a variety of tests.

Finally, the only empirical analysis focused directly on the promotion-as-signal hypothesis is found in DeVaro and Waldman (2012) (for related results, see Belzil and Bognanno 2010; DeVaro et al. 2012). Related to a result in Bernhardt (1995), that paper first extends the theory to show that the signaling aspect of promotions should be larger for workers of lower schooling levels, because, even before promotion, workers with higher schooling levels are already thought of as having higher ability. DeVaro and Waldman then use this result to derive three testable implications: (1) holding performance fixed, the probability of a first promotion should be an increasing function of the education level; (2) the wage increase from a first promotion should be a decreasing function of the education level; and (3) the first two relationships should hold more strongly for first promotions than for subsequent ones. Employing the same dataset investigated in Baker et al. (1994a,b), they then find results that support signaling being important for understanding promotion practices concerning bachelors and masters degree holders, whereas the evidence concerning the importance of signaling for high school graduates and doctoral degree holders is mixed. They also consider various alternative explanations for their findings and argue that none of the alternatives explain their empirical results.

16. To be precise, Schonberg (2007) develops two testable implications for asymmetric learning. The first, which she finds clear evidence for among university graduates, is the result originally due to Greenwald (1979, 1986) that workers who turn over should be drawn from the low end of the ability distribution. The second is that in a world of asymmetric learning the return to ability should be positively related to tenure at the firm. For this prediction she finds mixed evidence concerning university graduates. However, I do not believe this second prediction is a robust prediction of asymmetric learning models. For example, Pinkston (2009) considers a related theoretical model, but he does not find Schonberg's second prediction. So my interpretation is that Schonberg's findings are consistent with asymmetric learning being important for university graduates.

3.3.3. *Pros and Cons*

There are clearly some positives associated with the promotion-as-signal hypothesis. The main one is its basic plausibility. Promotions are typically publicly observable events, and workers, especially successful ones, provide their job-assignment histories on their resumes. This practice is consistent with the history of job assignments being important for prospective employers because of its information content, which is exactly the promotion-as-signal argument. It is also plausible that large wage increases at promotion are due at least partly to signaling. That is, if a worker's job-assignment history is an important consideration for prospective employers, then it is plausible that when a worker's current employer improves that history by a promotion, the employer also increases the worker's wage to stop the worker from being bid away.

The approach also has significant empirical support both in terms of various empirical studies and being able to explain some important findings in the empirical wage- and promotion-dynamics literature. First, on net the various empirical studies in the literature support asymmetric learning as an important factor in real-world labor markets. Second, the only empirical investigation focused on the promotion-as-signal hypothesis is found in DeVaro and Waldman (2012), which finds evidence consistent with the hypothesis for bachelors and masters degree holders, although they find mixed evidence for high school educated workers and doctoral degree holders. Third, the hypothesis is consistent with two important empirical findings concerning promotions; that is, there are large wage increases upon promotion, but these wage increases are small relative to wage differences across adjacent job levels.¹⁷

In addition to the positives discussed above, however, there are also some negatives. Specifically, some of the important empirical findings concerning wage and promotion dynamics are inconsistent with most models of asymmetric learning. Two stand out. First, in most pure asymmetric learning models a worker's salary increase in a period in which there is no promotion is completely determined by observable characteristics, such as schooling, labor market experience, and firm tenure. But numerous studies, such as Baker et al. (1994a,b), make it clear that this is not the case. Second, the approach does not easily explain why the size of wage increases early at a job level forecast speed of promotion. The reason is that in a standard asymmetric-learning model a firm will not reward a worker when no positive information is publicly revealed, so in the absence of promotions the firm should not give higher wage increases to the higher productivity workers.

But for both issues it is possible that richer models of asymmetric learning can match the evidence. For example, Novos (1995) considers a model of asymmetric learning without promotions where, upon starting employment at a firm, a worker privately learns how much disutility the worker will receive from staying at this specific firm, which subsequently affects the worker's probability of accepting a competing wage offer in the future. The result is that the current employer pays a wage increasing in worker ability, even though ability is privately observed by the

17. The approach is consistent with wage increases upon promotion being small relative to wage differences across adjacent levels if workers accumulate general human capital as they age. The approach can also explain the finding discussed earlier that wage increases upon promotion are positively related to the number of workers at the level from which the promoted worker is drawn. That is, this prediction is consistent with the promotion-as-signal hypothesis, because the signaling value of a promotion should be positively related to the number of workers who were competing for the promotion.

firm, where it does this to reduce the probability of turnover for the higher ability workers. It is possible that incorporating the Novos approach into an asymmetric-learning model with promotions would result in a model that both captures large wage increases upon promotion due to signaling and is not subject to the two criticisms discussed in the above paragraph.¹⁸

3.4. Symmetric Learning with Human Capital Accumulation and Job Assignment

The last approach I discuss is the symmetric learning approach to wage and promotion dynamics first explored in Gibbons and Waldman (1999b). That approach combines symmetric learning with human capital accumulation as in Becker (1962, 1964) and job assignment as in Rosen (1982) and Waldman (1984b). This approach is the one most successful at capturing the wide variety of empirical findings concerning wage and promotion dynamics found in the internal labor market literature. But even this approach has some drawbacks.

3.4.1. Basic Description

As indicated, Gibbons and Waldman (1999b) combine symmetric learning, human capital accumulation, and job assignment. In their model workers look identical upon labor market entry but in fact vary in terms of their innate abilities; at the end of each period firms observe worker outputs and update their beliefs concerning each worker's ability. As in Harris and Holmström (1982) discussed in Section 3.1, learning is gradual because of a stochastic term in the production function. Another key assumption is that workers accumulate general human capital as they age with the result that each worker's "effective" ability grows over time, although expected effective ability falls when output is very low. Further, the process of human capital accumulation is multiplicative; that is, workers with higher innate ability accumulate human capital at a faster rate. Also, there are three job levels that vary in terms of the marginal return to effective ability, where the process of human capital accumulation means workers on average move up the job ladder as they age. Finally, wages are determined by spot-market contracting.

Gibbons and Waldman (1999b) show that this framework captures most of the empirical findings concerning wage and promotion dynamics in internal labor markets discussed in Section 2.1. For example, the model explains why real wage decreases are not rare but demotions are. Real wage decreases are not rare, because with learning a worker receives a real wage decrease when realized output is so low that expected effective ability falls. However, this rarely translates into a demotion, because demotion also requires expected effective ability to cross a critical value at which productivity across the two jobs is the same. The model also explains large wage increases upon promotion because promoted workers on average have large increases in expected effective ability. In addition, it shows that large wage increases early at a job level predict quicker than average promotion. This follows because a large wage increase early on means significant

18. Golan (2009), Li (2009), and Pinkston (2009) are other papers with asymmetric-learning analyses not subject to one or both criticisms. Also, the second criticism above implicitly assumes workers with the same observable characteristics. If workers have different observable characteristics, such as heterogeneous schooling levels, then it is possible that a large wage increase early on—for example, due to higher schooling—could predict speed of promotion if, as is plausibly the case, workers with higher schooling also on average are promoted more quickly. This argument could explain the Baker et al. (1994a,b) finding that early wage increases predict promotion, because that test does not control for the schooling level. It would be easy to empirically investigate this argument.

growth in expected effective ability; thus, on average, the worker achieves the expected effective ability required for promotion more quickly. The model also explains serial correlation in wage changes, that wage increases at promotion are small relative to the difference between average wages across adjacent job levels, and is consistent with serial correlation in promotion rates.¹⁹

Gibbons and Waldman (1999b) also show that this framework can explain many of the results concerning performance evaluations discussed in Section 2.3 given the additional assumption that supervisors evaluate individuals relative to other workers with the same labor market experience. This part of their analysis builds on a discussion in Harris and Holmström (1982). For example, Medoff and Abraham (1980, 1981) find that for a given job, wages are positively related to labor market experience, whereas performance evaluations are either unrelated or slightly negatively related to experience. In the Gibbons and Waldman framework, wages for a given job are positively related to labor market experience because general human capital increases with experience. But if workers are evaluated relative to others with the same labor market experience, then performance evaluations for a given job fall with experience, because workers with high expected innate ability are promoted out of the job as they age, while those with low expected ability are promoted into the job. The framework can also explain differences between cross-sectional and longitudinal analyses of the same dataset and explain why performance evaluations predict both future promotions and future wage increases.²⁰

3.4.2. *Theoretical Extensions and Related Empirical Tests*

Important extensions of this framework appear in Gibbons and Waldman (2006). That paper first addresses empirical findings concerning the role of schooling in wage and promotion dynamics. In this model workers vary in terms of their schooling levels, where higher schooling means higher expected innate ability. They show that with this enrichment, the model captures the major empirical findings discussed in Section 2.2. For example, the model provides an explanation for why higher schooling improves promotion probabilities. That is, higher schooling means higher starting levels of expected effective ability, which, in turn, means expected effective ability on average grows faster and passes the critical value required for promotion more quickly. The model also explains why schooling is positively related to the wage even after controlling for experience and job assignment and why the returns to experience may be positively related to schooling, although the evidence on this issue is mixed, as mentioned before.

In the second part of their 2006 paper Gibbons and Waldman address cohort effects (see also Gibbons and Waldman 2004). Remember, cohort effects mean that, even after controlling for differences in the composition of workers in a cohort, a cohort's average wage years after entry into a firm reflects to some degree the cohort's average starting wage. Their 1999b model is not consistent with this finding, but their 2006 paper shows that the framework is consistent with the finding when task-specific human capital is added. Task-specific human capital means

19. Gibbons and Waldman (1999b) show serial correlation in promotion rates in their full-information benchmark analysis, but they are unable to show that the framework necessarily exhibits serial correlation in promotion rates given symmetric learning.

20. DeVaro and Waldman (2012) provide evidence using the Baker et al. (1994a,b) dataset consistent with performance evaluations being absolute measures of productivity. This evidence throws some doubt on the explanation given above for the Medoff and Abraham (1980, 1981) findings.

human capital accumulated in one period is more valuable later, when the worker is performing similar tasks. Specifically, Gibbons and Waldman (2006) assume an old worker assigned to the high-level job is more productive when the worker has prior experience on this job. They show that with this enrichment, their framework captures the cohort effects found by Baker et al. (1994a,b) if, during a boom, entering cohorts both earn higher wages and enter the firm on average at higher levels of the job ladder. This approach can also potentially explain the economywide and industry-level cohort effects found in recent papers, such as Oyer (2006), Kahn (2010), and Oreopoulos et al. (2012).²¹

Some recent studies empirically estimate the Gibbons and Waldman (1999b) model using large datasets from other countries (U.S. datasets cannot typically be used for this purpose, because they do not contain job-level information). One such study is Lluís (2005). She uses longitudinal data from the German Socio-Economic Panel and generalized method-of-moments techniques. Her results generally support the framework, although the evidence that learning is important is weak. In particular, the evidence is consistent with learning being important in job assignment for younger workers, but for older workers the evidence is weak.²² She hypothesizes that the mixed evidence for learning may reflect the apprenticeship system in Germany, because much of the learning about worker ability may occur during the apprentice period. But an alternative explanation, as discussed next, is that her findings are in fact consistent with a more complete analysis of the Gibbons and Waldman framework.²³

There are also studies related to the Gibbons and Waldman (2004, 2006) arguments concerning task-specific human capital. For example, Dohmen (2004) finds that, consistent with task-specific human capital being important, a worker's performance evaluation falls after a promotion but quickly rises as the worker gains experience at the new job level, while Shaw and Lazear (2008) find a similar result by looking directly at productivity.²⁴ Also, in an interesting recent paper Gathmann and Schonberg (2010) find support for task-specific human capital in an empirical investigation of the jobs workers leave and those they move to when they switch employers.

21. Other interesting theoretical extensions appear in Clemens (2010) and DeVaro and Morita (2010). Clemens extends the framework by allowing for two lower level jobs rather than one, where one type of lower level job is part of a fast track, because the speed of human capital accumulation is higher, which in turn translates into higher rates of promotion. He also provides empirical evidence using the Baker et al. (1994a,b) dataset that supports the predictions he derives from this approach. DeVaro and Morita focus on internal promotion versus external recruitment (see footnotes 8 and 10 for related discussions) using a symmetric learning model with human capital accumulation and job assignment. They derive various predictions, including increased use of internal promotion at large firms, and then provide empirical support using a large cross-section of British employers.

22. Lima and Pereira (2003) find a similar result using Portuguese data. Their focus is on the wage premiums associated with promotion. They find that toward the bottom of the job ladder learning is an important factor behind these wage premiums, whereas at the top learning is unimportant. Hunnes (2011) uses Norwegian data and an empirical methodology similar to that employed by Lluís (2005). Hunnes finds stronger evidence for learning, but in his analysis the strongest evidence is at the top hierarchical levels. See also Dias da Silva and van der Klaauw (2011).

23. Another related study is Smeets and Warzynski (2008), which provides evidence concerning span of control and dynamics. The authors argue that their findings are consistent with an enriched version of the Gibbons and Waldman (1999b) framework.

24. DeVaro and Waldman (2012) do not find this pattern in their analysis of the Baker et al. (1994a,b) dataset.

In contrast to the general empirical support for task-specific human capital being important, the evidence for the Gibbons and Waldman argument concerning task-specific human capital and cohort effects is more mixed. In a recent paper Kwon et al. (2010) find that cohort effects are due to workers hired during a boom having higher promotion rates rather than the Gibbons and Waldman prediction that during a boom initial job assignments are higher on the job ladder. As conjectured by Kwon et al., possibly these results can be explained by an extension of the Gibbons and Waldman argument where it is job assignments early in the career—rather than just the initial job assignment—that increase productivity later in the career and thus improve assignments and wages later in the career. Also, Schmieder and von Wachter (2010), mentioned in Section 3.1.2, find results using the Displaced Worker Survey that seem to more directly contradict the Gibbons and Waldman argument concerning task-specific human capital and cohort effects.

3.4.3. *Pros and Cons*

The pros here are straightforward. The theoretical analyses show that the approach can explain a wide set of the empirical findings in the literature on wage and promotion dynamics in internal labor markets. These include what I have referred to as basic empirical findings, findings concerning the role of performance evaluations, and findings concerning schooling. Also, incorporating task-specific human capital, which seems realistic, allows the model to explain cohort effects, although as discussed, the evidence for this part of the argument is mixed.

On the negative side there are two related issues. First, Gibbons and Waldman (1999b, 2006) do not consider the idea that—at least under their assumption that innate ability is a one-dimensional fixed attribute—most learning should occur early in careers. This is potentially problematic if empirical findings for older workers can only be explained by assuming learning is significant. Second, as discussed above, some empirical investigations of the Gibbons and Waldman framework find evidence for symmetric learning only for younger workers.

As a final point, it is unclear to me how significant these issues are. In their 1999b paper Gibbons and Waldman show that many of the empirical findings they focus on can also be explained in their framework under the assumption of full information. It is thus possible the two issues discussed above are not problems for their framework at all. As stated above, in a world where innate ability is a one-dimensional fixed attribute, learning should be mostly confined to the early part of workers' careers. So possibly the correct perspective is that the Gibbons and Waldman framework provides the right explanation for the main empirical findings in Section 2, where at low values of labor market experience it is their symmetric-learning arguments that apply, whereas at high levels their full-information arguments apply. Further theoretical and empirical work exploring this possibility would be helpful.

3.5. Overview and Synthesis

Among the candidate models considered (which were chosen because they were the ones with the most empirical support), clearly the framework that combines symmetric learning, human capital accumulation, and job assignment is the one the literature currently suggests best explains empirical findings concerning wage and promotion dynamics in internal labor markets. Of course, it is possible this model is superior on this dimension only because the other frame-

works have not been developed in ways that make clear the extent to which they can explain the empirical evidence. But I believe this is unlikely. The more plausible explanation is that symmetric learning, human capital accumulation, and job assignment are all important elements in the operation of real-world internal labor markets.

But I also believe the evidence does not support the idea that the basic model investigated in Gibbons and Waldman (1999b) is sufficient for explaining all the evidence. Rather, various enrichments seem important.²⁵ First, both because of its real-world plausibility and because of the growing evidence supporting its presence, incorporating task-specific human capital as in Gibbons and Waldman (2006) seems important. Second, the evidence in favor of asymmetric learning along with recent evidence in favor of the promotion-as-signal hypothesis suggests that asymmetric learning is also important. In other words, most models assume learning is either purely symmetric or purely asymmetric, but in fact there is no reason that real-world learning cannot be a mix of the two. And my sense is that the evidence supports this.²⁶

In addition, incentives associated with promotion must also be important. But it is unclear whether it is best to incorporate the type of classic tournament explored by Lazear and Rosen (1981), or whether, along the lines of Zájbojník and Bernhardt's (2001) analysis, tournaments based on the promotion-as-signal hypothesis are more realistic. The difference concerns whether the firm commits to optimal values for future high wages associated with promotions or whether these future high wages arise as the result of signaling. Future theoretical and empirical work focused on distinguishing between these possibilities would be of interest.²⁷

The evidence also suggests that the Gibbons and Waldman assumption of spot contracting is not fully accurate. Many empirical findings point to the "market" being important in wage determination, so spot contracting will typically give better predictions and explanations than a model in which workers are completely insulated from the aggregate labor market.²⁸ But there are aspects of the evidence—such as nominal wage rigidity, the type of cohort effects found by Beaudry and DiNardo (1991), and Green Card effects—that suggest that wages do deviate from the market wage in important ways (for a related empirical analysis and discussion, see Gibbs and Hendricks 2004).²⁹ It is an open question whether these types of deviations can be incorporated convincingly into the theoretical modeling.

There are a few subjects that deserve more attention at both the theoretical and empirical levels. One subject is the connection between wage and promotion dynamics in internal labor markets and the turnover decision. How a worker's career progresses during a stay at a single

25. See Coupe et al. (2006) for an interesting empirical analysis of the academic economist labor market that is consistent with this view.

26. Kahn (2008) is a recent paper that mixes symmetric and asymmetric learning in the manner I have in mind. See also Lazear (1986a), Waldman (1990), and Pinkston (2009).

27. Waldman (2011) discusses the extent to which existing empirical evidence supports the classic approach or that based on the promotion-as-signal hypothesis. That paper also discusses a hybrid approach that combines the two approaches and possibly matches the data better than either of the two earlier approaches viewed in isolation.

28. Lazear and Oyer (2004) show that, even in Sweden's highly regulated labor market, the "market" is important in wage determination.

29. "Green Card effects" refers to rules or guidelines sometimes employed that place bounds on a worker's pay increase in any period. See Milkovich and Newman (1987) and Baker et al. (1994a) for empirical analyses and discussions and Peterson (2010) for a theoretical analysis.

employer should be closely related to voluntary and involuntary turnover decisions and also to how the worker performs at the new job. On the empirical side a few papers develop evidence along these lines. For example, Baker et al. (1994a,b) have results concerning entry and exit rates at different levels and also comparisons of wage growth and promotion outcomes for new entrants versus incumbents, and Treble et al. (2001) provide a similar analysis. But more empirical investigation of this issue would be helpful. Similarly, there is limited theoretical work on this topic, and more theoretical attention to it could prove fruitful, especially if the empirical literature matures to the point that the facts are clear.³⁰

A final subject that deserves more attention is bonus payments. Most empirical research in this literature focuses on salaries rather than on bonuses. This is probably because salary data are frequently more readily available, and because some early empirical work in this literature focused on salaries and ignored bonuses. But there are recent findings that suggest bonuses work quite differently than salaries. For example, Lin (2005) finds that bonuses vary more with aggregate economic conditions than do salaries and also that within a level bonuses vary more than do salaries. Also, Belzil and Bognanno (2008) find that promotions cause increases in base pay but not in bonus pay. These results suggest that salary and bonus play somewhat different roles in compensating workers and thus that further empirical and theoretical work on this issue could be fruitful.³¹

4. Empirical Evidence on Human Resource Practices

An important topic in the study of internal labor markets is the type of human resource practices firms employ to increase worker productivity. And in particular, much of the recent literature on this topic has focused on “traditional” versus “innovative” human resource practices. In this section I focus on the empirical literature on the subject. Section 5 discusses the theoretical literature, and Section 6 discusses international differences concerning internal labor markets—most of which can be connected to differences in human resource practices (for an earlier survey on human resource practices, see Ichniowski and Shaw 2003).

4.1. The Basics

The literature on human resource practices makes a distinction between what are referred to as “traditional” and “innovative” practices. Traditional practices are those that were predominant

30. Recent theoretical work that moves in this direction includes Ghosh (2007), Ricchetti (2007), and Peterson (2010).

31. One issue concerning bonuses that has received empirical and theoretical attention is that bonuses are more important at higher levels of job ladders. This is documented empirically in a number of papers, including Baker et al. (1994a,b) and Ricchetti (2007). Possible theoretical explanations include: bonus payments are more important at higher job levels because of diminished career concerns as workers age (see Gibbons and Murphy 1992); bonus payments are more important at higher levels, because bonuses are more important when returns to effort are higher (see Lemieux et al. 2009); and incentives associated with future promotions are smaller at higher levels (see Boschmans 2008). Also, see Ekinci (2011) for an interesting recent theoretical and empirical exercise that integrates these three perspectives.

in the United States prior to the 1980s, whereas innovative practices have become more common recently. Traditional practices are less focused on ensuring that a firm's workers are highly skilled, that incentives for superior performance are high, and that information sharing is high. These practices include hourly pay or salary compensation where there is little connection between pay and performance, narrowly defined jobs and no job rotation, limited screening for other than managerial employees, no work teams or quality circles, little formal on-the-job training, and the use of layoffs when product demand declines.

In contrast, innovative practices are focused more on recruiting and developing workers with high skills, eliciting high performance, and sharing information. These practices include the use of problem-solving teams and quality circles, job rotation, more effort and resources put into worker screening during the recruitment process, more on-the-job training, more use of incentive pay, and higher job security. As discussed in more detail in Section 5, where the theoretical literature is discussed, these practices seem to constitute a set of complementary or interlocking parts whose main goal is the transformation of how decisions are made. That is, one of the goals of the employment of these practices is a shift in decisionmaking away from managers toward production workers.

As discussed in Cole (2000), these practices first emerged among a limited set of large Japanese manufacturers in the 1960s and then became widespread among large Japanese manufacturers in the late 1960s and 1970s. The practices served to improve the quality performance of these large Japanese manufacturers, and to successfully compete, U.S. firms began to adopt these practices starting in the 1980s. Such studies as Osterman (1994, 2000), Lawler et al. (1995), and Cappelli and Neumark (2001) document the adoption of these practices in U.S. firms and, in particular, show the rapid growth in adoption during the 1980s and 1990s (see also Ichniowski et al. 1989; Black and Lynch 1996, 2004; and Gittleman et al. 1998). As an example, Lawler et al. find that the use of problem-solving teams almost doubled among large U.S. firms between 1987 and 1993.

In terms of understanding the time-series evidence, it is also useful to consider in greater detail the nature of the increased employment of these practices over time. First, survey evidence like that found in Osterman (2000) shows that early adopters tended not to revert back over time to the use of more traditional practices. Also, a significant part of the growth in the use of these practices was due to a higher proportion of firms employing them over time. But this is not the sole source of the growth. Rather, there is also clear evidence that firms that employ innovative practices tend to use larger numbers of these practices over time (see again Osterman 2000).

4.2. Different Types of Evidence

Before discussing the effects on firm performance of the adoption of innovative practices, I briefly discuss the different types of evidence that have been brought to bear on the issue. There are a number of different approaches. Early studies that looked at the impact of innovative human resource practices tended to be case studies typically of a single firm or a small set of firms. Well-known studies that take this approach include Krafcik (1988) and Wilms (1995), who look at a single auto assembly plant; Berg et al. (1996), who focus on apparel manufacturing; and Ichniowski (1992), who examines paper manufacturing.

Although these types of studies certainly provide valuable evidence, they can also be limited: inferences are drawn from observations concerning a small number of firms or factories within firms. And in such a study there is the possibility that the effects found are not in fact due to the adoption of innovative work practices but rather to some other difference that is correlated with the employment of these practices. For example, maybe innovative practices tend to be employed on average by higher quality managers, and it is these managers rather than the practices per se that are responsible for the higher productivity frequently associated with innovative practices. This type of scenario provides an alternative explanation for Krafcik's (1988) and Wilms' (1995) findings in their classic studies of the New United Motor Manufacturing, Inc. auto assembly plant.³²

To avoid some shortcomings of the standard case-study approach, several papers employ what has come to be called "insider econometrics" (for a detailed description of this approach, see Ichniowski and Shaw, this volume). This approach combines the best aspects of the case-study methodology with the positive aspects of systematic statistical analysis. In this approach researchers first do the equivalent of a case study to understand the nature of the production process and the data needed to test well-formulated hypotheses. Then, after collecting the required data, state-of-the-art statistical techniques are employed to investigate which of various hypotheses are supported by the data. This approach provides the highest quality evidence in this area, so much of the discussion that follows focuses on these studies.

In the insider-econometrics approach, there are two distinct sets of papers. One set focuses on single firms, while the other looks at multiple factories and firms in the same industry. Examples of the former include Lazear's (2000) study of piece rates on the productivity of workers installing windshields, the Nagin et al. (2002) study of piece-rate pay and call center productivity, and the Hamilton et al. (2003) study of teams in apparel production (see also Knez and Simester 2001; Bartel 2004; Freeman and Kleiner 2005). Examples of the latter include the Dunlop and Weil (1996) analysis of module versus bundle production in the apparel industry, the Ichniowski et al. (1997) study of various innovative work practices in steel production, and the Boning et al. (2007) follow-up study of steel production (see also MacDuffie 1995; Kelley 1996; MacDuffie and Pil 1996).

A final set of studies are those that conduct nationwide cross-industry surveys of businesses concerning their human resource practices. These studies are useful for documenting the prevalence of innovative human resource practices within a country at a specific time, but they are somewhat limited in terms of understanding the details of what drives the employment of these practices and their impact. Examples of such studies focused on the United States include Huselid and Becker (1996), Black and Lynch (2001, 2004), and Cappelli and Neumark (2001). Studies on other countries include Greenan and Guellec (1997) on France, Michie and Sheehan (1999) on Great Britain, and Eriksson (2003) on Denmark.

32. In that case a plant shut down by General Motors was reopened as a joint venture by GM and Toyota employing many of the same workers but using Toyota management. At the reopening innovative work practices were introduced, and productivity improved. But a case-study approach cannot easily determine the extent to which the improved productivity was due to the innovative practices versus other changes associated with the new management.

4.3. Basic Effects of the Adoption of Innovative Work Practices

The extensive empirical investigation of the adoption of innovative human resource practices makes clear that in most cases adoption of such practices increases productivity. Of course, this is not surprising. It is unlikely the employment of these practices would become increasingly common over time unless there was a return associated with their use. In terms of understanding which factors explain the returns and growing use of these practices, however, what is needed is detailed evidence concerning the nature of these returns and patterns of adoption.

One finding is that the increased productivity associated with the use of innovative work practices is not always solely due to the increased productivity of an existing workforce: it can also be partly due to upgrading the workforce. For example, Lazear (2000) investigated worker productivity and firm profitability at the Safelite Glass Corporation after the firm moved from hourly pay to piece-rate pay. Consistent with standard economic theory of incentive pay, worker productivity of the existing workforce rose. But this only accounted for about half of the overall rise in productivity at the firm. The other half was the result of an improved ability to attract highly productive workers and possibly fewer exits of the most productive workers. A second related example is found in the Hamilton et al. (2003) analysis of an apparel factory. In their analysis a move from individual piece rates to team production and team-based incentive pay raised productivity substantially, and in fact the high-productivity workers (i.e., those most likely to be hurt monetarily by moving away from individual piece rates) were the first to voluntarily join the newly forming teams.

The next finding relates to the details concerning the manner in which innovative practices help the productivity of an existing workforce. Specifically, there is clear evidence that adopting a larger number of innovative practices increases productivity more than adopting one or a few practices. This result is not surprising, because if this were not the case, it would be hard to understand why firms that employ innovative practices seem on average to employ larger numbers as time passes. What is of more interest is the substantial evidence indicating that the productivity increase associated with employing a bundle of innovative practices is not simply the sum of increases associated with each practice individually. Rather, the productivity increase associated with employing a bundle of practices frequently significantly exceeds this sum.

A study that nicely captures this idea is the classic Ichniowski et al. (1997) investigation of steel production. That paper employs a panel dataset that covers almost all finishing lines in integrated steel mills in the United States. For these lines they consider 26 different human resource management practices, which they then translate into four systems of practices—a system that employs mostly traditional practices, one that employs mostly innovative practices, and two intermediate systems. One intermediate system uses innovative practices focused mostly on communication and information sharing; the other adds teamwork and formal training. A main finding is that, comparing these four systems, worker productivity increased with the number of innovative practices employed. In fact, the system that employed a full set of innovative practices raised productivity on average more than twice the amount of the system associated with the next highest number of innovative practices. Further, the introduction of any single practice had a statistically insignificant effect on productivity. So the conclusion is that innovative work practices improve productivity, but in addition there seem to be strong complementarities.

Other studies have also found or argued for important complementarities.³³ For example, Knez and Simester (2001) study the introduction by Continental Airlines of an employee bonus based on firmwide performance, where, contrary to the standard free-riding argument, Knez and Simester find evidence consistent with this firmwide performance bonus improving productivity. They argue (and present anecdotal evidence consistent with their argument) that the use of teams or work groups at the firm increased the extent of mutual monitoring, which allowed the firmwide bonus to be successful. Similarly, in their paper on apparel manufacturing, Hamilton et al. (2003) suggest that the simultaneous introduction of module production and group-incentive pay allowed the introduction of teamwork to significantly increase productivity.

In addition to the effects on productivity, there is also a question of how the introduction of innovative practices affects other important outcome variables, in particular, output quality and firm profitability (an increase in productivity does not necessarily translate into increased profits, because innovative practices can also translate into increased costs).³⁴ As is the case for productivity, there is strong evidence that introducing innovative practices positively affects quality. This has been found in various studies, including MacDuffie (1995), Ichniowski et al. (1997), and Boning et al. (2007).³⁵ The evidence for a positive impact on profit is weaker, but in some cases one can infer that profits were also positively affected. For example, in their analysis of steel finishing lines, Ichniowski et al. (1997) estimate a significant profit increase for the lines that employed a full set of innovative practices. Of course, that these innovative practices have not been universally adopted suggests that their profitability might vary across different settings. I turn to this issue now.

4.4. Patterns of Adoption and Related Findings

In addition to detailed evidence concerning the effects of adopting innovative work practices, evidence has also been developed concerning patterns of adoption. As discussed earlier, in the United States innovative practices started to be adopted in the early 1980s, and there has been substantial growth since then both in the number of firms employing these practices and the number of practices the average such firm employs. But this diffusion has not been random. One clear pattern concerning adoption is that innovative practices are much more common in new factories and in those that have reopened under new management (e.g., see Kochan et al. 1986; Ichniowski and Shaw 1995; Ichniowski et al. 1997).

There are three possible explanations for this finding. First, there may be transition costs associated with having an operating factory move from using traditional work practices to using innovative practices. Because the first firms to adopt innovative practices should be those where the profitability of adoption is highest, if these transition costs are significant, then at any point in time adoption should be higher at new and reopened factories. Second, there may be an

33. See Ennen and Richter (2010) for a recent survey of the empirical literature concerning complementarities in organizations.

34. Wolf and Heinze (2007) find support for the idea that innovative work practices also reduce the gender wage gap.

35. See Frick et al. (2008) for empirical evidence suggesting that at least in some circumstances innovative work practices can lead to decreased rather than increased quality.

agency problem. It is possible that innovative work practices are profitable everywhere, but if a manager has little experience in managing a factory that employs innovative practices, it may not be in the manager's best interests to have the switch occur (e.g., because it makes him or her more easily substituted with a manager who has such experience). Third, it is possible that not all managers are sufficiently familiar with the productivity advantages associated with innovative practices, and it is the managers at new factories and newly reopened factories that, on average, are more likely to know about these advantages.³⁶

A second factor that is important in explaining who adopts innovative work practices is the complexity of the production process. In this case the evidence more clearly suggests the reason: the profitability of adoption is higher for more complex production processes. For example, Boning et al. (2007) find that adoption rates for innovative practices are higher and the profitability of adoption is higher for production lines that make more complex shapes. Similarly, Dunlop and Weil (1996) find that innovative work practices—in particular, what they refer to as “module production”—are employed by apparel manufacturers that produce smaller batches and employ quicker turnaround. This is not surprising, because many innovative practices concern increased communication and improved problem solving by production workers, and such practices quite plausibly have higher returns when production is more complex.

A final related finding is that the adoption of innovative practices is more likely and more profitable when the production process employs new computer-aided information technologies. Results along this line appear in numerous studies, including Milgrom and Roberts (1990), Dunlop and Weil (1996), Bresnahan et al. (2002), and Bartel et al. (2007). This finding can be interpreted as an example of the point made earlier that innovative work practices are more valuable and thus more likely to be adopted when production processes are more complex.³⁷

5. Theoretical Models Concerning Human Resource Practices

This section discusses various theoretical models that have been put forth to explain the use of innovative human resource practices. Much of the discussion focuses on the issue of complementary work practices, but I also discuss models that do not rely on complementarity.

5.1. Complementary Practices

The main theoretical approach for modeling the role of innovative human resource practices is to assume the practices are complementary. Complementary activities refer to activities such that “if the levels of any of the subset of activities are increased, then the marginal return to

36. One piece of evidence consistent with the first possibility is found in Ichniowski and Shaw (1995). They find that the introduction of new managers who, on average, might be more open to change does not have a statistically significant effect on the likelihood that a production line or factory changes from traditional to innovative practices. However, Lynch (2007) found results consistent with the third possibility. Specifically, she finds that employers who are best situated to learn about new practices are more likely to adopt them.

37. Bloom and Van Reenen (2007, 2010) have found evidence that suggests other factors might also be important for adoption of innovative work practices. For example, their results suggest that innovative practices are more likely to be adopted when product market competition is high, whereas extensive labor market regulation, family ownership, and government ownership tend to result in less use of innovative practices.

increases in any or all of the remaining activities rises" (Milgrom and Roberts 1990: 514). The idea that innovative work practices are complementary immediately explains why innovative practices are frequently employed in bundles and why the marginal return to adopting them can increase (over a range) with the number of practices adopted. For an example of the latter, complementary practices can explain the Ichniowski et al. (1997) finding that the work system containing the highest number of innovative practices was associated with an increase in productivity more than double the increase associated with the system associated with the next largest number of such practices.

An example of this type of argument is the Milgrom and Roberts (1995) analysis of Lincoln Electric. The Lincoln Electric case is a classic example of a firm characterized by what are now called innovative work practices, although it is interesting to note that Lincoln has employed these practices since roughly 1945. Three of the practices employed by Lincoln Electric are as follows. First, Lincoln made heavy use of piece rates. All production and many nonproduction workers at the firm had their compensation at least partly determined by piece rates. Second, a large proportion of the firm's stock was held by the firm's employees (initially accomplished through direct stock purchases and later through an employee stock ownership plan). Third, there was a high degree of job security accomplished through a no-layoff policy.

Milgrom and Roberts (1995) provide an explanation for these three practices using the idea of complementarity. It is well known that piece rates improve worker incentives, but there is the downside known as the "ratchet effect": if outputs are too high, then the firm learns the rate is too high and lowers it for subsequent periods. In turn, if this reduction is anticipated by workers, then the positive incentive effects of the piece rate are reduced.³⁸ Milgrom and Roberts argue that Lincoln was able to avoid this problem through the high level of employee stock ownership. The idea is that high employee stock ownership reduces the incentive for the firm to lower piece rates and in this way transfer rents from workers to the firm. Finally, because layoffs reduce employee stock ownership, the no-layoff policy was used to commit to a high level of employee stock ownership for future periods.³⁹

5.2. Four Additional Arguments Concerning Complementarities

The argument in Milgrom and Roberts (1995) concerning Lincoln Electric is just one example of a theoretical analysis that describes how specific innovative work practices can be complementary. In this section I describe four other important arguments of this type.

The first concerns the use of group-based incentive plans. As discussed in Alchian and Demsetz (1972), the free-rider problem suggests that individual piece rates should be superior to group-based incentive plans. But possibly because of the difficulty of measuring individual output, many firms employ group-based incentive plans rather than individual piece rates for a significant proportion of the workforce. The argument is then that other innovative work practices are employed because they support the use of group-based incentive plans.⁴⁰ For

38. Theoretical analyses concerning the ratchet effect appear in Lazear (1986b), Gibbons (1987), and Carmichael and MacLeod (2000).

39. Baker et al. (1994c) discuss another complementarity in Lincoln's practices, which is a complementarity between Lincoln's use of piece rates and its use of bonuses.

40. A variant of this argument appears in Che and Yoo (2001). In that paper group-based incentives are optimal in a repeated-game setting, because such incentives lead to high worker effort through peer sanctions or mutual

example, Kandel and Lazear (1992) argue that firms may spend resources on such activities as indoctrination and the formation of quality circles to establish and enforce group norms that ameliorate the free-rider problem through peer pressure (see also the related discussion concerning corporate culture in Kreps 1990).⁴¹ Also, because many highly productive workers might not want to join a firm where incentives are tied to group rather than individual output, another innovative practice potentially complementary to group-based incentive plans is the application of additional effort and resources to worker recruitment.⁴²

A second argument focuses on the decentralization of decisionmaking. Many firms that have adopted innovative work practices employ such practices as group-based decisionmaking teams and quality circles that move decisionmaking from managers to lower level employees. In this argument decentralized decisionmaking is employed, possibly because better decisions can be made by those with on-the-spot knowledge; and then other innovative work practices are employed because they support this decentralization (for early discussions of Japanese labor market practices along this line, see Koike 1977, 1988; Aoki 1986, 1988; for more recent analyses, see Morita 2001, 2005).⁴³ For example, if lower level employees make decisions, then it is important that these employees are cooperative, highly skilled, and provide high effort. Cooperation can be achieved by group-based incentive plans consistent with the argument of Holmström and Milgrom (1991) discussed next, higher skills can be achieved by higher levels of on-the-job training, while group-based incentive plans should induce higher effort than can no-incentive pay. Also, because new ideas can lead to the elimination of jobs, it is also important, as argued by Aoki (1988), that firms offer high levels of employee security. Along the same line, Carmichael and MacLeod (1993) argue that practices like job rotation can add to the range of jobs to which a worker can be assigned, and this can help a firm commit to high levels of job security.

The third argument is that of Holmström and Milgrom (1991, 1994) concerning multitasking. A standard problem in the theory of multitasking is that incentive pay that is based on measurable output inefficiently distorts effort away from important tasks whose value to the firm is not measurable. In particular, Holmström and Milgrom (1994) translate this phenomenon into an argument concerning complementarity. Specifically, if the firm provides high incentive pay associated with measured performance, then it is important that the firm also employ practices that limit the resulting distortions. Holmström and Milgrom argue that one way firms can do this is to couple high incentive pay with worker ownership of assets, because, for

monitoring. After showing this result, Che and Yoo then demonstrate that team production and job security are employed because they are complementary to group-based incentives and peer sanctions.

41. Experimental evidence supporting the importance of peer pressure in teams can be found in Falk and Ichino (2006), Mohnen et al. (2008), and Mas and Moretti (2009).

42. The empirical analysis in Hamilton et al. (2003) discussed earlier throws some doubt on certain aspects of this argument (see also related results in Knez and Simester 2001; Burgess et al. 2010). As discussed, in that analysis the firm was able to increase productivity by moving to a group-based incentive plan from individual piece rates. This transition should not happen if, as argued above, group-based incentive plans are only used when individual piece rates are not feasible. Also inconsistent with the above argument, Hamilton et al. find that the high-productivity workers were usually the first to voluntarily join the newly forming teams.

43. See Mookherjee (2006) for a related discussion of decentralized decisionmaking from the standpoint of mechanism design.

example, ownership will cause workers to provide more effort and invest more resources into maintaining the asset. They also argue that, due to complementarity, high incentive pay should be coupled with more discretion on the part of workers concerning what the job entails.

In addition to a theoretical analysis, in their 1994 paper Holmström and Milgrom argue that their framework matches empirical evidence found in a number of studies. Their theoretical approach predicts that high incentive pay, asset ownership by employees, and worker discretion should all covary positively. For example, a change in an exogenous parameter that increases the return to using high incentive pay should increase the degree to which high incentive pay is used, but because of complementarity, it should also increase employee asset ownership and worker discretion. This prediction is supported by empirical findings in Anderson and Schmittlein (1984) and Anderson (1985) concerning the choice between in-house and independent sales agents in industrial selling. They find covariation of exactly the type predicted. That is, independent sales agents had higher incentive pay, more discretion, and (at least in one important dimension) higher asset ownership. Further, the variables predicting the choice between in-house and independent sales agents were also consistent with the theoretical predictions. Holmström and Milgrom (1994) also relate their theoretical predictions to findings in several other studies, including Shepard (1993) and Slade (1996) concerning gas stations and Brickley and Dark (1987) and Krueger (1991) concerning fast food.

The final argument is a variant of the Aghion and Tirole (1997) theory of real versus formal authority. One of their main results is that when choosing whether to use centralized or decentralized decisionmaking, firms face a trade-off between incentives and agency costs. On the one hand, decentralization increases incentives for workers to acquire information. On the other, there is an agency cost, because the interests of the employees and those of the firm are typically not perfectly aligned. As a result of this trade-off, there is a complementarity between an increased use of incentive pay and decentralization accomplished through practices such as problem-solving teams and quality circles. The argument is that higher incentive pay serves to ameliorate the agency problem associated with decentralization by aligning workers' interests with those of the firm.⁴⁴

5.3. Other Theoretical Models

This section discusses theoretical models of innovative work practices that do not focus on complementarities. Rotemberg (1994) focuses on altruism in the workplace. He argues that in the

44. One problematic feature of the Aghion and Tirole (1997) framework is that delegation entails the principal giving formal authority to the agent when it is still the principal's organization; that is, the behavior does not seem credible, because in real-world organizations the principal could always undo the delegation decision (for discussions and analyses of this point, see Baker et al. 1999; Gibbons 2003). However, an alternative argument that gives similar predictions is that the principal does not delegate by ceding to the agent irrevocable control but rather commits to delegation by ex ante choosing actions that make it costly for the principal to over-rule the agent. I thank Bob Gibbons for pointing out this argument to me. Also, see Acemoglu et al. (2007) for further theory and interesting empirical evidence on the trade-off between incentives and agency costs in the decentralization decision.

A related argument appears in Van den Steen (2010). In that argument centralized decisionmaking is associated with low incentive pay, because high incentive pay can lead to agents who disobey the orders or instructions of their principals. See also Van den Steen (2009).

presence of altruism, group-based compensation can increase worker productivity. The argument is straightforward. Given group-based compensation and altruism, each worker increases his or her effort level, because the worker internalizes to some extent the effects added effort has on other workers' compensation. Rotemberg also argues that it can be profitable for a firm to induce altruism in this type of setting by allowing time for socialization and other related behaviors. Overall, Rotemberg's argument is a quite plausible additional mechanism to the Kandel and Lazear (1992) peer-pressure argument for how the free-rider problem can be avoided in firms characterized by group-based compensation.⁴⁵

Ortega (2001) provides a new explanation for job rotation (see also Eriksson and Ortega 2006). Rather than focusing on the benefits that job rotation may have on developing an employee's human capital, Ortega argues that the returns to job rotation are mostly in terms of firm learning. In Ortega's model the firm is initially uncertain about the productivity of its various workers at different job assignments, and there is also uncertainty concerning the potential profitability of the various jobs. He shows that in this setting job rotation is superior to job specialization in terms of how much the firm learns along these two dimensions.⁴⁶ Hence, job rotation should be employed when the returns in terms of learning are high and costs are low.

In addition to presenting the theory, Ortega argues that it is a good match for empirical evidence on job rotation. He focuses on two pieces of evidence. First, as found by Campion et al. (1994), the use of job rotation is negatively related to a worker's tenure at the firm. Second, as found by Gittleman et al. (1998), job rotation is positively related to whether the firm is using a new technology. Ortega argues that each of these findings is consistent with his theory. First, high tenure means that the firm already has a lot of information about the worker, so the additional information that can be gathered through job rotation is of little value. Second, new technology means job rotation is valuable, because the firm has little information about its current jobs.⁴⁷

Zábojník (2002) focuses on centralization versus decentralization. In particular, this paper considers a setting similar to that considered by Aghion and Tirole (1997) discussed above. The main point is that a firm may decentralize decisionmaking through such practices as problem-solving teams, even when managers are better informed than production workers. The reason is that it can be cheaper to induce workers to provide high effort when the project or method of

45. See Bandiera et al. (2005, 2008, 2009) for interesting empirical evidence that supports the idea that social ties among workers can be important.

46. Ortega (2001) builds on Meyer (1994), who also looks at the effect that job assignment can have on the rate at which firms learn about workers' abilities but does not specifically focus on job rotation. For an alternative theoretical approach to job rotation, see Prescott and Townsend (2006).

47. Ortega also argues that the human capital explanation for job rotation is inconsistent with this evidence. But this logic seems less clear. In terms of the human capital theory, it is possible that what is valuable is a little bit of experience in a number of jobs. In turn, this version of the human capital theory is consistent with the evidence, in that high tenure means the worker likely already has at least a little experience in several jobs, so additional job rotation is not needed, whereas new technology means workers do not have the needed experience with the firm's current jobs, so additional job rotation is very valuable. Additionally, to the extent job rotation is a costly investment in human capital acquisition, then standard human capital theory suggests it should be undertaken early in careers, which, in turn, is another reason job rotation should be negatively related to firm tenure. I thank Jan Zábojník for pointing out this last argument to me.

production chosen is that favored by the workers rather than the one favored by the manager. In other words, to the extent workers provide higher effort when they believe the project or method of production has a higher likelihood of success, the firm may be able to increase productivity by letting the workers decide, even when the manager is better informed.⁴⁸

The last paper I consider here is Akerlof and Kranton (2005) (see also Akerlof and Kranton 2008). They take the perspective, common in sociology and psychology, that norms matter. In particular, how an employee behaves in a particular situation (e.g., how much effort a worker expends) depends on the situation and the worker's identity, where identity refers to the worker's social category (e.g., man or woman, black or white) and self-image. The basic idea is that a worker who identifies with the firm or work group will, monetary incentives held fixed, choose higher effort than will a worker who does not identify with the firm or relevant work group.

This perspective can explain the employment of a number of innovative work practices. The idea is that, because a worker provides higher effort when he or she identifies with the firm or work group, the firm has an incentive to adopt practices that serve to foster this type of identification. So, for example, a firm might adopt high levels of screening during the recruitment process, because screening can be used to ensure that new employees are of a type conducive to such identification. Or similarly, the formation of work groups may be beneficial, because workers more easily identify with a work group than with the firm itself. One problem, however, is that Akerlof and Kranton (2008) argue that identification is a substitute for monetary incentives. To the extent this is the case, then we should expect the practices just mentioned not to be used in conjunction with high levels of incentive pay, which is exactly the opposite of what the evidence suggests. But possibly the Akerlof and Kranton discussion of this issue is incomplete in the sense that maybe certain types of incentive pay can be used to help establish identification, which in turn could explain why these practices are used together.

5.4. Overview

The evidence seems quite clear that complementarity is important for understanding the move to innovative work practices. There are several aspects of the evidence that point in this direction. First, innovative work practices are frequently adopted in bundles. Second, there is evidence of an increasing marginal return in terms of productivity to adopting additional practices. Third, the evidence suggests the return to adopting a single practice in isolation is small or possibly even zero. Each of these findings is consistent with the basic idea of complementarity, which is that the return to adopting any specific practice is positively related to the number of other practices adopted.

So the more difficult question is, of the various theories concerning complementarity that have been proposed, which seem most promising as an explanation for the evidence? The literature is far from giving a conclusive answer to this question. But some tentative conclusions can be drawn. First, some theories put forth have some support in the data, so my sense is

48. Zábojník (2002) shows this logic is correct when it is costly for firms to induce high worker effort strictly through contracting, which is the case given either liquidity constraints or risk aversion. A related argument appears in Van den Steen (2006). In that argument different priors lead to the same result: delegation can have a positive effect on worker effort, but there is also the cost that delegation reduces coordination both inside and across firms. See also De Paola and Scoppa (2009) for a related analysis.

that the right answer is not that there is a single theory that is correct and the others have no explanatory power. Rather, it is likely that several theories are important for understanding real-world organizations.

For example, as discussed, the Holmström and Milgrom (1991, 1994) theory concerning balancing incentives in a multitasking world seems consistent with various studies on sales agents. However, there is some question concerning whether one of the basic premises of the free-riding argument is correct. That is, given the popularity of group-based incentive plans and the findings in Hamilton et al. (2003) on the returns of moving from individual piece rates to group-based incentive plans, it is questionable whether group-based incentive plans are used primarily when individual piece rates are not feasible (see footnotes 40 and 42 for related discussions). But there are other parts of that argument that seem quite plausible. For example, for whatever reasons group-based incentive plans are adopted, it seems reasonable that activities used to enforce high-effort norms are employed as a way of avoiding the potential free-rider problem.

Second, to the extent that one of the theories is the correct explanation for the bulk of the evidence, my vote is on the argument that decentralized decisionmaking is employed because better decisions can be made by those with on-the-spot knowledge, and, in turn, many innovative practices are employed, because they are complementary with decentralization. On the one hand, this argument ties together the largest number of innovative practices. Specifically, group-based decisionmaking teams and quality circles are explained as practices that directly serve to decentralize decisionmaking, while various other practices (e.g., group-based incentive plans, high levels of on-the-job training, job rotation, and high levels of job security) are employed as ways to support the decentralized decisionmaking. On the other hand, detailed empirical analysis (e.g., Ichniowski et al. 1997) suggests that the extensive use of group-based decisionmaking (i.e., decentralization) is central to the increased productivity associated with innovative work practices.⁴⁹

Finally, a subject that deserves more attention in future research is that of layering. In a closely related empirical literature it has been shown that over time, hierarchies have become flatter or, equivalently, layering has occurred—that is, in the typical firm there are fewer layers between the CEO and the bottom of the organization, and the average number of workers reporting to each manager has increased (for an early discussion, see Osterman 1996; for systematic empirical evidence, see Rajan and Wulf 2006; Guadalupe and Wulf 2010). There are several possible explanations for the phenomenon, such as improvements in information technology decrease the need for middle managers, as argued originally by Leavitt and Whisler (1958). My point is that, if a central aspect of innovative work practices is decentralized decisionmaking, it is possible that one reason for layering is the adoption of these practices and the resulting decentralized decisionmaking, which potentially requires fewer middle managers. Empirical work focused on this possibility would be of significant interest.

49. In comparison to production lines that employ traditional work practices, Ichniowski et al. (1997) find that productivity rises 6.7% for lines that employ a full set of innovative work practices and 3.2% for lines that emphasize teamwork and communications. In contrast, productivity on average is only 1.4% higher for lines that emphasize communications with less stress on teamwork. See also Colombo et al. (2007) and Jones and Kato (2011) for evidence that supports the idea that group-based decisionmaking is central for understanding why innovative work practices lead to increased productivity.

6. International Differences

There is a companion literature to the one discussed in Sections 4 and 5 that addresses international differences in how internal labor markets operate. This literature is closely related to the earlier one in that many of the differences can be thought of as differences in human resource practices. In this section I discuss the literature on international differences. In particular, one focus is on trying to understand what can be learned by thinking about the two literatures together. Note that because most of the literature on international differences is focused on U.S.-Japanese differences, that will be the focus here also.⁵⁰

6.1. U.S.-Japanese Differences

Here I describe the major differences that have been identified concerning the operation of U.S. and Japanese internal labor markets. Before proceeding, there are two points worth emphasizing. First, many of these differences are closely related to differences in innovative and traditional human resource practices discussed previously. Second, much of the evidence showing large differences in the operation of U.S. and Japanese internal labor markets is from studies that are now decades old. I come back to these points in Section 6.3.

I start by describing U.S.-Japanese differences in internal labor markets that are closely related to those between traditional and innovative human resource practices.⁵¹ First, such studies as Kagono et al. (1985) and Lincoln et al. (1986) find that decisions are made at lower levels of the hierarchy in Japanese firms than at U.S. firms (see also the earlier work of Clark 1979; Cole 1979). For example, Lincoln et al. conducted a study of 55 U.S. firms and 51 Japanese firms in terms of the hierarchical level at which decisions were made. They found that in the Japanese firms decisions were made at lower hierarchical levels on average than in the U.S. firms. This finding is similar to the earlier discussion of innovative work practices in which some innovative practices serve to move decisionmaking away from managers and to lower level employees.

Second, there is substantial evidence that Japanese firms offer more on-the-job training, and correspondingly Japanese employees have higher levels of firm-specific human capital (e.g., see Koike 1977, 1988; Hashimoto 1994; MacDuffie and Kochan 1995). Further, much of this literature focuses on higher levels of multiskilling in Japanese firms, where “multiskilling” refers to acquiring the human capital needed to do multiple jobs, which occurs, for example, with heavy use of job rotation. Studies that discuss the prevalence of multiskilling in Japanese firms include Koike (1977, 1988), Dertouzos et al. (1989), and Ito (1992). Note that higher levels of on-the-job training and job rotation were also part of the discussion concerning innovative human resource practices.

Third, Japanese firms are characterized by higher levels of continuous process improvement. For example, in Japanese firms, through group decisionmaking teams and quality circles, lower level employees are more frequently solicited for suggestions concerning improvements in the production process (for discussions, see Koike 1977, 1988). Also, Dertouzos et al. (1989) found that in the late 1980s, engineers in Japanese steel production were located in a manner that

50. I especially thank Hodaka Morita for suggestions and discussions that were helpful in formulating the discussion in this section.

51. For an overview of the operation of internal labor markets in Japanese firms, see Ariga et al. (2000).

allowed for quicker responses to day-to-day operational problems than was the case in U.S. steel production.

Fourth, long-term employment is higher and turnover rates lower in Japanese firms. This has been found by numerous authors, including Hashimoto and Raisian (1985), Mincer and Higuchi (1988), Blinder and Krueger (1996), and Kato (2001). For example, Hashimoto and Raisian compared U.S. and Japanese labor markets by analyzing data from the Special Labor Force Report for the United States and the Basic Survey of Employment for Japan. They found that long-term job retention rates were higher in Japan and that average job tenure was also higher. These ideas that long-term employment is higher and turnover is lower in Japanese firms are similar to the earlier emphasis on job security in firms that employ innovative work practices.⁵²

The last two differences do not have a close relationship with the discussion of traditional and innovative work practices. Fifth, as discussed, for example, in Holzhausen (2000), in Japanese firms promotion to managerial ranks occurs later in careers; correspondingly, there is little differentiation in terms of wage and promotion rates for white-collar workers early in their careers. More specifically in terms of the latter point, in large Japanese firms workers with the same educational background are treated similarly in terms of wages, wage growth, and promotion rates early in their careers, but after approximately 10–15 years of experience, wage growth and promotion decisions depend more heavily on performance evaluations. Of further interest, although outcomes do not vary much early in careers, the evidence suggests that many young white-collar workers in Japan do have a clear sense of their long-term career prospects.

Sixth, within-firm income dispersion is smaller in Japan. For example, Koike (1977, 1988) compares wage differentials between managers and average white-collar workers in Japan and various European countries and finds that Japan has one of the smallest wage differentials. As it is typically believed that within-firm income dispersion is higher in the United States than in Europe, this clearly suggests much higher within-firm income dispersion in the United States than in Japan.⁵³

6.2. Candidate Models for Explaining U.S.-Japanese Differences

Some theoretical approaches for explaining U.S.-Japanese differences in internal labor markets rely on models characterized by multiple equilibria.⁵⁴ One set of models focuses on the connection between adverse selection and turnover. The best known of these papers is

52. This issue has also been studied more recently in Farber (2007), Kawaguchi and Ueno (2010), Ono (2010), and Kambayashi and Kato (2011). Together the results in these papers suggest that long-term employment in the Japanese economy fell by the end of Japan's Great Recession (which lasted from approximately 1992 to 2007) but that it still remains higher than in the United States.

53. Genda et al. (2010) find another difference that has not previously been emphasized: the disadvantages of entering the labor market during a recession tend to be larger in Japan than in the United States.

54. The first paper I am familiar with that uses a multiple equilibria approach to explain U.S.-Japanese labor market differences is Okuno-Fujiwara (1987). That paper investigates multiple equilibria in a setting of contracting and involuntary unemployment that builds on earlier analyses in Calvo (1979) and Shapiro and Stiglitz (1984).

Acemoglu and Pischke (1998), which builds on Greenwald (1979, 1986) and Gibbons and Katz (1991).⁵⁵

Acemoglu and Pischke consider a labor market setting in which a worker's current employer knows more about a worker's ability than do prospective employers, so turnover is reduced because of the resulting adverse-selection problem. What is new here is the focus on on-the-job training. The adverse-selection problem means that a worker's current employer has monopsony power after the training period. This monopsony power gives the firm an incentive to offer and pay for general training of its workers (while at the same time reducing a worker's incentive to pay for general training). Based on this logic, Acemoglu and Pischke identify the possibility of multiple equilibria. In what might be called the Japanese equilibrium, the adverse-selection problem is severe, causing little turnover and high monopsony power, which, in turn, results in high on-the-job training. In what might be called the U.S. equilibrium, the adverse-selection problem is mild, so turnover is higher, monopsony power is lower, and the result is a lower level of on-the-job training. In addition to developing the theoretical argument, Acemoglu and Pischke present evidence using data on German apprentices that supports the theory.⁵⁶

A second argument appears in Prendergast (1992). Prendergast focuses on delayed promotion and higher firm-specific human capital in the Japanese case. In Prendergast's model each employer has private information about each young worker's long-term career prospects, and the firm must decide whether to reveal this information to workers, which would increase incentives for workers with high potential. In the U.S. equilibrium firms promote young workers with high potential, which signals potential and results in high incentives. In the Japanese equilibrium, instead, the return to training low-ability young workers is high, and firms choose to retain high incentives for low-ability workers by not promoting young workers and in this way not revealing private information. One problem with this argument is that, as mentioned above, even though there are no promotions early in careers in Japan, many young white-collar workers in Japan do seem to have a clear sense of long-term career prospects.⁵⁷

Morita (2001, 2005) also presents a multiple-equilibrium model. His argument serves as an explanation for differences in human capital accumulation, including multiskilling, decentralized decisionmaking, continuous process improvement, and turnover. His model builds on earlier discussions in Koike (1977, 1988) and Aoki (1986, 1988) and is related to one of the arguments concerning decentralization in Section 5.2. Basically, Morita identifies a set of complementarities across these variables that leads to the possibility of multiple equilibria. When workers are multiskilled, they have the knowledge required to make better decisions, so de-

55. Other studies that take an adverse selection and turnover approach to explain U.S.-Japanese differences include Prendergast (1989) and Chang and Wang (1995). Katz and Ziderman (1990) and Chang and Wang (1996) also consider models similar to the ones discussed here but do not relate their analyses to U.S.-Japanese differences.

56. Although the empirical work of Acemoglu and Pischke (1998) concerns Germany, because there are many similarities between German and Japanese labor markets (see Dertouzos et al 1989), their empirical findings can be interpreted as suggesting that adverse selection is also important in the Japanese labor market.

57. A related empirical result is found in Umezaki (2001), who shows a strong correlation in Japan between task assignments when young and subsequent promotion outcomes. In other words, because young workers in Japan with better long-term career prospects seem to be assigned different tasks than others in their age cohort, in contrast to Prendergast's (1992) argument, even in the absence of any initial differentiation of wage and promotion outcomes, young workers should be able to infer their long-term prospects.

centralized decisionmaking becomes more attractive. In turn, the combination of multiskilling and decentralized decisionmaking makes continuous process improvement feasible. Thus, over time the high levels of continuous process improvement mean that each firm is characterized by high levels of firm-specific human capital. Finally, the high levels of firm-specific human capital reduce turnover and increase average job duration.

In Morita's (2001, 2005) argument continuous process improvement is more beneficial when workers have high levels of firm tenure, so the return to adopting continuous process improvement is positively related to the number of other firms that adopt it. That is, when firms adopt continuous process improvement, they are less likely to raid other firms' employees, because skills are not transferable, so job durations are higher. As a result, any given firm has a higher incentive to adopt continuous process improvement. Thus, there can be two equilibria. In the Japanese equilibrium all firms adopt continuous process improvement, which lowers the turnover rate and makes this choice profitable. In contrast, in the U.S. equilibrium firms do not adopt continuous process improvement, which raises the turnover rate and makes choosing continuous process improvement unprofitable. Morita argues that historical events during World War II explain the different equilibrium choices in the two countries.

The last theoretical argument I discuss here is the one put forth in Owan (2004), which employs the promotion-as-signal hypothesis. There are two key assumptions in Owan's model. First, in addition to varying in terms of ability, a firm's workers also vary in the quality of worker-firm matches. Second, a worker's current employer privately learns the worker's ability before learning the quality of the worker-firm match. Given these assumptions, Owan shows that depending on various factors (e.g., the distribution of worker characteristics and the relative value of firm-specific human capital across jobs), one of two possible equilibria will arise. In an early-promotion equilibrium high-ability workers are promoted after the firm learns ability but before learning the quality of worker-firm matches. In a late-promotion equilibrium there are no promotions until the firm learns both ability and the quality of worker-firm matches.

The main point of Owan's (2004) analysis is that the differences between these two potential equilibria match the differences in U.S.-Japanese internal labor market operations discussed above. Think of the late-promotion equilibrium as the Japanese equilibrium and the early-promotion one as the U.S. equilibrium. First, the late-promotion equilibrium clearly matches the late-career promotions and the early-career reduced differentiation in wage and promotion outcomes in Japan. Second, Owan shows that the late-promotion equilibrium has no turnover, because the lack of early promotions serving as a signal causes adverse selection to be severe and the secondary market for workers to shut down, whereas in the early-promotion equilibrium high-ability workers with bad matches leave their initial employers. So the late-promotion equilibrium matches more long-term employment and less turnover in the Japanese case. Third, the lack of promotion signaling in the late-promotion equilibrium means that the asymmetry of information is more severe in this equilibrium, which results in less income dispersion. Thus, the late-promotion equilibrium also matches the smaller dispersion of incomes in the Japanese case.⁵⁸ Finally, Owan also provides a discussion for why Japan is characterized by the

58. Owan (1999) shows how a related model also explains higher levels of firm-specific human capital in Japan.

late-promotion equilibrium and the United States by the early-promotion equilibrium; as in Morita's (2001, 2005) argument, part of Owan's discussion focuses on historical events.⁵⁹

6.3. Convergence

As is made clear above, much of the literature on U.S.-Japanese differences is based on data or observations that are decades old. This is potentially important. As discussed in Section 4, innovative work practices were introduced in Japan prior to being introduced in the United States, and after the introduction in the latter country, there was and likely still is gradual diffusion of these practices. This suggests that, at least for those differences related to dissimilarities between traditional and innovative human resource practices, the differences are likely much smaller today than they were in the past. Another way to put this is that such studies as Osterman (1994, 2000) and Cappelli and Neumark (2001) show there has been significant growth since the 1980s in the employment of innovative human resource practices in the United States, whereas there is no similar empirical literature suggesting increases during this time in the use of innovative work practices in Japan.⁶⁰ Thus, at least for the differences related to innovative human resource practices, there is likely less divergence between the two countries today than there was 20 or 30 years ago.

The idea that some of the differences today are much smaller than they were in the past introduces an interesting possibility concerning what drives these differences. That is, it is likely that the later introduction of innovative work practices in the United States and their gradual diffusion was a major driving force for many of the large differences observed between the United States and Japan in the 1980s and 1990s. As time passed and diffusion continued, differences became smaller—possibly substantially so. Note that I am not claiming here that there is nothing to explain once one takes into account the late introduction and subsequent diffusion of innovative work practices in the United States. Rather, I am arguing that any full picture of what drives differences between the U.S. and Japanese labor markets needs to take the likelihood of convergence into account.

The other issue that this perspective suggests is the relative weight one should put on the various international differences that have been identified concerning the United States and Japan. As innovative work practices have diffused across the former country, some differences that are related to innovative practices have very likely gotten smaller. But for a couple of the differences there is little evidence suggesting convergence. Specifically, in terms of later promotion and less differentiation in wage and promotion outcomes early on, lower income dispersion, and possibly lower turnover seen in Japan, I see little evidence for convergence. So possibly, future empirical work should focus on whether it is correct that convergence has been important for some differences but not for others, whereas future theoretical work might focus more on the differences that seem to be less subject to convergence.

59. See Moriguchi (2003) for a related argument in which the difference in the size of the macroeconomic contractions during the 1930s between the United States and Japan is used to explain subsequent differences between the U.S. and Japanese labor markets.

60. In fact, some recent evidence suggests that some of the distinctive features of Japanese internal labor markets have become less pronounced in recent years. See, for example, Hamaaki et al. (2010), Kawaguchi and Ueno (2010), and Ono (2010).

6.4. Overview

Because many of the differences between U.S. and Japanese internal labor markets are related to differences between traditional and innovative human resource practices in the United States, there should be a close linkage between theories used to explain the movement from traditional to innovative work practices in the United States and theories used to explain differences between the two countries' internal labor markets. In other words, if part of what is driving the differences between U.S. and Japanese internal labor markets is that innovative work practices are more commonly used in the latter country than in the former, then the arguments for what is happening in the United States over time and those concerning U.S.-Japanese differences need to be tightly linked.

The above discussion concerning convergence is consistent with this idea. It attributes at least some of the difference between U.S. and Japanese internal labor markets (and possibly much of it early on) to the later introduction of innovative work practices and subsequent gradual diffusion in the United States. This notion is consistent with the discussion in Section 4, which gave a prominent role to gradual diffusion of innovative work practices in understanding the trends in the use of innovative work practices in the United States. In following up this idea, it might be of interest to compare current U.S. and Japanese internal labor markets but only consider U.S. firms that have adopted innovative work practices. This approach would provide a sense of how much of the U.S.-Japanese differences in internal labor markets is due to gradual diffusion and how much is due to differences that remain even after U.S. firms adopt innovative work practices (for a related analysis, see Ichniowski and Shaw 1999).

In addition, to the extent that there are remaining differences even after taking into account gradual diffusion, the question remains: what drives these differences? Of the theories that I have reviewed, the one that shows the most promise is that presented in Morita (2001, 2005), which is related to the earlier arguments of Koike (1977, 1988) and Aoki (1986, 1988). On the one hand, for various reasons, the other arguments are somewhat lacking in terms of providing a convincing explanation for the gamut of U.S.-Japanese differences. Prendergast's (1992) model relies on young Japanese workers not knowing their career prospects, which seems inconsistent with the evidence, while Owan's (2004) model—although interesting—relies on an ad hoc assumption concerning job-match information being revealed later to firms than information about worker abilities.⁶¹ Also, although there is empirical support for Acemoglu and Pischke's (1998) model, that argument explains a limited number of differences. On the other hand, Morita's argument explains a large number of differences, and it is also heavily focused on information sharing and decentralized decisionmaking, which are central in most descriptions of the differences between the U.S. and Japanese settings.

But even Morita's argument has the drawback that it does not explain one of the key U.S.-Japanese differences: early promotion and early differentiation in the U.S. setting and late promotion and late differentiation in the Japanese case. Possibly, one could extend Morita's argument to capture this important difference by focusing on how different levels of firm-specific

61. This assumption is important for Owan's (2004) explanation for why Japan is characterized by late promotions and the United States by early promotion. Since other aspects of Owan's argument are appealing, maybe much of what Owan argues is correct, but there is a different explanation for this particular U.S.-Japanese difference.

human capital affects whether equilibrium is characterized by early or late promotions. But this possibility can only be resolved with further theoretical research.⁶² Alternatively, there may be a way to combine Morita's and Owan's arguments.

Finally, although the discussion in this section focuses on differences between U.S. and Japanese internal labor markets (because that is the focus of most of the literature), much of the discussion likely also applies to comparisons of Japanese internal labor markets with those found in many other industrialized countries. That is, it is not just the case that innovative human resource practices spread from Japan to the United States and then gradually diffused in the United States, but rather this later adoption and gradual diffusion is also true of many other industrialized economies. So, to the extent that many of the differences between the operation of U.S. and Japanese internal labor markets discussed above are due to differences in the employment of innovative human resource practices in the two countries, it would be natural to expect that similar differences in internal labor market operations between Japan and other industrialized countries are also due to differences in the employment of innovative human resource practices.⁶³

7. Conclusion

The literature on internal labor markets has matured to the point that for some branches of the literature, there is now a very healthy two-way interaction between theory and empirical work. On the one hand, numerous theoretical papers try to provide explanations for empirical phenomena and, more specifically, for patterns found in the data. On the other, numerous empirical papers try to test the most promising theories. In turn, combining theoretical and empirical contributions has the potential to advance our understanding of various issues in internal labor markets in important ways.

In this survey I have focused on this two-way interaction between theory and empirical work. In particular, I examined three topics in the extensive literature on internal labor markets to both show the benefits of a rich interaction between theory and evidence and draw some conclusions in each case about which theoretical approaches look most promising. The first topic I considered is wage and promotion dynamics in internal labor markets. Various distinct theoretical approaches have been put forth concerning this topic. After reviewing the various theories and the relevant empirical literature, my conclusion is that a model that combines symmetric learning, human capital accumulation, and job assignment—as in Gibbons and Waldman 1999b, 2006—holds the most promise for explaining the various empirical findings.

62. My idea here is related to the Harris and Holmström (1982) argument discussed in Section 3. Firms would like to partially insure workers against uncertainty concerning true innate ability, and one way to potentially do this is to employ late promotions and little differentiation early in careers. This strategy is feasible in the Japanese case, because the high levels of firm-specific human capital mean that a worker who is revealed to be of high innate ability early on cannot be hired away by another firm. But in the U.S. case, because of the lower levels of firm-specific human capital, this strategy is infeasible—a young worker who is revealed to be of high innate ability who is not promoted or given a high wage would be bid away.

63. One exception may be between Japan and Germany. Dertouzos et al. (1989) argue that even early on, the operation of West Germany's internal labor markets had similarities to those found in Japan that were not seen in most other industrialized countries.

But other theoretical approaches, such as tournament theory and asymmetric learning, also seem important for a full understanding of what drives wage and promotion dynamics inside firms.

The second literature I focused on is that concerning the growing use by firms of innovative human resource practices. After reviewing the empirical and theoretical literatures, my primary conclusion was that—as argued by numerous authors, including Milgrom and Roberts (1990, 1995) and Holmström and Milgrom (1994)—complementarity is a driving force for understanding the growing use of these practices. The evidence is less clear concerning which of the various theories put forth to explain the nature of these complementarities is most important. But the argument that the driving force is a desire to move decisionmaking from managers to lower level employees because better decisions are made by those with on-the-spot knowledge seems to be the argument that best matches the evidence.

The third literature I considered is that on international differences in internal labor markets, where most of this literature focuses on U.S.-Japanese differences. One conclusion here is that at least some of the historical difference between the United States and Japan likely stems from the later initial adoption of these practices and their gradual diffusion in the United States. However, some differences likely remain even after taking this factor into account, and my sense is that the correct explanation for the remaining disparities lies in the differing incentives for decentralized decisionmaking in the two countries, as emphasized initially by Koike (1977, 1988) and Aoki (1986, 1988) and more recently by Morita (2001, 2005).

I have shown how a close partnership between theory and empirical evidence can be used to reach a deeper understanding of the driving forces behind the operation of internal labor markets than can be reached by either empirical evidence or theory taken in isolation. Hopefully, future work concerning wage and promotion dynamics and the use of innovative human resource practices—as well as research on other topics on internal labor markets—will continue to pursue the close two-way interaction between theory and empirical evidence described in this chapter.

Technological Innovation and Organizations

Pierre Azoulay and Josh Lerner

1. Introduction

In a handbook that takes a broad view of organizational structure, it might be wondered whether a chapter devoted to the relationship between technological innovation and organization is appropriate. After all, is not innovation just one relatively modest facet of economic activity?

There are two responses to this question. First, since the 1950s, economists have understood that technological innovation is critical to economic growth. Our lives are more comfortable and longer than those of our great-grandparents on many dimensions. At the heart of these changes has been the progress of technology. Innumerable studies have documented the strong connection between technological progress and economic prosperity both across nations and over time. Since the work of Abramowitz (1956) and Solow (1957), the importance of technological change has been generally understood, an understanding that has been deepened by studies in recent years documenting numerous positive effects of technological progress in specific areas, such as information technology (Bresnahan et al. 2002).

Second, innovation represents a particularly extreme ground for understanding organizational economics. This setting is one where information and incentive problems, which exist in the backdrop of many models of organizational structure and effectiveness, are front and center. These problems are at the heart of the innovation process. As Holmström (1989: 307) observes in his classic essay:

One would expect modern finance theory to give good general advice on how to manage investments into research and development. But a quick look at finance textbooks reveals answers that are based on a very stylized conception of the problem and rather less illuminating than one would hope.

We thank Harvard Business School's Division of Research for financial support. Bob Gibbons, John Roberts, and participants in a meeting of the NBER Working Group in Organizational Economics devoted to reviewing early drafts of chapters from this handbook provided helpful comments. All errors and omissions are our own.

Thus, if we can understand organizational issues in the innovation setting—where performance often cannot be accurately measured, where knowledge often flows between entities, and where contracts may not be enforceable—we are likely to have a better understanding of these questions more generally. In this sense, the study by an economist of the relationship between innovation and organizational structure is akin to that of a physicist studying reactions in extremely young stars to gain insights that will be useful here on earth.

In this chapter, we begin by examining the relationship among internal organization, innovation inputs, and research productivity. We then turn to the relationship between contracting and innovation, and finally to the consequences of innovation for organizations.

Technological innovation is a large topic with many empirical and theoretical challenges. Nonetheless, we can highlight several conclusions that emerge from our discussion:

- Our understanding of contracting and innovation is probably the most developed of any of the major topics delineated here. At least in part, this reflects the close connections between theoretical and empirical research on this topic.
- In far too many other topics, however, there has been a disconnect between the insights of theoreticians and the work by empirical researchers.
- Most of what economists know about technological innovation and organizations does not stem from the mining of traditional datasets. On the contrary, some of the more lasting insights come from the collection of original fine-grained data at the project level. Case studies also inform the state of economists' knowledge on these topics (see Baker and Gil, this volume).
- An essential difficulty facing large-sample empirical research has been an inability to distinguish between association and causation, and, in some cases, a failure even to think carefully about this distinction. Empirical research is likely to advance considerably if some of the experimental methodologies employed in labor economics and related fields can be adopted here.
- Many valuable insights into these questions can be gleaned from fields outside economics, including sociology and more traditional managerial studies.
- The greatest gains in future years will be achieved by looking inside the “black box” of the firm and understanding the internal workings of the innovation process.

Reflecting the substantial size of this topic, we have limited our discussion in several important ways. First, we have focused on technological, not organizational, innovations. Readers interested in the adoption of new management techniques and their consequences for firm performance could turn to the work of Nick Bloom, John Van Reenen, and their collaborators (Bloom and Van Reenen [2010] provide a concise introduction to this fascinating topic). We have also focused only on research concerning the development of new ideas and approaches, and not on the diffusion of those ideas. Finally, we have ignored industry-level perspectives, such as the study of shake-outs and the industry life cycle, which have been the subject of other reviews (Klepper 2008).

2. Research and Development Productivity and Internal Organization

What makes an organization more or less innovative? For a long time, the literature on this topic focused solely on the relationship between innovation and firm size, following Schumpeter's (1942) conjecture that large firms had an inherent advantage at innovative functions relative to smaller enterprises. From the vantage point of twenty-first-century economists, the Schumpeterian hypothesis has not stood the test of time. It turns out to have been the intellectual by-product of an era that saw large firms and their industrial laboratories (e.g., IBM, AT&T, and DuPont) replace the independent inventors who accounted for a large part of innovative activity in the late nineteenth century and early twentieth (Lamoreaux and Sokoloff 2009).

At an anecdotal level, the Schumpeterian hypothesis does not accord with casual empiricism, as in several new industries (medical devices, communication technologies, semiconductors, software), industry leadership is firmly in the hands of relatively young firms whose growth was largely financed by public equity markets (e.g., Boston Scientific, Cisco, Intel, and Microsoft). But more systematic tests of Schumpeter's argument have been inconclusive too. A vast empirical literature, reviewed by Cohen and Levin (1989), has failed to uncover a robust relationship between firm size and innovation inputs.

What explains the relative failure of the empirical program started by Schumpeter's mid-century prophecy? An important reason is institutional change in the form of the emergence of vibrant markets for ideas that heralded a new division of innovative labor between large and small firms (Teece 1986; Gans and Stern 2000; Arora et al. 2002; Gans et al. 2002). If would-be innovators have the ability to cooperate with incumbent firms to appropriate the returns from technological innovation, regressing research and development (R&D) expenditures on firm sales will not be very illuminating.

Long before the emergence of modern ideas markets, some of Schumpeter's contemporaries, however, had some misgivings about the ability of large firms to generate technological innovations. For instance, Jewkes (1958: 55) argued:

It is erroneous to suppose that those techniques of large-scale operation and administration which have produced such remarkable results in some branches of industrial manufacture can be applied with equal success to efforts to foster new ideas. The two kinds of organization are subject to quite different laws. In the one case the aim is to achieve smooth, routine, and faultless repetition, in the other to break through the bonds of routine and of accepted ideas. So that large research organizations can perhaps more easily become self-stultifying than any other type of large organization, since in a measure they are trying to organize what is least organizable. The director of a large research institution is confronted with what is perhaps the most subtle task to be found in the whole field of administration.

This section is devoted to fleshing out Jewkes's intuition by reviewing work by economists and other social scientists studying how other organizational characteristics impinge on the process of technological innovation. For organizing the discussion, we distinguish between studies of that focus on the *intensive margin* (the degree of effectiveness achieved by firms as they attempt to organize their innovative activities) from those that focus on the *extensive margin* (whether firms are able to innovate at all in the face of technological transitions).

2.1. Beyond Firm Size: Opening the Innovation Black Box

Perhaps the earliest indication that the internal organization of firms deserved more attention than it had traditionally received from economists came from empirical studies of the innovation production function in the often-cited National Bureau of Economics Research conference volume edited by Zvi Griliches (1984), *R&D, Patents, and Productivity*. Pakes and Griliches (1984) found that when estimating patent production functions, the magnitude of the coefficient on R&D investment fell drastically in the within-firm dimension of the data. Similarly, Scott (1984) found that fixed firm effects explained about 50% of the variance in R&D intensity. Of course, firm effects constitute a measure of economists' ignorance, and since 1984 a sizable body of research has emerged to explain the magnitude and relative stability over time of these firm effects. The literature has focused on three broad features of organizations: (1) the design of incentive systems; (2) firms' abilities to manage spillovers of knowledge, with a particular emphasis on the causes and consequences of job mobility among engineers and scientists; and (3) firms' choice of organizational structure, including (but not limited to) acquisition behavior.

2.2. Motivating Innovation: The Role of Incentive Systems

Firms provide incentives to their employees in all realms of economic life. Why would the design of incentive systems for innovative tasks differ from that appropriate for "humdrum" tasks? Holmström (1989) provides a number of reasons that make the provision of incentives for innovation a difficult task. First, innovation projects are risky and unpredictable; second, they are long-term and multistage; third, it might not be clear *ex ante* what is the correct action for the agent to take; and finally, they tend to be idiosyncratic and difficult to compare to other projects.

To this list, we would add two additional characteristics: innovators tend to bring to their labor a certain degree of intrinsic motivation, and innovation is very often a team activity.

Manso (2011) is the first economist to formalize the trade-off between the exploration of untested actions and the exploitation of well-known actions, which has long been a focus of organization theorists (March 1991). He uses a class of decision problems called "bandit problems," in which the agent does not know the true distribution of payoffs of the available actions. Exploration of new untested actions reveals information about potentially superior actions but is also likely to waste time with inferior actions. Exploitation of well-known actions ensures reasonable payoffs but may prevent the discovery of superior actions. Embedding the bandit problem into a traditional principal-agent model, Manso focuses on the features of incentive schemes that encourage exploration. He finds striking departures from the standard pay-for-performance contracts that are optimal when the principal is focused on eliciting effort for known actions. The principal should tolerate early failure and reward long-term success; she should provide some job security to the agent and should provide feedback on performance to the agent.

Ederer and Manso (2011) devise a laboratory experiment in which subjects are randomly assigned to incentive plans, including (1) a flat wage, (2) a standard pay for performance contract, and (3) a pay for future performance contract. They find that forward-looking incentives

result in more exploration and higher profits. These results suggest that appropriately designed incentives do not lead to a crowding-out effect, contrary to earlier arguments that incentives are likely to undermine creativity (e.g., Amabile 1996).

To test the potency of exploration incentives to stimulate innovative activities in a real-world setting, one of the main difficulties is to find agents who are at risk of receiving either exploration- or exploitation-type incentives. Azoulay et al. (2011) focus on alternative funding mechanisms for elite biomedical scientists that appear to provide just this kind of variation. The lifeblood of academic life sciences in the United States is provided by so-called R01 grants awarded by the National Institutes of Health. These grants are relatively short term (the modal length is 3 years), and renewal is both competitive and not forgiving of failure. In addition, brilliant scientists can be appointed as investigators of the Howard Hughes Medical Institute. HHMI investigators continue to be housed in the same institutions but labor under a very different set of incentives. They are explicitly told to “change their fields” and are given the resources, time (5-year renewable appointments, with a lax first review and a 2-year phase down in case of termination), and autonomy (they do not need prior authorization to change the direction of their research) to accomplish this.

Compared with a set of equally eminent scientists at baseline, the authors find that the program appears effective in boosting the rate of production of particularly creative scientific papers—those in the top percentile of the citation distribution. The impacts are even larger for other outcomes, such as the production of trainees who go on to win early-career prizes or election to the National Academy of Sciences.

In the absence of random assignment, the conclusions must remain tempered, despite the care taken to match control scientists with treated scientists, based on observable characteristics. But taken as a whole, these two papers certainly suggest that tolerance for early failure and rewards for good performance over the long term are effective ways to motivate agents engaged in idiosyncratic, nonrepetitive tasks. Of course, many questions remain to be addressed. For example, how does one design incentives to attract the most creative agents? Also, in a setting with multiple agents, what is the optimal balance between individual and team incentives to motivate exploration? In particular, can exploration-type incentives be effective when the principal must rank the agents she oversees to determine a prize, such as in a promotion tournament? These are important questions for future research.

Another generic theme is that of incentive balance, when several tasks compete for the agent's attention, but the principal's ability to infer effort from output is much higher for one set of tasks relative to another set. The main result from this literature is that it may be optimal to provide low-powered incentives in such situations, to avoid distorting the agent's allocation of effort toward the task that is easier to meter. Cockburn et al. (1999) illustrate the implications of this principle in the setting of drug discovery R&D. Pharmaceutical firms would like their researchers to generate many useful patents, but if the scientists are not connected to sources of knowledge located outside the firm, their creativity will eventually run dry. Conversely, if the scientists solely focus on staying on the frontier of science, the firm will find itself running a (possibly very good) biology department but will have little tangible output (actual new drugs) to show for its R&D investment. Cockburn et al. show that pharmaceutical firms resolve this tension by keeping incentives for basic and applied output in balance. On the one hand, scientists will be rewarded and promoted based on their individual standing in their scientific

subfield, using traditional academic criteria, such as publications and citations. On the other hand, research teams will be rewarded on the basis of their applied output. In practical terms, a group that generates more useful patents than expected in a given year will see its budget increase the following year. Cockburn et al. (1999) find that firms tend to adopt both or neither of these practices, rather than adopting one without the other.

Innovation settings differ from more traditional ones because employee-technologists often work on something because they find it personally rewarding. Intrinsic motivation is important, because it has implications for job design and wage setting. In a fascinating survey of life scientists on the job market, Stern (2004) finds that pharmaceutical firms who give their scientists freedom to choose their own projects and otherwise remain connected to open science pay 15% less on average, holding scientist ability constant. This finding provides a rationale for firms to harness their employees' preferences in the way they organize research activities, in addition to the crowding-out effect of extrinsic incentives often stressed by psychologists (Amabile 1993).

Of course, firms need to balance the wage savings associated with employee autonomy against the probability that some of the knowledge generated internally will leak out to their competitors. As it turns out, the management of knowledge spillovers from innovative activities is a topic that has also received considerable attention.

2.3. Spillovers of Knowledge and Internal Organization

In his famous 1962 essay, Kenneth Arrow focused economists' attention on the nonrival nature of knowledge and the attendant disclosure problem. Ever since, economists have been focused on firms' ability to actively manage knowledge spillovers. The starting point for the discussion is that knowledge is not as public a good as initially thought, and therefore, distance between the transmitter and the receiver of knowledge matters in determining the extent of spillovers. Jaffe et al. (1993) observed that despite their ethereal nature, knowledge spillovers might leave a paper trail in the form of citations to prior art recorded in patents. By constructing a large dataset of patents and matching the location of inventors for both cited and citing patents, they documented that these citation patterns exhibit a pronounced degree of localization.¹

However, physical proximity is not necessarily the only, or even the most relevant, concept of distance that economists should consider when attempting to estimate the magnitude of knowledge spillovers. To the three dimensions of physical space, it seems worthwhile to add technological space: advances in the state of knowledge in one particular technological area are likely to spur relatively more developments in technological areas that are thematically related. Jaffe (1986) was the first to construct a measure of technological distance between firms by using the distribution of firms' innovative efforts across patent classes, and he found that the R&D productivity of a focal firm was indeed positively correlated with the R&D of technological neighbors.

Social distance might also impinge on the extent of spillovers. Here the network metaphor is particularly apt, whether one thinks about degrees of separation between scientists in a

1. As documented by Thompson and Fox-Kean (2005), this exercise is fraught with difficulties because of the difficulty of finding nonciting patents that can serve as a control group and capture the agglomeration patterns that are due to other factors than knowledge spillovers.

coauthorship network, of the relationship between a corporate parent and its subsidiaries, or about the vertical linkages between buyers and suppliers. Adams and Jaffe (1996), focusing on the chemical industry, showed that the effects of parent firm R&D on plant-level productivity decrease with both geographic and technological distance between the research lab and the plants. Moreover, spillovers from technologically related firms are significant in magnitude but are diluted by the firms' own R&D intensity. This article stands out in the vast empirical literature, because it simultaneously attends to the three concepts of distance mentioned above.

In a similar vein, Azoulay et al. (2010) estimate the magnitude of spillovers generated by the untimely death of 112 academic superstars in the life sciences on their coauthors' research productivity. They find a lasting and significant decline in publication output, which is surprisingly homogeneous across a wide range of coauthor characteristics. But they do not observe a differential effect of a prominent collaborator's death for co-located coauthors. They interpret their findings as providing evidence that part of the scientific field embodied in the "invisible college" of coauthors working in a particular area dies along with the star.

A second fundamental idea in the study of knowledge spillovers is that of *absorptive capacity*: absorbing spillovers from other firms requires doing research yourself (Cohen and Levinthal 1989, 1990). Using a dataset that combines the Federal Trade Commission's line of business information with Levin et al. (1987) survey data, these authors find that spillovers from input suppliers can be absorbed with less R&D investment than spillovers from government and university labs. In the setting of pharmaceutical drug discovery, Cockburn and Henderson (1998) document strong correlations between the extent of ties between firms and academic science (mostly through coauthorship of scientific articles) and these same firms' research productivity. Moreover, building absorptive capacity has implications for the organization of R&D activity. Henderson and Cockburn (1994) use detailed data at the research program level from ten pharmaceutical firms and show that firms that adopted the practices of open science to motivate and reward scientists increased their research productivity (as measured by important patents per dollars invested) significantly during the 1980s.

A more recent literature stresses that there are other ways—beyond performing basic R&D—for firms to absorb outside knowledge. In a fascinating case study of the semiconductor industry, Lim (2011) shows that IBM's competitors were able to quickly imitate its design of copper interconnects by working closely with equipment suppliers, collaborating with some key academic labs, and hiring newly minted PhDs and postdoctoral fellows in the relevant scientific subfields.

2.4. The Mobility of Engineers and Human Capital Externalities

In her seminal study of the computer and semiconductor cluster in Silicon Valley, Annalee Saxenian (1994) drew the attention of economists to the high rates of job hopping among engineers. She ascribed the sustained success of Silicon Valley firms to the rapid movement of technical professionals among firms in the region and pointed out that an accident of Californian legal history precluded the enforcement of noncompete agreements in the state. Since then, an ever-expanding empirical literature has documented more systematically that job hopping is indeed a source of knowledge spillovers, and that these spillovers tend to be geographically localized (Almeida and Kogut 1999; Fallick et al. 2006).

What is less clear from this evidence, however, is whether these spillovers correspond to true externalities or whether there exist mechanisms through which the labor market can internalize the effects. Pakes and Nitzan (1983) present a model in which engineers bond themselves to their firms by accepting lower entry wages. Moen (2005), using matched employee/employer data from Norway, compares the wage-experience profiles of engineers and nontechnical white collar workers and finds that they are steeper for the former group of employees than for the latter. This suggests that the potential externalities associated with labor mobility are partially internalized in the labor market.

Our knowledge of the practices used by firms to manage outgoing and incoming knowledge spillovers is still fragmentary. The best-known evidence probably pertains to the role of scientific superstars documented by Zucker et al. (1998). These authors document a robust correlation between the rates of founding of new biotechnology firms and proximity to scientists who are leaders in the relevant subfields of biology. In the same spirit, Lacetera et al. (2004) show that pharmaceutical firms are more likely to change the organization of their drug discovery operations toward the open science model after hiring academic superstars. In this line of research, the direction of causality has not been clearly established, for a number of reasons. First, high-quality data on employee mobility is hard to come by. A popular approach has been to rely on patent or publication data to ascertain the movement of employees across firms, but it is obviously problematic to base mobility on potentially endogenous output measures (Almeida and Kogut 1999; Rosenkopf and Almeida 2003). Second, even if mobility could be measured with less error, there is always the possibility that scientists' or engineers' movements in and out of firms are driven by expectations regarding future firm productivity. A productive avenue for mobility research is to gather much more detailed data on individuals to extract exogenous variation in exposure to talent. Life cycle events, such as marriage, birth of children, and becoming "empty nesters" might provide such variation. An alternative is to focus instead on policy changes that affect rates of mobility among technical personnel. Marx et al. (2009) exploit Michigan's inadvertent reversal of its noncompete enforcement legislation to demonstrate that noncompetes decrease inventor mobility by 34%. Although this effect is not by itself surprising, the study's design can be thought of as providing a plausible first stage to study the effect of engineers' mobility on productivity.

2.5. Organizational Structure

In their efforts to broaden the range of organizational characteristics that impinge on the innovation process, economists and other social scientists have focused on various aspects of organizational structure. We focus here on three of the most salient: the choice between centralized and decentralized R&D activities, the effect of takeover and acquisitions on innovation, and the design and composition of R&D project teams.

2.5.1. *Corporate R&D Laboratories versus Decentralized Innovation*

Managerial scholars have long debated the relative merits of centralized R&D labs and decentralized R&D activities (Rosenbloom and Spencer 1996). Centralized R&D labs can potentially engage in nonlocal search activities and focus on long-term projects, but they run the risk of slowly evolving into ivory towers. Decentralizing R&D investment into divisions prevents

employee-technologists from losing sight of market imperatives, but it might result in a slow degradation of technological and scientific competencies. Some recent studies appear to support the view that centralized R&D more effectively supports wide-ranging innovative activities.

Using a sample of 71 large research-intensive corporations, Argyres and Silverman (2004) show that firms with centralized R&D labs generate more highly cited patents than do firms with decentralized or hybrid R&D structures. Lerner and Wulf (2007) combine information about structure with data on incentives provided to corporate R&D managers among Fortune 500 firms. They find that long-term incentives (stock options and restricted stock) result in patents that are more heavily cited, but this relationship is driven solely by firms with centralized R&D.

Together, these studies suggest that aligning the incentives of corporate R&D staff with those of the firm as a whole can mitigate the risk that research output loses relevance, with important caveats. First, patent citations are far from an ideal measure of the relevance of the research to the firm's product markets; sales from innovative products would be a more appropriate metric. Second, the choice of structure is potentially endogenous, and the studies provide suggestive conditional correlations, not estimates of causal effects. The relative virtues of centralized and decentralized R&D structures remain a relatively open question.

2.5.2. Takeovers, Mergers, and Acquisitions: Much Ado about Nothing?

In the 1970s and 1980s, the rise of Japan as an industrial giant stirred a debate in the United States and Europe about the effects of takeovers and merger activity on the rate and direction of R&D undertaken by firms. This prompted several studies probing the link between corporate restructurings and the intensity of R&D among U.S. manufacturing firms. Although the zeitgeist that provided the impetus for these studies has changed radically in the past 20 years, two papers by Bronwyn Hall stand out as particularly informative (Hall 1990, 1991).

As usual, the devil lies in the details of the econometric exercise, but in both cases, the effects she uncovers are of a relatively small magnitude—certainly smaller than what the hyperbolic statements of policymakers at the time would have implied. Hall finds that public firms involved in acquisitions where both partners are in the manufacturing sector have roughly the same pattern of R&D spending as the sector as a whole, and that the acquisition itself does not cause a reduction in R&D activity. Moreover, the target's R&D capital seems to be valued more highly by the acquirer than by the stock market itself (Hall 1991). In a second paper, Hall also studies the effects of leveraged buyouts. Here, she finds a more pronounced negative effect of increased leverage on R&D intensity, but because the firms taken over as a prelude to leveraged buyouts tend to be in less R&D-intensive segments, it seems unlikely that the leveraged buyout wave of the 1980s and early 1990s had a significant negative effect on R&D expenditures (Hall 1990).

2.5.3. Performance of R&D Project Teams: The Role of Social Structure

Employee-technologists are very often organized in project teams. Economists have long studied the provision of incentives in teams, including peer pressure (Kandel and Lazear 1992) and collective rewards (Che and Yoo 2001). Here we draw attention to a distinct attribute of R&D teams that has been shown to play a role in explaining their performance: the structure of the social networks to which team members belong.

Economists have contributed very little to this vibrant area of social science research. In light of the relevance of the results to the rate of technological innovation inside organizations, we chose to include a bare-bones exposition of the key idea, partly in the hope of stimulating economists' interest in the topic. Sociologists characterize social networks as cohesive or closed when many redundant contacts exist among network members. In a closed network, information flows quickly from one individual to another. In contrast, social networks can be rich in structural holes, that is, when some individuals can broker ties between subgroups that would have otherwise no opportunity for communication (Burt 1992). A central trade-off arises because network closure among team members makes coordination easier—which is beneficial in the execution phase of a project. At the same time, assembling in a team individuals whose social worlds do not overlap provides learning benefits, because it ensures that team members will be exposed to diverse sources of information (Burt 2004). In a fascinating paper, Reagans et al. (2004) provide evidence from a contract research organization that sheds light on how organizations can resolve this tension. Using the fact that employees participate in several distinct teams over the period during which they collected the data, these authors show that the most effective project teams have both high internal density (i.e., strong ties exist among team members) and high external range (i.e., team members have ongoing relationships with employees belonging to a diverse set of other project teams).

Of course, an economist might be skeptical of the empirical results for a variety of standard reasons. We might rightly wonder about simultaneity or omitted variables, though the authors have designed the study while attending to these concerns. More importantly, the outcome variable—time to project completion—is not ideal, especially as other research has found that employees in brokerage positions extract higher wages from their employers. Nonetheless, the effects the authors uncover are important in magnitude and statistically significant. Given the explanatory power of social network theories, it would seem that economists ignore these findings to their own detriment.

2.6. The Extensive Margin: When Established Firms Fail to Innovate at All

Rather than ask whether large firms invest more in R&D relative to small ones, another line of research focuses on evaluating theoretically and empirically the costs and benefits of market incumbency.

One branch of the literature provides an explanation for the dominance of entrepreneurial firms in new industries. Aron and Lazear (1990) present a model in which new firms pursue high-variance strategies and hence are more likely to introduce new products. Prusa and Schmitz (1994) test their argument by examining the introduction of new software programs. The authors suggest that new firms appear to be more effective at creating new software categories, whereas established firms have a comparative advantage in extending existing product lines. It should be noted that models like that of Aron and Lazear pertain to innovation generally, not necessarily to technological innovation.

A distinct stream of research explores the conditions under which market incumbents can adapt in the face of technological change. Here there has been a closer connection between theoretical work and empirical studies. The theoretical debate is well known and has been reviewed elsewhere (e.g., Reinganum 1989). In brief, models of technology races make sharply

different predictions about the innovation incentives of incumbents and entrants depending on (1) the nature of uncertainty (i.e., can investment shift the timing of the new product's introduction?) and (2) whether the innovation is radical or incremental (i.e., is the new product so obviously superior that demand for the old product disappears?) (Gilbert and Newberry 1982; Reinganum 1983).

Because these features are hard for researchers to measure, empirical work has attempted to test the implications of racing models rather than compare the models directly. Lerner (1997), in his empirical examination of the disk drive industry, is a good example of this approach. For each product generation, he finds that firms who followed the leader in the previous generation display the greatest propensity to innovate. Interestingly, the same pattern does not exist in situations where strategic incentives are muted, as is the case when the firm is a division within a vertically integrated firm. Lerner interprets these findings as providing support for Reinganum's model of technological racing, but it is not clear that innovation in the disk drive industry should be construed as radical. In particular, the old and new generations of products tend to coexist for a period of time, because they typically appeal to distinct customer segments.

Christensen (1997) provides a different interpretation of the same phenomenon. According to his analysis, the new product generation initially poorly serves the needs of the incumbent's customers, but its quality eventually catches up. This presents an ideal situation for entrants to exploit incumbents' blind spots, which stem from their single-minded focus on existing customers. Christensen goes on to recommend that established firms systematically create "skunkworks" to incubate their next generation of products, far from the paralyzing influence of the old business.

Economists will naturally be skeptical of such a blanket recommendation. The disk drive industry is characterized by a weak appropriability regime (patents can be invented around), and it would be hazardous for an entrant to try to license an innovation to an established firm. The conclusions may be therefore highly contingent on particular industry characteristics. Nonetheless, the reasons behind the apparent bias of incumbents in favor of home-grown technology is a recurrent theme of the managerial literature, and its persistence and effects are worthy of attention by economists.

Other strands of the managerial literature put forth a conception of radical and incremental innovations based on supply-side considerations: A radical innovation is one that destroys, or at least does not build on, the technological capabilities of incumbent firms (Tushman and Anderson 1986). In her study of the photolithographic industry, Henderson (1993) notes that it is entirely possible for innovations to be incremental in an economic sense but radical in an organizational sense, and she provides evidence that incumbents have particular difficulty adapting to such architectural changes. Using qualitative evidence, she explores the mechanisms that might explain the incumbents' lack of success in commercializing architectural innovations. She advances two types of explanations. The first focuses on dysfunctional incentives and stilted communication channels; the second emphasizes behavioral biases that affect the managers of incumbent firms. One lesson from recent advances in behavioral corporate finance is that cognitive biases can magnify the salience of agency problems in firms (Baker et al. 2007). The study of internal capital markets—especially in the presence of informed but biased R&D managers—seems a very promising area for future research. So far, the growing literature on internal capital markets (reviewed by Gertner and Scharfstein, this volume) has been largely focused on resource

allocation in diversified publicly listed conglomerates. Although attention has increasingly been paid to the role of divisional boundaries on R&D investment and productivity (e.g., Seru 2010), further progress in this area will probably require access to finer-grained, project-level data.

Before moving on to other issues, we can venture a few conclusions. First, most of what economists know about technological innovation and organizations does not stem from the mining of traditional datasets. On the contrary, some of the more lasting insights come from the collection of original data at a level that is usually finer grained than the whole organization. Case studies also inform the state of economists' knowledge on these topics. Second, the empirical literature has been rather casual in its treatment of endogeneity issues, though there are of course exceptions (e.g., Stern 2004). What is missing are more systematic attempts to estimate the causal effect of various features of firms' internal organization on innovative outcomes.

3. Contracting and Innovation

One of the most fertile areas of research in recent years has been the relationship between innovation and contracting. Thanks to a variety of theoretical work, we now better understand the critical importance of contracting in the innovation process and the ways in which contract structure can affect the innovations being undertaken.

3.1. Why Is Contracting Important for Innovation?

One of the dominant features of many high-technology industries has been a reliance on contracting. In many cases, start-up firms, rather than going head-to-head with established incumbents, will choose to license technologies to their peers. Such industries as telecommunications and biotechnology have been profoundly shaped by this business model.

It is natural to wonder what the rationale for this approach in technology-intensive industries is. Gans and Stern (2000) suggest that there are several reasons firms will choose a cooperative strategy, including avoidance of thinner profit margins and duplicative investments associated with head-to-head competition. They argue that a cooperative strategy is more likely for start-ups in three cases: when intellectual property rights are stronger (which puts the start-up firm in a better bargaining position with potential licensors), when intermediaries who can facilitate and reduce the costs of such transactions are present, and when established firms have made expensive investments (e.g., in a sales force) that the start-up would need to duplicate. The authors show that these patterns not only hold theoretically but also in a survey of the commercialization strategies of more than 100 start-up firms.

This rationale for cooperative commercialization is compelling, but efforts to contract on technology often encounter many challenges. In many instances, academic technology managers or corporate executives seeking to commercialize early-stage technologies have encountered real difficulties. They may find investors unwilling to invest the time and resources to examine early-stage technologies, or offering only modest payments in exchange for large stakes in innovations that the scientists, technology transfer officers, and company executives believe to be quite valuable.

Much of this reluctance stems from the information problems that surround innovations, particularly in technologically advanced industries, which often scare off potential investors. The work of Guedj and Scharfstein (2004) highlights the importance of these information

problems. The paper documents the extent of agency problems among young biotechnology firms, which emerges from a comparison with established pharmaceutical companies. The authors show that the young firms—particularly those with large cash reserves—are more likely than their more established peers to push drug candidates forward in clinical trials, but the success rate in these trials is much lower. The evidence points to an agency problem, in which managers of single-product early-stage firms are unwilling to drop the development of their only viable drug candidates, and the difficulty that outside shareholders have in monitoring innovative activities.

The consequences of these difficulties have been illustrated by Shane (1995) and Majewski (1998), who examine the decisions of biotechnology firms to raise capital through public markets and alliances. Through their different methodologies, these authors show that firms turn to alliance financing when asymmetric information about the biotechnology industry is particularly high. During these periods—which are measured through such proxies as the variance of the returns of biotechnology securities—firms are likely to delay the time until their next equity issuance and to rely on alliances rather than public offerings as a source of external financing. The authors argue that the greater insight on the part of the pharmaceutical company into the nature of the biotechnology firm's activities allows it to make successful investments at times when uninformed public investors are deterred by information problems.

3.2. Contract Structure and Innovation

Much academic interest in recent years has surrounded the question of how firms contract for innovations and the implications of these contracts. The seminal work of Aghion and Tirole (1994) has inspired a variety of investigations.

This work builds on the tradition, beginning with Grossman and Hart (1986) and Hart and Moore (1988), that depicts incomplete contracting between a principal and an agent. A typical assumption is that it is impossible for the two parties to write a verifiable contract, enforceable in a court of law, that specifies the effort and final output of the two parties. This is because there are many possible contingencies, not all of which can be anticipated at the time the contract is drafted. Due to this nonverifiability problem, these models suggest that it is optimal for ownership of the project to be assigned to the party with the greatest marginal ability to affect the outcome. This party, who will retain the right to make the decisions that cannot be specified in the contract *ex ante*, should also receive any surplus that results from the project. Because of this incentive, the party will make the decisions that maximize—or come close to maximizing—the returns from the project.

Aghion and Tirole (1994) adapt this general model to an R&D alliance between two firms. In their basic model, the authors assume that the research unit is without financial resources of its own, cannot borrow any funds, and has no ability to commercialize the innovation itself. As a result, it turns for financing to a customer, a firm that may intend to use the product itself or to resell it to others but cannot make the discovery independently. The success of the research project is an increasing function, though at a decelerating rate, of both the effort provided by the research unit and the resources provided by the customer.

Developing a contract between the two parties is challenging. Even though the ownership of the product can be specified in an enforceable contract, and the resources provided by the customer can also be so specified, uncertainty precludes writing a contract for the delivery of a

specific innovation. Similarly, an enforceable contract cannot be written that specifies the level of effort that the research unit will provide.

Aghion and Tirole (1994) consider two polar cases: when the research unit has the *ex ante* bargaining power and when the customer does. When the research unit has the bargaining power, the ownership of the research output will be efficiently allocated. If the marginal impact of the research unit's effort on the innovative output is greater than the marginal impact of the customer's investment, then the research unit will receive the property rights. If not, the research unit will transfer ownership to the customer in exchange for a cash payment. This result is similar to that of Grossman and Hart (1986).

When the customer has the bargaining power, a different pattern emerges. If it is optimal for the customer to own the project, it will retain the project. If, however, the total amount of value created would be greater were property rights to be allocated to the research unit, the ideal outcome will not be achieved, because the cash-constrained research unit will not have enough resources to compensate the customer. As a result, an inefficient allocation of the property rights occurs, with the customer retaining the rights to the invention.

This work has inspired a variety of empirical investigations. Lerner and Merges (1998) examine the determinants of control rights in a sample of 200 alliances between biotechnology firms and established pharmaceutical firms. This setting is particularly auspicious, because it exhibits wide variation in contractibility (e.g., early-stage versus late-stage projects) and bargaining power (e.g., does the start-up have other products in development or is it essentially a single-product firm?). They analyze the share of 25 key control rights allocated to the financing firm by regressing the assigned number of rights on independent variables denoting the project stage and financial conditions, as well as on controls for a variety of alternative explanations. The results are generally consistent with the framework developed by Aghion and Tirole (1994): the greater the financial resources of the R&D firm, the fewer control rights are allocated to the financing firm; in contrast, there is no evidence that early-stage projects are associated with more control rights being assigned to the research-based firm.

Lerner and Malmendier (2010) expand on this line of research. They point out that the key variable in Lerner and Merges (1998) is a bit of a grab bag. Among these 25 decision rights, which ones really matter? They also point out that Aghion and Tirole's (1994) canonical model should not be taken too literally. Rather, they ask what central incentive problem the proper assignment of these rights should alleviate. Based on insights gained from conversations with practitioners, they conjecture that pharmaceutical firms are especially worried that their biotechnology partners will inappropriately cross-subsidize other projects using the payments received as part of a specific drug development project. They go on to develop a simple model in the spirit of Aghion and Tirole but tailored to the specifics of the context at hand. This leads them, in turn, to focus on the allocation of a specific contractual clause: a termination right coupled with broad transfer of intellectual property and associated payments. The model makes some specific predictions: (1) such clauses should be more frequently observed when the direction of research is less contractible (e.g., when the alliance does not center on a "lead compound" with a specific chemical formula); and (2) this correlation should be much weaker, or even go away, when the biotechnology firm is not financially constrained (e.g., when the biotechnology firm has low net income). These sharp predictions are borne out in the empirical analysis and appear robust to a number of carefully examined alternative explanations.

Whereas Aghion and Tirole (1994) do not explicitly depict a role for the public market, Lerner et al. (2003) argue that variations in the availability of public financing will affect the bargaining power of R&D firms. During periods when public financial markets are readily accessible, these firms may be able to finance projects through either public equity issues or alliances. But during periods when equity issues are more difficult, R&D firms may have few alternatives to undertaking alliances. In the latter periods, it is also reasonable to assume that the R&D firm's bargaining power will be considerably reduced.²

The authors examine these patterns in biotechnology, noting that equity financing in the industry has undergone dramatic variations over the years. These shifts have been largely in the nature of industrywide shocks. The authors show that in periods when public equity financing is readily available, the agreements are more likely to grant key control rights to the R&D firm. This pattern—consistent with the theory of Aghion and Tirole (though, of course, with other theories as well)—holds even after controlling for variations in the quality of the technology in the agreement. Lerner et al. (2003) then examine whether the agreements are successful in terms of the progress of the product under development. Alliances that grant the bulk of the control to the R&D firm are more successful, an effect that is more pronounced in weak financing markets, as Aghion and Tirole (1994) predict.³

Finally, the authors examine the likelihood of renegotiation. If it would have maximized innovative output to assign control to the small biotechnology company, but this allocation of control was precluded by financial market conditions, there should then be a distinct pattern in renegotiations. In particular, when financing conditions for biotechnology firms improve, the agreements that assign the bulk of the control to the financing firm should be disproportionately renegotiated. The empirical results are consistent with this pattern.⁴

Robinson and Stuart (2007) take a different approach, examining 125 alliances involving genomics research at young biotechnology firms. The authors consider a variety of characteristics of these contracts, including the use of equity, extent of up-front payments, contractual provisions employed, provisions regarding termination, and length of the agreement. Although it is difficult to do justice to so many disparate analyses in a brief summary, the key findings are the resemblance between strategic alliances and venture capital contracts⁵ and the importance of contractual provisions that are difficult to verify. The authors interpret the latter conclusion as

2. As noted above, the posited relationship between the strength of the public equity market and the bargaining power of the R&D firm is not explicitly modeled in the Aghion-Tirole model. Under the plausible assumption that in the subset of parameters where the R&D firm chooses an alliance instead of public equity issue, the strength of the market still affects the R&D firm's bargaining power in choosing the terms of the alliance, an extension to their model could deliver this result. The claim that control rights are more likely to be transferred to the financing firm during periods of diminished public equity market activity is also supported by theoretical work by Aghion and Bolton (1992) and Holmström and Tirole (1997).

3. Of course, if we assume that having the R&D firm control the alliance is inevitably efficient, then it is hard to distinguish the Aghion-Tirole hypothesis from one where the lack of financial resources leads the R&D firm to make important concessions. The results regarding the renegotiations of alliances, however, seem less consistent with this alternative hypothesis.

4. See Elfenbein and Lerner (2003) for another example of an analysis of these issues.

5. This point has also been raised in the work of legal scholars, such as Bernard Black, Ronald Gilson, and Robert Merges. For one example, see Merges (1995).

raising doubts about the substantial literature on incomplete contracts most closely associated with Grossman, Hart, and Moore.

3.3. Spin-offs and Firm Boundaries

A consequence of the ability of start-up firms to enter into contracts with established firms is that industry structure may change. The prospect of garnering profits through licensing—or alternatively, through successful head-to-head competition—may lead individuals to leave established firms and begin new concerns. A variety of work has examined these changes to industry structure and the consequences for innovation.

Much of this literature highlights the difficulties that firms face when managing multiple projects in a single organization. This literature has been largely motivated by the diversification discount puzzle: the empirical observation that diversified firms appear to trade at prices that are significantly below those of comparable portfolios of specialist firms.

Much of the literature has highlighted the presence of agency problems in firms. Jensen (1986), for instance, suggests that CEOs have a tendency to use the cash flows from the business to overinvest in unprofitable projects. Scharfstein and Stein (2000) argue that the presence of agency problems at both the CEO and divisional manager level may lead to firms overinvesting in weaker projects and neglecting stronger ones, particularly when there is a substantial divergence in the projects and when the CEO has low-powered incentives.⁶

Several works have explicitly examined the trade-off between undertaking an innovative project in a major corporation and in a start-up firm. Typically, they assume that an employee makes a valuable discovery while working for an established firm. These models usually assume that substantial informational asymmetries preclude the established firm from learning (at least initially) about the project's prospects. In some cases, the difficulties of contracting and bargaining lead to an independent firm being established. Wiggins (1995) predicts that projects that are high risk, take longer to develop, and are less capital intensive will be more likely to be pursued in independent firms. Although employing a somewhat different theoretical setup, Anton and Yao (1994) similarly conclude that more radical innovations will be more likely to be pursued in start-ups.⁷

These issues are captured nicely in a model by Hellmann and Perotti (2011), who explore the challenges that an inventor who has developed an incomplete idea faces. They argue that if the would-be entrepreneur can find a third party (e.g., a venture capitalist) to evaluate his idea, he will be able to validate his concept and decide whether to invest more resources into it. But the third party may be tempted to report to the inventor that the idea is worthless, and then steal the idea and commercialize it herself. They argue that the likelihood a third party will respond truthfully depends on the extent to which her skills are complementary with, or simply identical to, those of the inventor.

6. Although the work is not cast in this manner, the findings of Steven Klepper highlighting the importance of disagreements among individuals as a driver of new firm formation (e.g., Klepper and Thompson 2005) may be seen as consistent with these arguments.

7. Dix and Gandelman (2007) and Hellmann (2007) are two more recent examinations of these questions.

Alternatively, the entrepreneur may take the idea to his employer. Although this approach may not be as efficient in some respects (the firm may not have as much expertise as a third party), Hellmann and Perotti argue that firms can more readily develop a reputation for trustworthiness and honesty. They argue that these commitments are least likely to be honored when the invention is very valuable: in these instances, individual investors are more likely to try their luck in the treacherous open market.

Acemoglu et al. (2003) take a somewhat broader view of these questions. They depict a world where firms can engage in two activities: adopting existing technologies from the world's best innovators and developing innovations themselves. They argue that managerial skill is relatively unimportant in the adoption process but is critically important to successful innovation. As a result, in countries where technology is more advanced—and hence, the returns from imitation are lower—it becomes critically important to select the right managers. Thus, they suggest, as countries approach the technological frontier, technology-intensive industries should become increasingly Darwinian, with younger firms, shorter relationships among firms, and more weeding out of managers.

On the empirical side, Gompers et al. (2005) contrast two views of the spin-off process. In one view, individuals already working for entrepreneurial firms—particularly those already backed by venture capitalists and located in hotbeds of venture capital activity—may find launching their own venture less daunting than others might for a number of reasons. These reasons include: they have already been exposed to a network of suppliers of labor, goods, and capital, as well as a network of customers (Saxenian 1994); they have already learned by doing how to establish an entrepreneurial firm; or individuals with a higher taste for risky activities may have already found their way to entrepreneurial firms, consistent with models of the sorting processes (Jovanovic 1979; Holmes and Schmidt 1990; Gromb and Scharfstein 2002).

Alternatively, individuals become entrepreneurs because the large bureaucratic companies for which they work are reluctant to fund their entrepreneurial ideas. As discussed above, established firms may be incapable of responding to radical technological changes that upset the established ways of organizing their businesses, or these hierarchical organizations may have a hard time assessing such investment opportunities (Stein 2002; Berger et al. 2005). After systematically examining which publicly traded firms had employees depart to start new venture-backed firms, Berger et al. and Stein conclude the findings appear to be more consistent with the view that entrepreneurial learning and networks are critical factors in the creation of venture-backed firms.

Azoulay (2004) examines instead the question of how the innovative process affects firms' vertical integration decisions. Pharmaceutical companies have long outsourced at least part of the process by which new drugs are evaluated (known as clinical trials) to specialists in these procedures. He argues that these trials typically are dominated by one of two tasks, routine compilation of data on the drugs' effectiveness and more fundamental analyses of the pharmaceuticals' workings.

The analysis suggests that firms respond to this variation. They will choose to undertake the project in-house, or alternatively outsource it, depending on the nature of activities that will dominate the trial process. In the more cutting-edge projects involving the production of new knowledge, they are more likely to use their own employees. A key driver of this choice, Azoulay

(2004) argues, is the difficulty of measuring contractor performance when undertaking truly innovative activities: the difficulty of designing appropriate incentives for innovation leads to the choice of firm boundaries.

3.4. New Organizational Structure and Innovation

Another area of considerable research interest has been the growth of new organizational structures to promote innovation. These have many intriguing features, which will well reward ongoing research.

Perhaps the most intriguing of these topics is the open source process of production and innovation, which seems very unlike what most economists expect. Private firms usually pay their workers, direct and manage their efforts, and control the output and intellectual property thus created. In an open source project, however, a body of original material is made publicly available for others to use, under certain conditions. In many cases, anyone who makes use of the material must agree to make all enhancements to the original material available under these same conditions. This rule distinguishes open source production from, say, material in the public domain and “shareware.” Many contributors to open source projects are unpaid. Indeed, contributions are made under licenses that often restrict the ability of contributors to make money on their own contributions. Open source projects are often loosely structured, with contributors free to pursue whatever area they feel most interesting. Despite these unusual features, recent years have seen a rise of major corporate and venture capital investments into open source projects.

Economics research into open source has focused on two issues. The first has been the motivation of contributors. Lerner and Tirole (2002) argue that the standard framework of labor economics can be adapted to capture activity in the open source environment. Even if there are no short-run monetary returns from working on open source projects, they argue that participation can have important signaling benefits in the long run. The paper highlights the importance of programmers’ desire to signal their quality—that is, the desire to impress prospective employers and financiers, as well as obtain peer recognition—as a spur to contributing to open source projects. The presence of these signaling incentives will lead to more success for open source projects where contributions are more visible to the relevant audience (e.g., peers or employers) and where the talent of the contributor is better discerned from his or her contributions. These observations lead to a series of predictions about the likely success and structure of open source projects.

The empirical evidence, particularly the survey work of Hann et al. (2004), is largely consistent with the belief that individual contributors to open source projects do ultimately benefit financially from their participation in these projects. The results suggest that the sheer volume of contributions to the Apache project have little impact on salary. But individuals who attain high rank in the Apache organization enjoy wages that are 14–29% higher, regardless of whether their work directly involves the Apache program.

The second issue on which economists have focused concerns the legal rules under which open source projects operate. The licenses differ tremendously in the extent to which they enable licensors and contributors to profit from the code that is contributed.

Lerner and Tirole (2005) argue that permissive licenses, where the user retains the ability to use the code as she sees fit, will be more common in cases where projects have strong appeal to the community of open source contributors—for instance, when contributors stand to benefit considerably from signaling incentives or when the licensors are well trusted. Conversely, restrictive licenses, such as the General Public License, will be commonplace when such appeals are more fragile. Lerner and Tirole also examine the licenses chosen in 40,000 open source projects. The authors find that, consistent with theory, restrictive licenses are more common for applications geared toward end users and system administrators. Similarly, projects whose natural language is not English—whose community appeal may be presumed to be much smaller—are more likely to employ restrictive licenses.

But many issues posed by open source are not unique to this setting. Open source can be seen as at the end of a spectrum of technology-sharing institutions. Many of these other institutions have encountered similar conflicts. Leaders of patent pools, for instance, have had to deal with the conflicting goals of the potential members, sometimes reconciling their disparate goals successfully and in other cases failing to overcome these gaps. To cite another example, the challenges of enlisting cooperation from commercial firms while guarding against opportunistic behavior are familiar to leaders of standard-setting organizations. These institutions have lengthy and well-documented track records; for example, the first patent pool dates back to the 1850s.

The modern study of patent pools has its origins in the work of Shapiro (2001), who uses Cournot's (1838) analysis to point out that patent pools raise welfare when patents are perfect complements and harm it when they are perfect substitutes. Although this observation is a useful first step in the antitrust analysis of patent pools, patents are rarely perfect complements or perfect substitutes. Indeed, antitrust authorities sometimes are unsure about the relationships among the patents. Moreover, frequently observed features of pools, such as provisions demanding independent licensing, cannot be analyzed in a setting where only the polar cases exist.

Lerner and Tirole (2004) build on this work, analyzing the strategic incentives to form a pool in the presence of current and future innovations that either compete with or are complementary to the patents in the pool. The authors begin with a very stylized model (though one that allows the full range between the two polar cases of perfectly substitutable and perfectly complementary patents) and then consider progressively more realistic scenarios. A major focus of the analysis is the process through which competition authorities examine patent pools. Recent antitrust doctrines are that only “essential patents” should be included in pools and that patent owners retain a right to license their invention separately from the pool (known as “independent licensing”). Among other conclusions, the paper highlights the effectiveness of the demands for independent licensing: a pool is never affected by the possibility of independent licensing if and only if the pool is welfare enhancing.

Lerner et al. (2008) empirically focus on patent pools. They construct a sample of 63 pools established between 1895 and 2001 and determine the structure of these agreements. They then analyze the determinants of the features of these agreements and highlight the extent to which the structure does appear to be consistent with theoretical predictions.

These areas are certainly not the only ones of interest to researchers in terms of new organizational forms and innovation. Open source and academia have many parallels. The most obvious

parallel relates to motivation. As in open source, the direct financial returns from writing academic articles are typically nonexistent, but career concerns and the desire for peer recognition provide powerful inducements. In recent years, academic institutions have begun more aggressively experimenting with new organizational forms, whether in the hopes of more thoroughly diffusing their discoveries (e.g., the Biological Resource Centers; Furman and Stern 2011) or to more effectively profit from their intellectual property.

Another fascinating and important area is the study of standard-setting bodies. This topic is important because how open a standard is can critically affect its evolution. The rapidity with which the standard is adopted and the incentives to innovate may be shaped by this decision. For instance, the Internet today runs on a nonproprietary architecture largely because the Internet Engineering Task Force in its early years had a strict policy of only incorporating technology where the developer agreed to license it on reasonable and nondiscriminatory terms. Had the Standard-Setting Organization had a more permissive policy (as indeed they adopted in the mid-1990s), the development of the Internet may have been very different (Bradner 1999). Although there have been some initial looks at standard-setting bodies and how they affect innovation (Lerner and Tirole 2006; Chiao et al. 2007; Greenstein and Stango 2007; Simcoe 2012), much more needs to be done.

4. The Financing of Innovation

Another cluster of relevant research has been in finance literature. Although the relationship between finance and innovation has been studied in many contexts not particularly relevant to organizational economics—for instance, work on the market reaction to the announcement of R&D projects and the value relevance of R&D expenditures in accounting statements—other work is very germane.

In this section, we highlight two relevant bodies of work. The first of these stresses the importance of capital constraints and the financing of innovation. The second focuses on financial intermediaries—particularly venture capitalists—and their role in fomenting innovation.⁸

Another source of uncertainty surrounds the ability of capital constraints—or limits on the ability to raise external financing—to affect the innovation process. Even if a firm has a great idea, it may be unable to raise the capital to market it.

4.1. Capital Constraints and Innovation

The examination of financial constraints has been an important topic in corporate finance. In practitioner accounts and theoretical models, the state of financial markets may limit a firm's ability to raise outside capital. This inability to raise capital may stem from information gaps or an inability to reach a satisfactory contract on the outcomes of a venture. In this environment, good projects may find it impossible to get financing on reasonable terms if the firm does not have enough internal funds.

8. Even here, there is other work we do not discuss. One example is work on R&D financing organizations, such as those typically seen in the biotechnology industry (Beatty et al. 1995).

A variety of empirical studies of financial constraints explore the investment behavior of firms and its sensitivity to changes in internally generated funds. Fazzari et al. (1988) find that firms with low or no dividend payout ratios are more likely to have investment that was sensitive to changes in free cash flow. The authors interpret their results as demonstrating that capital constraints likely affect companies that do not pay dividends, as they forego investment when internal cash is not available. In a similar vein, Lamont (1997) looks at companies that have oil-related production and nonoil-related businesses. He finds that investments in the nonoil-related businesses are dramatically affected by swings in the world price of oil. This is true even though the firm's nonoil businesses were largely uncorrelated with the prospects for their oil businesses. He interprets this result as suggesting the capital constraints limit the ability of firms to raise outside financing.

Since Arrow (1962), it has been understood that not only investments in physical goods but also innovation should be affected by an inability to raise capital. The substantial information problems surrounding R&D projects make it difficult to raise external capital to finance them. As a result, firms with promising projects may be unable to pursue them.

The sensitivity of innovation to capital constraints has been corroborated in a number of studies. For instance, Himmelberg and Petersen (1994) look at a panel of small firms and show that the sensitivity of R&D investment to cash flow seems to be considerably greater than that of physical investment. This suggests that the problems discussed above are if anything more severe for innovation as opposed to more traditional capital investments.

Economists have also studied the impact of debt on R&D spending. The classic study in this mold, Hall (1990), shows that firms that take on more debt and increase their leverage tend to reduce R&D spending. Similar conclusions are offered by Greenwald et al. (1992).

Thus, even if a firm develops an invention, it may not have the resources to commercialize it. The difficulty of raising capital stemming from the information problems surrounding the proposed innovation may preclude the development of innovations that would be otherwise successful.

4.2. Financial Intermediaries and Innovation

A second relevant stream of the finance literature on innovation has examined the relationship between intermediaries and innovation. Much of the attention here has focused on venture capital organizations, that is, independently managed, dedicated capital focusing on equity or equity-linked investments in privately held high-growth companies.

Venture capital has attracted extensive theoretical scrutiny. These works suggest that venture capitalists promote innovation by mitigating agency conflicts between entrepreneurs and investors. The improvement in efficiency might be due to the active monitoring and advice that is provided (Hellmann 1998; Marx 2000; Cornelli and Yosha 2003), the screening mechanisms employed (Chan 1983), the incentives to exit (Berglöf 1994), the proper syndication of the investment (Admati and Pfleiderer 1994), or investment staging (Sahlman 1990; Bergemann and Hege 1998).

Theorists have suggested a variety of mechanisms by which venture capital may affect innovation, but the empirical record is more mixed. It might be thought that establishing a relationship between venture capital and innovation would be straightforward. For instance, one could look

at regressions across industries and time to determine whether, controlling for R&D spending, venture capital funding has an impact on various measures of innovation. But even a simple model of the relationships among venture capital, R&D, and innovation suggests that this approach is likely to give misleading estimates.

Both venture funding and innovation could be positively related to a third unobserved factor, the arrival of technological opportunities. Thus, there could be more innovation at times when there was more venture capital, not because the venture capital caused the innovation, but rather because the venture capitalists reacted to some fundamental technological shock that was sure to lead to more innovation. To date, only two papers have attempted to address these challenging issues.

The first of these papers, Hellmann and Puri (2000), examines a sample of 170 recently formed firms in Silicon Valley, including both venture-backed and nonventure firms. Using questionnaire responses, the authors find empirical evidence that venture capital financing is related to product market strategies and outcomes of start-ups. They find that firms that are pursuing what they term an “innovator strategy” (a classification based on the content analysis of survey responses) are significantly more likely to obtain venture capital and to obtain it more quickly. The presence of a venture capitalist is also associated with a significant reduction in the time taken to bring a product to market, especially for innovators. Furthermore, firms are more likely to list obtaining venture capital as a significant milestone in the lifecycle of the company compared to other financing events.

The results suggest significant interrelations between investor type and product market dimensions, and a role for venture capital in encouraging innovative companies. Given the small size of the sample and the limited data, Hellmann and Puri (2000) can only modestly address concerns about causality. Unfortunately, the possibility remains that more innovative firms select venture capital for financing, rather than venture capital causing firms to be more innovative.

In contrast, the second paper, Kortum and Lerner (2000), examines whether these patterns can be discerned on an aggregate industry level rather than on the firm level. These authors address concerns about causality in two ways. First, they exploit the major discontinuity in the recent history of the venture capital industry: in the late 1970s, the U.S. Department of Labor clarified the Employee Retirement Income Security Act, a policy shift that freed pensions to invest in venture capital. This shift led to a sharp increase in the funds committed to venture capital. This type of exogenous change should identify the role of venture capital, because it is unlikely to be related to the arrival of entrepreneurial opportunities. They exploit this shift in instrumental variable regressions. Second, they use R&D expenditures to control for the arrival of technological opportunities that are anticipated by economic actors at the time but are unobserved by econometricians. In the framework of a simple model, they show that the causality problem disappears if they estimate the impact of venture capital on the patent-R&D ratio, rather than on patenting itself.
