Even after addressing these causality concerns, the results suggest that venture funding does have a strong positive impact on innovation. The estimated coefficients vary according to the techniques employed, but on average a dollar of venture capital appears to be three to four times more potent in stimulating patenting than a dollar of traditional corporate R&D. The estimates therefore suggest that venture capital, even though it averaged less than 3% of corporate R&D from 1983 to 1992, is responsible for a much greater share—perhaps 10%—of U.S. industrial innovations in this decade.

Some of the most interesting theoretical work in recent years has focused not on the question of whether venture capitalists spur innovation but rather on the societal consequences of the relationship between venture-backed entrepreneurship and innovation. Landier (2006) presents a model in which entrepreneurial ventures succeed or fail on the basis of ability and luck.⁹ He argues that as the venture progresses, the entrepreneur is likely to learn about the probable eventual success of the venture, but that the decision to continue or abandon it will not be the same in all environments. In particular, the decision depends critically on how expensive it would be to raise capital for a new venture from investors after a failure. In this setting, Landier shows, multiple equilibria can arise. If the cost of capital for a new venture after a failure is not very high, entrepreneurs will be willing to readily abandon ventures, and failure is commonplace but not very costly. Alternatively, if the cost of capital for failed entrepreneurs is high, only extremely poor projects will be abandoned. Thus, societies may differ dramatically in the prevalence of experimentation in high-risk, innovative ventures.

5. Conclusion

In this chapter, we review the key features of the literature on innovation and organizational structure. We highlight the key areas where work has been undertaken, as well as the limitations of the literature to date.

Stepping back, two metathemes emerge across the strands of literature reviewed above. The first is that there is now a much more fruitful back-and-forth between theoretical and empirical work than was the case at the inception of the field. The patent race literature, for example, was only loosely motivated by empirical observations and did not (at least initially) necessarily provide much grist for the empiricist's mill (e.g., Cockburn and Henderson 1994). Similarly, much of the early empirical work on the relationship between firm size and innovation was atheoretical.

In recent years, these two approaches have been moving more closely together. Consider, for example, the response to the rise of an active market for early development projects in the biopharmaceutical sector. These changes have made salient—in theorists' minds—the possibility of appropriating at least part of the returns from innovation on the ideas market, rather than on the product market. In addition, they have stimulated both theoretical work and empirical investigations that test these theories' specific predictions, either in different papers (Gans and Stern 2000; Gans et al. 2002) or sometimes in a single paper combining theory and evidence (Lerner and Malmendier 2010). These developments bode well for future research in this area.

The second theme pertains to the style of empirical work practiced by applied economists studying innovation and organizations. Although aware of the perils involved in sweeping generalizations, it seems clear to us that we are lagging behind other subfields of microeconomics in our treatment of endogeneity and unobserved heterogeneity. It is possible that our subject matter provides inherently fewer opportunities to exploit natural experiments, relative to the type of questions studied by health, development, or labor economists. An alternative explanation is that we have collectively been too reluctant to place identification at the center of our preoccupations. This reluctance is not always for the worse. Researchers often face trade-offs between

9. See also Gromb and Scharfstein (2002) for a thoughtful theoretical analysis that touches on many of these issues.

the importance of the problem they tackle and the degree of confidence they can achieve in providing answers to this problem.

At the same time, we suggest that putting relatively more emphasis on the establishment of causal relationships—as opposed to the careful documentation of conditional correlations—would be a welcome development. One hallmark of the fields of technical change and organizational economics is that researchers often laboriously produce the data that they analyze rather than simply consuming existing sources of administrative data, such as the Current Population Survey or the Panel Survey of Income Dynamics. Thus, in the quest for exogenous sources of variation, we face potentially fewer constraints than do researchers in other subfields of economics, provided that we channel more effort into addressing identification problems at the time of a project's inception. Stern's (2004) study of compensating differentials in the entry-level science labor market is an exemplar of this particularly creative genre. More studies in that vein on the traditional concerns of the field (e.g., the estimation of knowledge spillovers) would enable us to step back and sort out what we can confidently claim to know from what is at most informed speculation.

Hierarchies and the Division of Labor

Luis Garicano and Timothy Van Zandt

1. Introduction

Knight (1921) saw the function of entrepreneurs (and others “of higher skill”) as making informed decisions in a world of uncertainty. Indeed, this would describe also the role of middle- and low-level managers, their assistants, and the technicians who collectively manage a large organization through decentralized decision processes.

This chapter reviews some research in economics on such managerial decision processes. Such research is not a mere technological exercise, akin to studying production on an assembly line. Rather, organizational processes are integral to the external interaction between an organization and other actors and to the internal functioning of the organization. Externally, these organizational processes constitute the decisionmaking by organizations, which is of inherent interest to economists, for whom organizations are among the actors in broader economic models. Internally, such coordination processes are what define organizations—what make organizations organized—and the division of decisionmaking tasks and the flows of information among members of an organization are what define organizational structure.

1.1. Complexity and Bounded Rationality

This topic is inherently tied to “bounded rationality,” where this term is defined broadly to include human limits on decisionmaking in complex situations. If the mythical unboundedly rational, all-capable owner-entrepreneur-manager existed, there would be no organizational processes to talk about, no need to delegate the coordination in organizations to several or many agents, and therefore no organization structure other than a center and everyone else. There would be few of the incentive problems that delegation creates and that are the focus of much of the theory of organizations. An organization could be modeled as a single rational agent, as in the classic “black box” theory of the firm.

That said, the research we review in this chapter is not about sophisticated models of the bounded rationality or behavioral biases of a single person but rather about the decentralization of organizational processes that such bounded rationality entails. The “microbiology” of

the individual manager is sacrificed to understand the organism-level “macrobiology” of the organization.

The basic elements of a model of organization processes are (1) a specification of the task or decision problem that the organization faces and (2) the capabilities of the potential managers and other organizational resources available for handling the task. A common feature of the models that we review is that the *complexity*—the difficulty of the task or decision problem compared to the capabilities of the individuals—is modeled explicitly. This contrasts with some behavioral approaches to bounded rationality.

Most of the literature we review has then closed such a model using a *constrained-optimal* approach. That is, the modeler characterizes the feasible decision procedures that are optimal—or that at least are good by some criterion, if it is too difficult to characterize optimal procedures—according to a performance criterion that may reflect computational or communication costs. It is logically consistent to have a model of bounded rationality in which agents cannot fully optimize and then to characterize optimal solutions to the design problem—because it is the theorist, not the agents in the model, who is performing the optimization. Yet what do we learn from such a characterization of constrained-optimal organizations?

Our approach is little different from the rationality assumption in most models of individual behavior in economics. We know that agents cannot be perfectly rational, but they are goal oriented, and this economic motivation is an important driver of human behavior. The rationality assumption is a powerful way to make these observations salient. Likewise, we understand that organizations are not constrained optimal, but organizations evolve and are designed in ways that are driven by performance goals and constraints. Hence, it can be elucidating to conclude that, for example, a particular hierarchical form or type of decentralization is prevalent because it is a good way for an organization to do well in a complex environment when the decisionmaking is done by managers, each of whom has limited capacity for absorbing information and making decisions. A powerful way to analyze this is for the theorist to outline explicitly the firms’ decisionmaking task and performance goals and the constraints on the individual managers, and then to characterize the constrained-optimal organizational forms and processes.

1.2. A Division of the Literature

We have divided the literature into three groups, which focus on different questions about organizations and feature different kinds of models.

1. *Knowledge hierarchies.* This group focuses on the benefits of and limits to specialization of the knowledge and skills that managers in an organization have, and the process of dividing tasks among specialized managers. In a typical model, the firm faces a flow of independent problems. Decentralization takes the form of different problems being handled by different people. In its simplest form, with homogenous problems and managers, this is a queuing problem. We devote our attention, however, to models with heterogeneous problems and managers, in which organizational performance depends on how well problems are handled by the right managers, that is, by how well the problems are matched to the knowledge available in the organization.

The other two groups have in common that they focus on aspects of joint and interrelated decisionmaking. As a consequence, a typical model has a task or decision problem that is decomposable but that cannot be divided into unrelated problems. Decentralization takes the form of different decisions being made by or different calculations being performed by different managers.

2. *Team theory.* Limits to communication and to the cognitive capability of an individual manager imply that interrelated decisions are made by different people with different information. This group of papers focuses on the design of optimal decision rules, given such decentralized information, and also compares different information structures and different assignments of decision variables. A typical model has the flavor of a Bayesian game (which captures the decentralization of information) with common payoffs.
3. *Information processing.* The task of making a decision involves not merely communication but also time-intensive thinking and information processing. The sharing of such information-processing tasks is a motive for decentralizing decisionmaking to managers who a priori do not even have private information. This final group of papers studies the structure of such decentralized information processing. A typical model has the flavor of a simple model of distributed computation. It starts with an information-processing task or decision problem and with a decomposition of such a problem into steps, which are then assigned to different managers.

2. Historical Debates

2.1. Markets versus Planning Bureaus

The term “organization” is often interpreted as a tightly coordinated bureaucracy in which individuals have specific functions and common purpose. However, more broadly, an organization is any collection of individuals or groups whose actions are coordinated and for which there is some criterion for evaluating the collective outcome, even if it is a weak criterion, such as Pareto efficiency. Hence, markets and bureaucratic structures, such as firms, are alternate forms of organizations.

Having thus included market mechanisms in the theory of organization, we can say that the first prominent discussions in economics about alternate forms of organizations and their relative efficiency for decisionmaking were debates about socialism from about 1910 to 1940.

Some early visions of planning under socialism held that economic activity would be directed entirely by a central authority, without any role for prices. However, it was later suggested that prices were necessarily part of efficient resource allocation mechanisms, because they arise naturally in such a constrained optimization problem. This argument is essentially that of both Barone (1935, originally published in 1908) and Mises (1951, originally published in 1922), although the former proposed a price-based planning mechanism, and the latter claimed that price-based planning was not possible because of the lack of private ownership and exchange of the means of production. (For details on the origin of these ideas, see Hayek 1935.)

The role of prices was soon accepted by many economists, along with the additional point that the computation of solutions to the planning problem, even using prices, was too large a task to be done centrally by a planning bureau and would require the communication of

too much information to the planning bureau. Hayek (1940: 125–126) summarizes this consensus. Therefore, later stages of the debate argued about whether socialist economies could use decentralized price mechanisms to allocate resources. Taylor (1929), Lange (1936, 1937), Dickinson (1939), and others proposed iterative mechanisms in which the adjustment of prices was controlled by the planning bureau. Hayek (1940) and others contended that such mechanisms would be too slow and cumbersome, but these authors never presented a model of how private-property markets reach equilibrium. Hence, the computational efficiency of the proposed planning mechanisms and of markets in capitalist economies could not be compared. This important gap has yet to be filled.

2.2. Markets versus Firms

In the 1930s, while some economists were comparing the efficiency of socialism and private-property market economies, other economists, such as Kaldor (1934), Robinson (1934), and Coase (1937), were drawing attention to the fact that even in private-property market economies, many transactions take place inside firms and are not regulated by price mechanisms. They suggested that the boundaries of firms are determined, in part, by the relative efficiency of markets and bureaucracies for processing information. However, this issue was also unresolved, because the authors discussed the process of managing a firm but did not make a direct comparison with how markets perform similar tasks.

One of the themes of that brief literature, which has consistently reappeared in the theory of organizations, is that information-processing constraints may be a limit to firm size. It was first observed that with centralized information processing (meaning that a single entrepreneur processed all information and made all decisions), there would be diseconomies of scale because of the fixed information processing capacity of firms. However, it was also noted that as firms grow, more managers are hired, and information processing is decentralized. Kaldor (1934: 68) responded that full decentralization of the coordination task is still not possible:

You cannot increase the supply of co-ordinating ability available to an enterprise alongside an increase in the supply of other factors, as it is the essence of co-ordination that every single decision should be made on a comparison with all the other decisions made or likely to be made; it must therefore pass through a single brain.

This idea suggests that information-processing constraints will lead not only to decentralized information processing but also to decentralized decisionmaking, in which multiple agents make decisions based on differing information.

These themes have been further developed by Williamson (1975, 1985) and others in the field of transaction economics and in the models of organizational processes described in this chapter.

3. The Cognitive Role of Hierarchies

A theme of information-processing models in Section 6 is that, even if the managers in an organization have identical skills and knowledge, there are advantages to dividing up complex tasks among such managers. However, another important value of team decisionmaking is that

it allows for specialization among the knowledge workers while providing mechanisms for the utilization of dispersed knowledge. We take up this theme first.

The main source of the increasing returns to knowledge specialization, as Rosen (1983) argued, is that an individual's investment in knowledge is a fixed cost that is independent of its subsequent utilization. Indeed, Sherwin Rosen (2002: 10) in his presidential address to the American Economic Association argued "for the economy as a whole, the most important reason by far for specialization and division of labor are scale economies in utilizing acquired skills."

Such a force would seem to push the economy to complete specialization: each individual would acquire one piece of knowledge and use it as intensively as possible. However, such complete horizontal specialization makes it impossible to match problems to solutions. Suppose a pediatrician only knows how to treat one type of tumor. How do we match the right child with this specialist? As specialization increases, it becomes harder to know who knows what. Organizations must find ways to determine who has the relevant knowledge.

This section considers a literature that focuses on the benefits of knowledge specialization and the problem of then allocating dispersed knowledge to determine the implications of these two forces on organizations. For these questions, it is sufficient to consider organizations that are a means of dealing with a flow of unrelated problems, each of which requires specific knowledge to be solved. The important modeling consideration is that knowing which knowledge a problem requires is itself a task that requires knowledge.

The organizational problem under these circumstances is then as follows. In the course of production, the organization must deal with a stream of problems. To solve them, specialized knowledge is required. Problems may differ by how difficult they are (some may be harder than others), in how often they come up (some are routine, the other are exceptional), and so forth. Agents can acquire specialized knowledge about problems, and the organization may determine the order in which different agents confront these problems and how they communicate with one another. The organization may also invest scarce resources in labeling problems.

Garicano (2000) combines these elements in a model of knowledge-based hierarchies. The hierarchical form, in which workers deal with the routine problems and managers deal with the exceptions, arises as an optimal way to structure the organization of knowledge. Crémer et al. (2007) extend this idea by allowing problems to be labeled through codes to facilitate the allocation of knowledge, as discussed by Arrow (1974). Each piece of the organization may develop variants of a given code or language, and then managers serve in these organizations as translators. We discuss these two ideas in turn.

These theories generate sharp predictions concerning the impact of information technology on organizations. Consider first knowledge hierarchies. The key trade-off is between the costs of communication and the costs of training and knowledge acquisition. By creating a hierarchy, training costs per worker are reduced, but communication costs rise. Thus, the cost of acquiring knowledge and of communicating affect the structure of the hierarchy. Lower training or acquisition costs lead to less reliance on the manager's knowledge, as more problems can be solved by frontline employees and thus less communication is necessary; conversely, lower communication costs are "deskilling": frontline employees need to acquire less knowledge, because relying on the knowledge of those above is now cheaper.

Similarly, drops in information and communication costs affect the scope of firms through the cost of common codes. With low information cost, specialized codes become less necessary,

and expanding the scope of the code can result in synergies without substantive information losses.

We discuss both theories next, along with some relevant empirical evidence.

3.1. Knowledge-Based Hierarchies: Management by Exception

Garicano (2000) shows that when matching problems and solutions is hard, hierarchies conserve the time of more-able agents by allowing them to use the time of less-able agents to deal with the routine problems. Alfred Sloan (1924), a former head of General Motors, wrote: “We do not do much routine work with details. They never get up to us. I work fairly hard, but on exceptions.” We study here under what conditions this is the case and the implications of such a view for organizational design.

The model of production and problem solving is as follows. A firm handles a flow of production tasks, which can be scaled, so that any worker can be fully occupied with her own flow. Each task requires specialized knowledge and production time to complete; if completed, it results in output (gross profit not including the cost of knowledge and production). We measure the quantity of knowledge by the effort, cost, and/or time required to acquire it. The production time, which could as well be thought of as managerial processing time, incorporates the time it takes to determine whether one has the knowledge required for the task and then (if so) to perform the task. In fact, the assumption in the model is that this production time is the same whatever the outcome of such processing, as if the sole or main part of such production were to understand what the task entails and how it matches one’s knowledge.

We take a continuous approximation, as if the tasks were perfectly divisible, and index the tasks by $z \in [0, \infty)$. We assume that different tasks involve the same proportions of knowledge, production time, and output. We normalize the units, so that these three quantities are equal to one another for each task, and we can set them to 1 per unit interval of tasks. What varies across tasks is their frequency, which is measured by a density $f(z)$, with cumulative distribution function F and induced measure ν . We index the tasks in decreasing order of frequency, so that f is a decreasing function.

Consider first the case in which there is no team production, in the sense that each worker in the firm either solves a task by herself or not at all. Suppose that such a worker acquires the knowledge necessary to solve the tasks in a set $A \subset [0, \infty)$. (We refer to A as the “worker’s knowledge.”) A particular problem arrives, and the worker can solve it with probability $\nu(A)$. At the level of flows, she completes fraction $\nu(A)$ of the one unit of tasks that reach her per unit time.

Her training or knowledge acquisition cost is c per unit of knowledge. That is, her cost of learning all tasks in set A is c times its Lebesgue measure $\mu(A)$. She should acquire knowledge about the most frequent tasks; given that the tasks are ordered from most to least frequent, this means the tasks in an interval $[0, \bar{z}]$ for some cutoff $\bar{z}$. The cost of such knowledge is $c\bar{z}$, and because each completed task generates one unit of knowledge, the value of such knowledge is $F(\bar{z})$. Her optimal cutoff is the solution to $\max_{\bar{z}} F(\bar{z}) - c\bar{z}$. It is the same for all workers.

Suppose now that workers may work in teams, so that a worker can ask other workers for help with the problems that he cannot solve. The worker who is asked can provide help at a time cost $h < 1$. This cost does not affect the time that the original worker devotes to the problem. We

assume $h < 1$ to capture the idea that the original worker's acquired understanding of the task facilitates the analysis of the task by other workers.

Crucially, again, a worker cannot know in advance whether he will be able to deal with a particular task until he has tried it—that is, he spends h when he is asked, regardless of whether the help is actually useful (e.g., a car mechanic often spends as much or more time on a car he cannot fix as on one he can). Consider, for example, a team where worker 1 knows problems in the set A_1 and worker 2 knows those in the set A_2 . Suppose they help each other. Worker 1 then spends fraction $t_1^h = h(1 - v(A_2))$ of his time helping worker 2. Each worker has one unit of time, so the fraction t_i^p of time that worker i spends in production on the tasks that reach him directly is $t_i^p = 1 - t_i^h$.

The total flow of problems that reach the workers is then $t_1^p + t_2^p$, and they are successful with any task in the set $A_1 \cup A_2$. Therefore, the joint output is¹

$$(t_1^p + t_2^p)v(A_1 \cup A_2) - c(\mu(A_1) + \mu(A_2)).$$

In general, to find the optimal organization among a large pool of workers, we can divide the workers into classes, indexed by i , such that workers within the same class i have the same knowledge A_i , spend the same time t_i^p in production and the same time t_i^h helping, and have the same rules ℓ_i for communication. These rules prescribe whom (which other class) they are supposed to ask first, whom next, and so forth. Then the team design problem is to choose A_i , t_i^p , t_i^h , and ℓ_i for each class, along with the measure β_i of workers in each class, to maximize per capita output—subject to the time constraint $1 \geq t_i^h + t_i^p$ and to the organization size constraint $\sum \beta_i = 1$.

Garicano (2000) shows that the solution is a simple hierarchy, where only the first layer of workers are involved in production and in asking questions, and the rest are problem solvers—that is, they spend all their time solving problems that are passed on to them from below. Moreover, production workers know the most common problems $[0, z_0]$; moving up the hierarchy, each successive layer i knows increasingly exceptional problems $[z_{i-1}, z_i]$, as shown in Figure 1. The key characteristic of this structure is management by exception.

To understand this last result, consider instead a hierarchical arrangement where agents in some layer know problems $[z, z + \varepsilon]$ (among others), which come up more often than a same-size interval $[z', z' + \varepsilon]$ of problems known by those who ask them questions. That is, $z < z'$ and hence $f(z) > f(z')$. This arrangement can be improved by swapping these intervals. Learning costs are unchanged, as all agents learn the same number of problems as before. Production is unchanged, because the total amount of knowledge is unchanged. But communication costs are lower, as those asking questions are now less likely to confront a problem they do not know. The crucial insight is that, by relying on management by exception, some specialization in knowledge can be attained while minimizing communication costs.

This principle of management by exception is very common in organizations. For example, in a hospital environment, residents (junior doctors) deal with the patient as she arrives, and the

1. Note that the analysis ignores for simplicity the stochastic aspect of problem arrival (i.e., there is no queuing in front of a manager when multiple workers requesting help arrive) and assumes that a certain measure of problems arrive with certainty at each level. See Beggs (2001) for a treatment of this aspect of the queuing problem.

Figure 1. Management by exception: Workers specialize in production and deal with the routine problems (those in z_w). Managers help these workers to deal with increasingly exceptional problems. Managers in layer 1 acquire knowledge z_1 ; those in layer 2, z_2 ; and those in layer 3, z_3 .

residents ask an attending physician for help only when the patient presents a difficult problem. In the production floor of a factory, production workers operate the machines, mechanical coordinators help them when the machine breaks down or stops, and production engineers are only called in when workers and coordinators both fail to deal with the production problem.² We discuss some more specific examples when we review the empirical literature below.

Note that the organization that emerges is pyramidal: each successively higher layer contains fewer workers. This is because an increasing share of the problems have been solved as one moves up the pyramid. Quantitatively, if there are n_0 workers in the first layer, then the flow of problems the organization can handle is n_0 . For each layer $i > 0$, fraction $1 - F(z_{i-1})$ of these make it to layer i , so $n_i = (1 - F(z_{i-1}))n_0$.³

To explore the comparative statics of this type of hierarchy, Garicano (2000) proposes a version of the model with an exponential distribution $F(z) = 1 - e^{-\lambda z}$ and solves for the optimal hierarchy. With the results established so far, we have only to determine the knowledge thresholds $\{z_0, z_1, \dots\}$, such that level i has knowledge $[z_{i-1}, z_i]$, that maximize the overall pay-off. However, this optimization problem can be solved using a decentralized “referral market” solution with shadow prices, developed in the dynamic model of Garicano and Rossi-Hansberg (2012). We follow this approach, because it is simpler and provides more intuition.

In this referral market, the salary of a problem solver is the result of the knowledge he adds to problems that could not be solved before him. Production agents who have a problem they cannot solve pass it on, in exchange for a referral fee r_0 that equals the expected value generated per problem passed up the hierarchy. In the context of the firm, where we think those exchanges would be likely to take place, r_0 is a transfer price or a shadow price. The earnings of a production agent are given by the problems that his knowledge allows him to solve on his own, plus the value

2. The example is taken from the observation of a Procter and Gamble plant in Spain.

3. A variant of this model can be obtained when knowledge is overlapping; that is, where the agent’s knowledge must be a superset of the knowledge of those below, for example, because the knowledge of the easier problems is required for the more difficult ones, knowledge is acquired through learning by doing, or the superiors supply instruction. Such a variant is described in Garicano (2000) and used as a building block in Garicano and Rossi-Hansberg (2006).

of the problems he confronts but cannot solve, minus his training costs:

$$w_0 = \max_{z_0} F(z_0) + (1 - F(z_0))r_0 - cz_0. \quad (1)$$

Likewise, a problem solver in layer i receives a referral fee r_i for problems he cannot solve and thus pushes further up the hierarchy. Given the knowledge z_{i-1} of the layers lower in the hierarchy and this referral fee, the optimal knowledge threshold z_i for layer i solves

$$\max_{z_i} \frac{1}{h} \left(\frac{F(z_i) - F(z_{i-1}) + (1 - F(z_i))r_i}{1 - F(z_{i-1})} - r_{i-1} \right) - c(z_i - z_{i-1}). \quad (2)$$

That is, he has the capacity to take on $1/h$ problem passed from below. He pays r_{i-1} for each of these. He solves each problem with probability

$$\frac{F(z_i) - F(z_{i-1})}{1 - F(z_{i-1})};$$

this hazard function is the conditional probability the solution is in his interval, given that it was not below. If he does not solve it, which happens with the complementary probability $(1 - F(z_i))/(1 - F(z_{i-1}))$, he can refer the problem to the next layer, receiving the fee r_i . His training cost is $c(z_i - z_{i-1})$.

Replacing $F(z) = 1 - e^{-\lambda z}$ and denoting the amount of knowledge of a level- i problem solver by $\hat{z}_i = z_i - z_{i-1}$, (2) is equivalent to

$$\max_{\hat{z}_i} \frac{1}{h} \left(1 - e^{-\lambda \hat{z}_i} (1 - r_i) - r_{i-1} \right) - c\hat{z}_i. \quad (3)$$

The first-order condition of the production worker problem is

$$\lambda e^{-\lambda z_0} (1 - r_0) = c, \quad (4)$$

and the first-order condition for a problem solver in layer i is

$$\frac{1}{h} \lambda e^{-\lambda \hat{z}_i} (1 - r_i) = c. \quad (5)$$

Note that the marginal cost of learning is the same for all agents, and that the marginal benefit has the same form for all agents—that is, except for the price of problems, nothing depends on how much those in previous layers learned. This lack of memory is a consequence of the constant hazard rate of the exponential distribution: conditional on a problem not having been observed in a given interval, the probability that it is in the next one is constant and is equal to λ in the limit where those intervals are very small. The stationarity of the first-order conditions suggests that the referral fee does not change with the layer, that is, $r_i = r$. The guess can be indeed verified, and it follows immediately that $\hat{z}_i$ is also the same for all $i > 0$, and we denote the common value by $\hat{z}_s$. A worker who asks once indeed finds it optimal to ask again and

again, until she finds the solution in this exponential case (the value of asking is analogous to the hazard rate—the probability that the problem will be known by the next layer, given that it was not known by the layer below). We can then simply solve the model and obtain closed-form solutions for all variables. The equilibrium referral fee is $r = 1 - h - (ch/\lambda) \log h$, and the amount of knowledge of each production agent and that of each problem solver are, respectively,

$$z_0^* = \frac{1}{\lambda} \log \left(\frac{h\lambda}{c} - h \log h \right), \quad (6)$$

$$\hat{z}_s^* = \frac{1}{\lambda} \log \left(\frac{\lambda}{c} - \log h \right), \quad (7)$$

with earnings at all layers given by

$$w = 1 - \frac{c}{\lambda} \left(1 + \log \left(\frac{h\lambda}{c} - h \log h \right) \right). \quad (8)$$

From (6)–(8) we obtain comparative statics for the tasks dealt with at each level and the spans of control (the ratio of workers in one level to workers in the next) in the optimal organization. First, a reduction in communication costs h increases the range of expertise of problem solvers (z_s) and reduces the range of expertise of production workers (z_0). Essentially, asking for help becomes cheaper relative to acquiring knowledge. As a consequence, the frequency $F(z_0)$ of decisionmaking of production workers decreases, and that of problem solvers increases. It also increases the span of control of problem solvers at each level, that is, the ratio n_i/n_{i-1} . Essentially, when communication costs are reduced, workers are less empowered.

Second, consider a reduction in the cost c of acquiring knowledge. This reduction could be the consequence of the introduction of expert systems and electronic diagnostics: each worker can solve, for a given investment in acquiring knowledge, a larger proportion of problems. For example, a machine operator can solve more problems for a given investment in learning if the machine is fitted with a diagnostic system. A reduction c increases the range of expertise of both problem solvers and production workers. As a consequence, the frequency of decisionmaking by production workers increases, and the frequency of decisionmaking by problem solvers ($1 - F(z_w)$) decreases, but more of the problems that reach any level are solved by that level. The reduction in c also increases the span of control of problem solvers. Again, the organization has become flatter, but workers are now more, rather than less, empowered. Production workers now can acquire knowledge more cheaply, so they ask relatively fewer questions. This increases the span of control of each problem solver, reduces the number of layers of problem solvers required, reduces the delay needed to obtain solutions to problems, and decreases the frequency with which problem solvers intervene in the production process.

Finally, changes in the density function as indexed by λ are (the inverse of) changes in the complexity of the production process. A more complex production process is one in which problems further out in the tails are more likely to be confronted. One can show that an increase in the complexity of the production process (a fall in λ) may increase or decrease the range of expertise of problem solvers (z_s) and production workers (z_w). However, it unambiguously

increases the frequency of decisionmaking by problem solvers ($1 - F(z_w)$) and decreases the frequency of decisionmaking by production workers ($F(z_w)$). It also reduces the span of control of problem solvers as they have to deal with more problems.

Garicano and Hubbard (2007b) extend the analysis to a world where there is both horizontal and vertical (or hierarchical) specialization. With multiple fields and uncertainty about which field will be necessary for production, generalists and specialists coexist—generalists arbitrage unpredictable differences in demand among fields and receive more stable earnings, whereas specialists use knowledge more intensively and earn more when the demand for their field is high. In such a world, an increase in the returns to horizontal specialization (e.g., because the size of the economy increases, and aggregate uncertainty about the allocation of demand across fields declines) reduces the value of the arbitrage among fields performed by generalists and increases equilibrium field specialization. As individuals become “narrower but deeper,” the benefit of leveraging their expertise increases. That is, increasing the returns to specialization also increases the value of leveraging individuals’ talent, and thus also increases both knowledge depth and the span of control of specialized problem solvers.

We now turn our attention to the second way that organizations (and hierarchy) structure the acquisition of knowledge by specialists: through specialized languages.

3.2. Organizational Languages: Managers as Translators

An alternative way to match problems with knowledge is by investing in labeling problems. As Arrow (1974) pointed out, agents often use technical languages to communicate with others about contingencies that are specific to their common environment. These specialized languages, or codes, economize in knowledge and communication costs within a group but at the cost of limiting communication with agents from outside the group. Communication across groups requires the use of specialized translators who span multiple languages and facilitate communication (e.g., for the reallocation of resources).⁴ Crémer et al. (2007) present an analysis of this problem. As they point out, the essential trade-off determining the scope of the language chosen is one between specialization and coordination. An organization that wants to capture more synergies by expanding its scope must acquire a more vague and imprecise common language to facilitate coordination among its units. The use of managerial hierarchies as integration devices weakens this trade-off somewhat.

We consider a simple version of the model by Crémer et al. (2007), which allows us to illustrate some of the main results of the analysis by making some functional form assumptions. In our story, a firm serves clients, whose types x are distributed on $[0, 1]$. On the front line are the salespersons, but they must communicate with a specialist—engineers in our story—to serve any client. The problem is to efficiently communicate the type of the client to the engineer.

4. Crémer (1993) generalizes this idea in his discussion of culture. Essentially, in his view, culture is a stock of shared firm-specific human capital, a knowledge stock shared by a substantial portion of the employees of the firm but not by the general population. This stock has three elements: a common code, a shared knowledge of facts, and a shared knowledge of rules of behavior. As in Arrow’s narrower discussion of codes, such a stock reduces communication costs. For example, a decision by an individual that commits her firm can be facilitated if there is a stock of facts (rules) that can help the agent predict the behaviors of others.

Communication is by a simple language in which each word denotes a set of client types, and each agent can only use a limited number of words, which thus define a partition of the set of types. For concreteness and simplicity, here let there be only 2 words.

Thus, the salesperson communicates that the type is above $\hat{x}$ (this is one word) or below $\hat{x}$ (this is the other word). The more types of clients included in a word, the less useful it is; to capture this, we assume the diagnosis cost that the engineer must incur to serve the client is equal to the breadth of the word (the measure of the set of types the word represents). This is the additional information that the engineer must acquire about the client after learning only that the type lies in the set corresponding to the word.

It is easy to see that the optimal code will be such that one word contains the more frequent events and the other word contains the less frequent ones. Furthermore, in an optimal code, broader words describe less frequent events. If not, the more frequent event in the broad word can be swapped with a less frequent one from a less broad word with a reduction in diagnosis costs.

Suppose that the distribution is given by a density f that is increasing (with cumulative distribution function F). Then the two words determine a simple partition into two intervals, $[0, \hat{x}]$ and $[\hat{x}, 1]$. The upper interval contains the more frequent words and hence is smaller: $\hat{x} > 1/2$. The optimal code problem reduces to

$$\min_{\hat{x}} F(\hat{x})\hat{x} + (1 - F(\hat{x}))(1 - \hat{x}).$$

Suppose now that there are two services, A and B . Each of them is composed of one salesperson and one engineer. They can organize in three possible ways:

1. separation (the two services use different codes);
2. integration (the two services share the same code); or
3. hierarchy (there exists a hierarchical structure supplying an interface between the services).

We establish next the circumstances under which each form is optimal. For expositional reasons, it is best to focus first on the comparison between the two pure forms, separation and integration, and then introduce the third form. But first we explicitly model the source of synergies.

To generate a need for coordination, there must be a potential synergy among the two services, which we model as follows. Customers arrive randomly, and there may be excessive load in one service and excessive capacity in the other. If that happens, the two services benefit from diverting some business from the overburdened service to the other. Formally, suppose that salespersons from services A and B deal with clients from two different distributions F_A and F_B , where $F_i(x) = (1 - b_i)x + b_ix^2$, where $b_A = b$ and $b_B = -b$, and $b \in [0, 1]$ measures the difference between the two distributions. When $b = 0$, both distributions are uniform; when $b > 0$, the distribution in A is skewed toward the lower end, and in B it is skewed toward the upper end. Let $\hat{x}_i$ be the cutoff between words of each service, with (by symmetry) $\hat{x}_B = 1 - \hat{x}_A$, and let $D_i(x)$ be the expected diagnosis cost in service i .

In a given period, salesperson i receives a random number y_i of clients, with the following distribution:

$$y_i = \begin{cases} 0 & \text{with probability } p, \\ 1 & \text{with probability } (1 - 2p), \\ 2 & \text{with probability } p, \end{cases}$$

where p belongs to the interval $[0, 1/2]$. This arrival process captures the effect of the variability in the expected number of clients of each type. Suppose that each engineer has the ability to attend to the needs of at most one client. If p is low, then each salesperson is likely to find one client per period. When p is high, although on average one client is arriving, it is quite likely that either none or two will arrive. Thus, p measures the importance of the synergy between the two services: a high p means that the services are likely to need to share clients, whereas a low p means that each service is likely to have its capacity fully utilized.

Finally, we assume that the profit that can be obtained when a client's problem is solved is 1. The per-client diagnosis costs is $\lambda \in (1, 2)$, so that if the engineer knows that the client's characteristics fall in an interval of size s , her diagnosis cost is $s\lambda$. This ensures positive profits. It also ensures that information must transit through a salesperson before being sent to an engineer; indeed, an engineer without information on the client's problem would have diagnosis costs greater than the profits obtained from solving it.

The organizational choice here is between segregating the services, so that salespersons from service A only communicate sales leads to engineers in A ; and integrating them so that a salesperson from A may communicate sales leads to either engineer. Should services communicate with each other, even at the expense of a common code?

In a *separated organization*, where the two services use different codes and there is no communication, each service uses a code adapted to its own distribution of types. Then $\hat{x}_A < 1/2$ and $\hat{x}_B > 1/2$. The expected profit given separate codes $\mathcal{C}_s$ is

$$\Pi_S(p, b, \lambda | \mathcal{C}_s) = 2(1 - p)(1 - \lambda D(b)).$$

Consider next an *integrated organization*. This requires that a salesperson from service A explain to an engineer in B the needs of his client, and vice versa. Indeed, because $\lambda > 1$, sending the problem to the engineer without explanation is not profitable. However, in this case the codes must be common in both services. What are the diagnosis costs in this case? The common language is the one that would be chosen when the density of tasks is the average of the two densities of the two services. In this case, because both services have opposing distributions, the average problem density is uniform. The optimal code has two equally imprecise words, with each word identifying the sales lead as coming from one-half of the distribution. The total profits given joint code $\mathcal{C}_j$ are then

$$\Pi_I(p, b, \lambda | \mathcal{C}_j) = 2(1 - p(1 - p)) \left(1 - \frac{\lambda}{2}\right).$$

Finally, in a *hierarchical organization*, the two services may exploit the synergy by employing a fifth agent who provides translation between the two services. Each service adopts a separate

code. When interservice communication is needed, the translator steps in. For instance, if salesperson *A* has two clients, he communicates to the translator the type of the “extra” client in the code used in service *A*. The translator will search for x , and then she will transmit the information to engineer *B* in the code used in service *B*. Hiring a translator requires incurring a fixed cost μ , but because the translator is specialized in language, we assume that her diagnosis cost is lower than that of the engineers. For simplicity we make the extreme assumption that the translator’s λ is zero. (The qualitative results of the analysis go through even if her λ is strictly positive, as long as it is lower than the engineers’ λ .) Then

$$\Pi_H(p, b, \lambda|\mathcal{C}_t) = 2(1 - p)(1 - \lambda D^t(b)) + 2p^2(1 - \lambda D^t(b)) - \mu,$$

where $\mathcal{C}_t$ is the code with translation, and μ is the fixed cost of the translator.

It can then be shown that if the cost of diagnosis is low, then the optimal organization is an integrated one with a common code. The synergies are captured, and the cost of having a language that is not well adapted are low. If diagnosis costs are high, separation is preferred, as it is important to ensure that a well-adapted language is used for each service. Finally, for in-between diagnosis costs, hierarchical structures are preferred. Organizations can attain some synergies, and languages are reasonably adapted to each separate environment.

An implication of the analysis is that hierarchies and codes are substitute modes of coordination: developments (e.g., improvements in information technology) that facilitate communication across units reduce the need for vertical communication and are likely to result in reductions in layers in firms. Moreover, the analysis allows for a comparison between horizontal and vertical coordination mechanisms. Horizontal mechanisms require common codes and thus result in less precise communication, given bounded rationality; vertical ones allow for more specialization of languages and knowledge sets but clearly increase delay, because communication takes one more step.

This work leaves an important unresolved aspect of codes to be analyzed. As Arrow (1974) argued, codes create an irreversible commitment by an organization, because they involve specific investments. As a result, a code (and a culture in the sense of Crémer 1993) results in an identity and a capability for the organization—to the extent that it adapts well to a current reality by developing a particular cognitive culture and structure for information processing, history does matter. Moreover, the presence of corporate culture imposes fixed costs of selective intervention—a merger cannot do as well if one exists—and thus it also has implications for the theory of the firm. This idea, which is close to what the management literature has called the “capabilities” of the firm, has been rarely explored in economics and should be the object of future work.

3.3. Empirical Evidence on Knowledge Hierarchies

The premise of the theories we discussed in Section 3.1 is that productive knowledge is embodied in individuals who have limited time. The efficient allocation of tasks must then be such that the time of more-knowledgeable individuals is only used when it cannot be substituted for the time of less-knowledgeable agents. This is accomplished through knowledge hierarchies in

which less-knowledgeable agents deal with routine problems, and the experts deal with the exceptions. We review the empirical evidence on two issues: (1) Do hierarchies indeed take this shape and allocate tasks in the manner suggested by the theory? (2) Do changes in the return to expertise, and thus to the depth of knowledge acquisition, affect the hierarchical structure of firms? Some related evidence, involving the wages at different positions of the hierarchy, is discussed later in the chapter.

3.3.1. *Case Evidence*

Knowledge hierarchies are prevalent in manufacturing. In a Kawasaki manufacturing plant in Japan operators do routine tasks; when a problem comes up that they cannot solve, it is recorded for later analysis by managers and engineers (Schonberger 1986). Similarly, at a Procter and Gamble plant in Barcelona, operators confronted with a problem first ask mechanical supervisors for help and then, if unsuccessful, the managers (most of whom are mechanical engineers). Variants of this organizational structure seem to be the norm at most manufacturing plants.

Customer service at software companies, hospitals, and banks is similarly structured. For example, in software development firms, the technical department is structured so that junior workers handle all calls initially, and they transfer upward the calls they cannot handle (Orlikowski 1996). In an experimental study using customer complaints randomly distributed to hospital employees, managers were randomly assigned 37% of initial complaints, but dealt, in a second instance, with 70% of the unsolved ones (Stevenson and Gilly 1991). The loan approval process in banks, as studied by Liberti and Mian (2009), has similar characteristics. Credit dossiers flow from the less to the more senior managers. The more risky, complex, and valuable the credit is, the more likely it is that it will be approved by a higher level of management. A similar phenomenon can be observed in medical services, where patients are first seen by a nurse, then by a resident, and only if necessary by an attending physician.

Using efficiently the existing knowledge of agents in the hierarchy is also a crucial factor in the structure of professional service firms (e.g., consulting, law, or investment banks). For example, at McKinsey the most routine parts of the assignment are dealt with by business analysts or associates; the more unusual and exceptional the assignment is, the more engaged managers and partners become. In fact, the whole business model of professional services is explicitly based on leveraging the highly valuable time of senior personnel through the use of relatively inexpensive associates (Maister 1993). Similarly, in research and development, the time of senior research scientists is leveraged through the use of large teams of junior scientists and postdocs who engage in the more routine tasks. In universities and other research institutions, knowledge hierarchies are highly prevalent, particularly in the physical sciences. This type of organization is also found in software development firms and open source software development, where bugs are dealt with by junior programmers and, if they prove complicated, go up the ladder to senior programmers.

Another interesting example of knowledge hierarchies can be found in military and intelligence services. Some information from the field is, if routine, dealt with by the frontline or field officer. If the information is unusual, it goes up the organizational ladder to a more knowledgeable officer, who decides what action to take. Information that is truly exceptional continues up to the top of the hierarchy (Wilensky 1967). Again, this conserves the time of the senior officers for the exceptional problems.

Knowledge hierarchies are also prevalent in upper-level management. The practice of having middle managers deal with the more routine management problems so that the very top managers only intervene in unusual circumstances is a well-established management practice: management by exception (Sloan 1924). In an empirical study of senior management Simons (1991) finds that management control systems are mostly used to allow senior managers to leverage their time by ensuring their attention is focused on those problems only they can deal with.

3.3.2. *Systematic Evidence*

A key implication of Garicano (2000) is the distinct impact of the two aspects of information and communications technology on the organization of firms. Improved knowledge access empowers frontline workers and flattens firms; cheaper communication does the opposite. Bloom et al. (2009) test this implication in a multinational sample of production firms and find strong empirical support for it. Specifically, they find that CAD/CAM, a key information technology in manufacturing, empowers production workers; that enterprise resource planning, the key new IT technology, empowers middle managers; and that communication technology shifts decisions away from both middle managers and workers and toward the top of the organization. This finding that information technology empowers lower-level managers, reducing layers and increasing spans, may also provide an explanation for the trend toward fewer hierarchical levels between division managers and CEOs and toward larger CEO span (Rajan and Wulf 2006).

Garicano and Hubbard (2007a) provide further evidence on the link between knowledge utilization and the structure of firms. Specifically, they first show that an increase in the returns to horizontal specialization will increase the returns to hierarchy, by increasing knowledge depth and the value of protecting the (now more valuable) individual's knowledge. They show that it follows that both the share of individuals who work in hierarchies and the ratio of lower-level to upper-level individuals should increase with market size, and test this (and other related propositions) using a unique dataset: confidential data on thousands of law offices from the 1992 Census of Services. These data are a large sample taken from all law offices located in the United States at the time, and contain office-level information on both the hierarchical organization of lawyers (i.e., how many lawyers are partners versus associates) and the field specialization of lawyers. These data are unique because they contain both information on individual hierarchical organizations and the breadth of their human capital for an entire industry.

They find that the empirical evidence is consistent with these propositions. The share of lawyers who work in hierarchies (i.e., in an office with at least one associate) is greater in larger local markets. This increase is correlated with increases in lawyers' field specialization in a way that is consistent with our model; specifically, the share of lawyers who work as partners in hierarchies remains constant, but the average number of associates who work under these partners increases. These findings seem robust, in that they hold also when looking only across small, isolated markets and persist when holding firm size constant. They appear mostly when analyzing lawyers who primarily serve business rather than individual clients. Finally, Garicano and Hubbard (2007a) find that these patterns are far weaker when examining the hierarchical margin between lawyers and nonlawyers, a margin where the division of labor among individuals

is constrained by regulation. This additional analysis provides evidence that is consistent with the view that the role of hierarchy in law offices is, in part, to support vertical specialization, because these results are stronger at hierarchical margins where the division of labor is not constrained and are strongest in segments where vertical specialization is most valuable.

4. Decomposing Decision Problems

4.1. Introduction

The debates in the 1930s on socialism and on the management of firms, reviewed in Section 2, both observed that decentralizing information processing and decisionmaking economizes on communication costs and distributes the decision tasks. Such decentralization requires that decision problems be decomposable into tasks that can be assigned to different agents.

In the knowledge hierarchies literature reviewed in Section 3, such decomposition is straightforward, because the organizational task consists of a flow of unrelated problems. In the other research streams we study in this survey, a single problem is decomposed into interrelated steps, and hence, the composition itself is a more fundamental feature of the model. In fact, the formal study of such decompositions—as an end in itself—was prevalent in the theory of organizations from the mid-1950s to the early 1970s, aided by advances in mathematical optimization methods.

In this section, we present in some detail a decomposition of a resource allocation problem. We focus on resource allocation, because it links several literatures and approaches (team theory, communication mechanisms, and information processing), because it is a fundamental economic problem both within and across organizations, and because the decomposition itself results in recognizable hierarchical procedures.

4.2. A Canonical Resource Allocation Problem

Consider a one-good resource allocation problem without externalities, framed as a payoff maximization problem of an organization, such as a firm. The firm has n production shops or operatives, indexed $i = 1, \dots, n$. The link among the shops is that each shop i receives an amount x_i of a resource that is in fixed supply x_R . Each shop also takes independent local decisions y_i . Fix a domain $X = \mathbb{R}$ or $X = \mathbb{R}_{++}$ for allocations and a domain Y for the local decisions. Then the firm's decision problem is

$$\begin{aligned} \max_{(x_1, y_1, \dots, x_n, y_n) \in X^n \times Y^n} & \sum_{i=1}^n \pi_i(x_i, y_i), \\ \text{subject to} & \sum_{i=1}^n x_i = x_R. \end{aligned} \tag{9}$$

The data in the problem are the shops' payoff functions $\{\pi_1, \dots, \pi_n\}$ and the amount x_R of the resource.

This canonical resource allocation problem has numerous interpretations. For example, each shop is a division in a firm; $\langle x_1, \dots, x_n \rangle$ is an allocation of a quantity x_R of a common resource, such as capital; y_i is a local decision variable for division i ; and π_i is the profit function of division i . Alternatively, each shop is a production shop; $\langle x_1, \dots, x_n \rangle$ is an assignment of production targets to the shops; x_R is the total required output; y_i is a local decision variable, such as inputs; and $\pi_i(x_i, y_i)$ measures inversely the cost of production; and the problem is to minimize the total cost of producing x_R . The resource could also be a consumption good, and each shop i could be a consumer whose weighted utility in an aggregate welfare function is π_i .

4.3. Decomposition between Local Decisions and the Resource Allocation

For each shop i , define $u_i: X \rightarrow \mathbb{R}$ by

$$u_i(x_i) = \max_{y_i \in Y} \pi_i(x_i, y_i). \quad (10)$$

We can think of the problem in (10) as a local decision made by shop i . The central office or headquarters focuses on the necessary coordination among the shops by solving

$$\max_{\langle x_1, \dots, x_n \rangle \in X^n} \sum_{i=1}^n u_i(x_i), \quad \text{subject to} \quad \sum_{i=1}^n x_i = x_R. \quad (11)$$

This decomposition and its implied communication is illustrated in Figure 2. Shop i must determine the entire function u_i and then communicate it to the central resource manager, who then solves (11) and communicates the resource allocation to the shops. We can think of the functions u_i as demands for resources communicated by the shops, and the resource manager responds with a resource allocation that balances the demands.

The benefits of such decomposition—compared to having a single person or office solve (9)—may be twofold. First, if the functions π_i are private information of the shops, then

Figure 2. Decomposition between local and global decisions. Shop i makes local decision y_i , given resource allocation x_i received from the center; u_i measures shop i 's maximized payoff (contribution to the firm), given any resource allocation.

Figure 3. Hierarchical decomposition of the resource allocation problems. Payoff functions are aggregated through an upward flow of information. Allocations are disaggregated through a downward flow of information.

communicating the single-variable function u_i is less complex than communicating the two-variable function π_i . Second, each of the single-variable optimization problems in (10) and the n -variable problem in (11) are less complex than the $2n$ -variable optimization problem in (9). Thus, the information-processing task is shared among more agents.

4.4. A Hierarchical Decomposition

The allocation of resources in the mechanism in Section 4.3 is centralized in the sense that the resource allocations emanate directly from the resource manager and are based on the pooled information of the shop managers. However, resource allocation procedures in organizations often have the hierarchical upward and downward flows of information seen in Figure 3. Examples include the capital budgeting processes of large firms and procedures for allocating resources in large nonmarket organizations such as governments, firms, and universities.

At the bottom of the hierarchy are the shops (or operatives, or whatever are the ultimate recipients of resources). In the upper tiers of the hierarchy are managers or administrators, grouped into offices; these are the nodes, such as a , c , and R , in Figure 3. We refer to the entire set of shops below one of these offices as a “division.” Information about the shops is aggregated by a flow of information up the hierarchy, and resources are recursively disaggregated by a flow of information down the same hierarchy.

Consider, for example, the capital budgeting cycle of a chain of local newspapers. Each reporter, writer, and salesperson (etc.) puts in requests for computer acquisitions with justifications. The head of the news department of each newspaper aggregates these requests and puts together an overall budget request, summarizing the department’s needs. The director of each

newspaper aggregates the requests from the newspaper's news, editorial, sales, and advertising departments, putting together a summary of the newspaper's needs, which is sent to central headquarters. There, the office of the director of capital budgeting aggregates these reports to compare the needs. At that point, the director does not decide on the computer acquisitions of each employee. Instead, she divides her capital budget among the newspapers. Each of these newspaper directors divides her budget among the departments, and then each department manager allocates the budget to the members of her department.

Such a decentralized procedure can replicate the decisions of a centralized procedure, as we now explain. In Figure 3, node b represents, for example, a news department in one of the newspapers. The subordinates of b , which we denote by Θ_b , are the reporters. Reporter 2's message to b is a summary of the payoff $u_2(x_2)$ that any allocation for computers would generate for the company (given optimal local decisions that the reporter would make). The aggregate payoff function for the news department, which we denote by $u_b = \bigoplus_{k \in \Theta_b} u_k$, is the following value function:

$$u_b(x_b) \equiv \sup_{\{x_k | k \in \Theta_b\}} \sum_{k \in \Theta_b} u_k(x_k), \quad \text{subject to } \sum_{k \in \Theta_b} x_k = x_b.$$

That is, it is the highest payoff to the firm that the reporters under b can generate when resources x_b are subdivided optimally among those reporters.

The aggregation of payoff functions is an associative and commutative binary operation, which we denote by $\oplus$. Thus, when office a , which in our story could represent the management of a newspaper, aggregates the reports u_b and u_c from the newspaper's two departments and thereby computes $u_a = u_b \oplus u_c$, it ends up with the same result as if it had directly aggregated the reports from the lowest level. That is,

$$\begin{aligned} u_a &= u_b \oplus u_c \\ &= (u_1 \oplus u_2 \oplus u_3) \oplus (u_4 \oplus u_5) \\ &= u_1 \oplus u_2 \oplus u_3 \oplus u_4 \oplus u_5, \end{aligned}$$

and so no information is lost by the hierarchical aggregation of information.

Consider now the disaggregation of resource allocations. Consider the example in Figure 3 and suppose that office a (the management of a newspaper) has to allocate an amount x_a of the resource to the shops below it (its reporters) to maximize the total payoff. It can either do so directly or instead (i) allocate amounts x_b and x_c of the resource to offices b and c to maximize the sum $u_b(x_b) + u_c(x_c)$ of their aggregate payoffs, and then (ii) instruct each department b and c to divide its allocation among its reporters to maximize the sum of those reporters' payoffs to the firm. Once again, there is no loss from this decomposition of the resource allocation decisions.

This property can be stated formally as follows. Let J be the set of offices (nonleaf nodes) in the hierarchy and, for $j \in J$, let θ_j be the shops below j in the hierarchy ("division j "). Let $\{x_i^*\}_{i=1}^n$ be a balanced resource allocation. For each office $j \in J$, let $x_j^* = \sum_{i \in \theta_j} x_i^*$ be the total resource allocation to the shops below j in the hierarchy. Then $\{x_i^*\}_{i=1}^n$ solves the overall

resource allocation problem in (11) if and only if, for each $j \in J$, $\{x_k^*\}_{k \in \Theta_j}$ solves j 's local resource allocation problem:

$$\max_{\{x_k \in \mathbb{R}\}_{k \in \Theta_j}} \sum_{k \in \Theta_j} u_k(x_k), \quad \text{subject to} \quad \sum_{k \in \Theta_j} x_k = x_j^*.$$

Thus, the hierarchically decentralized upward flow of payoff functions and downward flow of resource allocations, as shown in Figure 3, yields the same allocations as a centralized procedure, as shown in Figure 2. The benefits of such decentralization are not made explicit in this model, but the informal idea once again is that it is useful to be able to share complex tasks among multiple managers.

4.5. An Example with Quadratic Payoffs

To make the preceding section more concrete and to provide an example to be extended in other models in this chapter, we describe the aggregation of payoffs and disaggregation of resource allocations for the particularly simple example of quadratic payoffs. Specifically, we assume that each shop i 's payoff has the form

$$u_i(x_i, \gamma_i) = \bar{u}_i - b_i^{-1}(x_i - \gamma_i)^2, \quad (12)$$

where $b_i > 0$ and $\bar{u}_i, \gamma_i \in \mathbb{R}$. Then the aggregate payoff function of division $j \in J$ is

$$u_j(x_j, \gamma_j) \equiv \bar{u}_j - b_j^{-1}(x_j - \gamma_j)^2,$$

where

$$\bar{u}_j = \sum_{k \in \Theta_j} \bar{u}_k, \quad b_j = \sum_{k \in \Theta_j} b_k, \quad \text{and} \quad \gamma_j = \sum_{k \in \Theta_j} \gamma_k.$$

We can see from these formulas that such aggregation of payoff functions involves merely addition—a simple example of an associative binary operation. The optimal allocation by office $j \in J$ to subordinate in $k \in \Theta_j$ is

$$x_k^* = \gamma_k + \frac{b_k}{b_j}(x_j - \gamma_j). \quad (13)$$

Intuitively, γ_k is the ideal allocation that maximizes k 's payoff, and γ_j would be the total allocation if all subordinates received their ideal allocations. Then $x_j - \gamma_j$ is the total amount by which allocations would have to be adjusted to achieve resource balance. This adjustment is apportioned to the subordinates according to the weights b_k/b_j .

4.6. But What Does the Administrative Staff Do?

We have thus seen the possibility of decomposing a resource allocation problem, as depicted in Figure 3. However, it does not explain why this would be advantageous. To identify the

advantages of such decentralization, we should model the bounded capacities of the individual administrators. We consider two approaches in Section 5:

1. The first, discussed in Section 5, uses team theory to tell a story analogous to the returns to knowledge specialization studied in Section 3: managers are bounded in the amount of information they may have; decentralization allows the organization to bring to bear more information on the problem. The difference between this model and that of the previous sections is that the different managers have heterogeneous information about different parts of a single coordination problem, and hence are working together to solve the problem.
2. The second approach, discussed in Sections 6 and 7, models the actual information-processing activities by which managers turn raw data into decisions. Managers are bounded in what they can do in any amount of time; decentralization allows the firm to use more, or more recent, data.

5. Team Theory: Decisionmaking with Dispersed Information

By “team theory,” we mean the statistical theory of teams, as in Marschak and Radner (1972). (This term has also been used more loosely to describe any model without conflict of interest, or even any model with some kind of collective decisionmaking.) We begin with an overview of team theory as a Bayesian game of common interest, followed by an explanation of why this can be a model of organizations. We discuss Geanakoplos and Milgrom (1991), which is a model of hierarchical disaggregation of resource allocations, in more detail.

5.1. Overview

Team theory considers group decisionmaking when the members have private information but share the same goals. Ideally, the group would pool its information and make decisions that are optimal conditional on the pooled information. However, how should the members of the group make decisions when such pooling of information is impractical due to communication constraints?

The simplest interesting class of problems is when there are n players who observe private signals about the state of nature and then simultaneously choose actions. This is a Bayesian game in which players have the same payoffs for every realization of the state and every action profile.

A richer example is the resource allocation model studied in Groves and Radner (1972), Radner (1972), Arrow and Radner (1979), and Groves (1983). The basic decision problem is the resource allocation problem (9) outlined in Section 4.3, and the organizational structures typically resemble the decomposition given there, with a central production manager allocating resources and each unit manager controlling the unit's local decision variable. These models consider fixed, finite exchanges of information that do not resolve all uncertainty before decisions are made. A small sample of other models is Beckmann (1958), Groves and Radner (1972), Marschak (1972), Crémer (1980), Aoki (1986), and Green and Laffont (1986).

Team theory can incorporate both implicit and explicit constraints on the information-processing capacity of individual agents. As an example of implicit constraints, Crémer (1980)

studies a quadratic version of the resource allocation problem and characterizes the optimal grouping of shops when resources can only be allocated within groups of a fixed size. The story is that any manager who allocates resources only has the capacity to do so for a fixed number of shops. As an example of explicit constraints, suppose that, in an extension of Crémer (1980), information about shops is available as noisy signals of the shops' payoff parameters. A manager has the capacity to process a fixed number of signals but can compute any statistically optimal decision rule conditional on this information. One could characterize how many shops should be assigned to each manager and which signals a manager should observe.

5.2. Hierarchical Resource Allocation with Dispersed Information

The hierarchically decomposed resource allocation procedures in Section 4.4 are an interesting setting in which to incorporate dispersed information and to understand the optimal team decision rules. In such hierarchies, the decisionmaking is the recursive downward disaggregation of resource allocations. The upward aggregation of payoff information determines the information that each office has when choosing how to allocate resources. In the procedures studied in Section 4.4, such aggregation yields all information each office needs to optimally allocate resources. However, it would be natural that offices lack such full information—perhaps because information is lost during the aggregation.

In Section 7, we examine a model of aggregation of information that leads to such a loss. We begin, however, with a paper by Geanakoplos and Milgrom (1991) (henceforth, GM91), which imposes exogenous constraints on the information available to each node of the hierarchy and thereby focuses on the optimal decision rules for the disaggregation of resource allocations. By incorporating some flexibility about the information available to each manager, the model also yields results about the benefits of decentralization and about optimal hierarchical structures.

Consider, then, a hierarchy such as shown in Figure 3. Write the payoff of shop i as $u_i(x_i, \phi_i)$, where ϕ_i is a random parameter that captures the uncertainty about i 's payoff function. Replace the upward aggregation of information by an exogenous information set ϕ_j for each office $j \in J$. A decision rule or strategy for office j gives j 's allocation to each subordinate k as a function $x_k(x_j, \phi_j)$ of j 's own allocation and of the realization of j 's information. We look for decision rules that maximize the total expected profit of the firm.

Because the disaggregation of resources is recursive, this game is sequential rather than static. Therefore, a manager's resource allocation to a subordinate conveys some of the manager's information. This could throw a wrench into the model, because (i) the inference and resulting decision rules could be complicated and (ii) without a model of communication complexity, the resource allocation could encode an arbitrary amount of information, thereby circumventing the implicit information processing constraints in the model. Therefore, GM91 restrict attention to information structures in which a subordinate's information about shops below that subordinate in the hierarchy are a sufficient statistic for her superior's information about those shops. This restriction is reasonable and would hold, for example, if the shops' payoffs are independently distributed and if each manager's information is obtained by a lossy aggregation of information received from his subordinates.

The optimal decision rules can then be derived recursively from the bottom of the hierarchy moving up. For any office j , let $u_j(x_j, \phi_j)$ be the maximum expected profit conditional on the

realization ϕ_j of j 's information and on the resources j receives, given that j and the offices subordinate to j follow optimal decision rules. Then office j solves

$$\max_{\{x_k\}_{k \in \Theta_j}} \sum_{k \in \Theta_j} E[u_k(x_k, \phi_k) \mid \phi_j], \quad (14)$$

and $u_j(x_j, \phi_j)$ is the value function for this maximization problem.

This model is nice enough in the abstract, but to say more about optimal hierarchies and the distribution of information in a hierarchy, a more quantifiable model is needed. Many functional forms for the payoffs would be intractable, because, in (14), $u_k(x_k, \phi_k)$ can depend in a complicated way on k 's information ϕ_k , leading to a complicated interrelationship among the information from different offices—in the derivation of both the optimal decision rules and the maximized expected profit.

To avoid this problem, we would like a functional form whereby $u_k(x_k, \phi_k)$ equals the full-information maximized payoff on the subhierarchy rooted at k plus a loss that depends on ϕ_k but not on x_k —and hence that does not matter for the solution to (14). That is, each office should then allocate resources as if the offices below had complete information, and we can attribute a loss to each office that equals the difference between the maximized payoff the office would achieve if it had full information and the actual payoff it achieves. The overall profit of the hierarchy equals the full-information maximized payoff plus the sum of the offices' losses.

Both quadratic payoffs and logarithmic payoffs have exactly this property. GM91 assume quadratic payoffs, as in Section 4.5:

$$u_i(x_i, \gamma_i) = \bar{u}_i - b_i^{-1}(x_i - \gamma_i)^2, \quad (15)$$

where γ_i is a random variable, but $\bar{u}_i$ and b_i are known constants. The kind of certainty equivalence that one expects from such quadratic payoffs holds in this recursive model. That is, the optimal decision rules have manager j set⁵

$$x_k^* = \hat{\gamma}_k^j + \frac{b_k}{b_j}(x_j - \hat{\gamma}_j^j), \quad (16)$$

where $\hat{\gamma}_k^j = E[\gamma_k \mid \phi_j]$, and $\hat{\gamma}_j^j = E[\gamma_j \mid \phi_j] = \sum_{k \in \Theta_j} \hat{\gamma}_k^j$. (That is, whereas γ_k is a random variable, $\hat{\gamma}_k^j$ is the expectation of this variable conditional on j 's information.) The loss of office j can be shown to be⁶

$$L_j((\gamma_k, \hat{\gamma}_k^j)_{k \in \Theta_j}) = -b_j^{-1}(\gamma_j - \hat{\gamma}_j^j)^2 + \sum_{k \in \Theta_j} b_k^{-1}(\gamma_k - \hat{\gamma}_k^j)^2. \quad (17)$$

5. This allocation rule is part of Proposition 1 in GM91 and is analogous to equation (A8) in Crémer (1980).

6. See Van Zandt (1996) for details on this particular form, which is similar to equation (9) in GM91 and equation (A12) in Crémer (1980).

GM91 write the expected payoff as the no-information expected payoff plus the sum of the values of the managers' information. This is done as follows. Suppose that no manager has any information. Then for all $j \in J$, $\hat{\gamma}_j^j = E[\gamma_j] \equiv \bar{\gamma}_j$, and for all $k \in \Theta_j$, $\hat{\gamma}_k^j = E[\gamma_k] \equiv \bar{\gamma}_k$. Hence, manager j 's loss is $L_j(\langle \gamma_k, \bar{\gamma}_k \rangle_{k \in \Theta_j})$. Define the ex post value of manager j 's information to be the difference

$$\tilde{v}_j \equiv L_j(\langle \gamma_k, \bar{\gamma}_k \rangle_{k \in \Theta_j}) - L_j(\langle \gamma_k, \hat{\gamma}_k^j \rangle_{k \in \Theta_j})$$

between j 's loss if j had no information and j 's actual loss. Then the total payoff equals the no-information total payoff plus $\sum_{j \in J} \tilde{v}_j$. Let U_R^{ni} be the expected value of the no-information payoff and let $v_j = E[\tilde{v}_j]$, which we call the "value of j 's information." Then the expected value of the total payoff is equal to $U_R^{\text{ni}} + \sum_{j \in J} v_j$. A little algebra shows that

$$U_R^{\text{ni}} = \bar{u}_R - b_R^{-1}(x_R - \bar{\gamma}_R)^2 - \sum_{i=1}^n b_i \text{Var}(\gamma_i) \quad (18)$$

and

$$v_j = -b_j \text{Var}(\hat{\gamma}_j^j) + \sum_{k \in \Theta_j} b_k \text{Var}(\hat{\gamma}_k^j). \quad (19)$$

The organization design problem in GM91 is to specify a hierarchy and information acquisition for each manager, given constraints on the possible information structures that a manager can acquire, to maximize the expected payoff minus the managerial wages. Observe that the value of a manager's information does not depend on his resource allocation; therefore, it is irrelevant whether a manager's information acquisition is decided after he learns his allocation or before.

A necessary condition for optimality is that the *value of each manager*, which we define to be the decrease in expected payoffs when the manager is fired, be no less than the manager's wage. In this hypothetical firing of a manager, we assume that the information structure for the remaining managers is not modified, and that the fired manager's immediate subordinates receive allocations from the manager's immediate superior, if he has one. If the manager is instead the root, then the manager's subordinates become the root managers of independent organizations. Because the role of managers is to acquire information in order to allocate resources, we assume that independent firms obtain their zero-information optimal allocation.⁷ The value of a manager other than the root depends on the information her immediate superior has about her immediate subordinates' payoff functions. An easily calculated upper bound on the value of a manager is the value v_j of the manager's information.

5.3. Benefit of Decentralization

The benefit of decentralization in this model is that it allows more information to be brought to bear on decisionmaking. As a particularly simple example, suppose that each manager can

7. Under symmetry assumptions, then, the allocation to each firm is proportional to the firm's size.

observe the aggregate payoff parameters of 3 immediate subordinates. Then a single manager can solve the allocation problem without error only if she allocates resources to 3 shops. However, q managers, organized in *any* hierarchy—including a uniform hierarchy—such that each has a span of 3, can solve without error the resource allocation problem for $2q + 1$ shops.⁸

5.4. Economies of Scale

The informationally integrated unit in GM91 is the hierarchy, and the size of this unit, for the purpose of characterizing economies of scale, is the number n of shops. In this section, an optimal hierarchy or firm size is one that maximizes per-unit profit (expected shop payoffs minus managerial costs).

The information-processing constraints in GM91 do not limit firm size without additional assumptions and regularity restrictions on hierarchies. This is because one can always merge two firms by making one a subsidiary of the other in a way that increases total expected payoffs but does not change the managerial costs. Specifically, the root manager of one firm is made a subordinate of any manager in the other firm. Even without acquiring information about the subsidiary, the immediate superior of the subsidiary can make advantageous transfers to the subsidiary based only on information about her own shops. For example, with quadratic payoffs, the manager equates the expected marginal payoffs of her immediate subordinates, conditional on her information. In the absence of information about the subsidiary, the expected marginal payoff of any transfer to the subsidiary is deterministic; however, the expected marginal payoff of transfers to the manager's other immediate subordinates depends on the realization of her information.

The hierarchy that results from the merger just described is typically not balanced. This model may have a bounded firm size under the restriction that the hierarchy be balanced; under the assumption that managers have access to only disaggregate information with a bound on the total amount of information, given a positive managerial wage; and under the following symmetry assumptions:

1. $b_i = 1$ for all i .
2. $\{\gamma_i\}_{i \in I}$ are iid, with mean 0 and variance σ^2 .
3. For any collection of shops, total resources are 0. (Coordination involves only transfers between shops.)
4. $\bar{u}_i = \sigma^2$. (This is merely a normalization that sets the no-information expected payoff to 0.)

Rather than providing a formal proof of the bounded firm size under these assumptions, we outline the intuition. If a manager has access to only disaggregate information, then the value of information is low, unless she is sufficiently close to some shops, in the following sense: she must have at least one subordinate whose division does not have too many shops. If the hierarchy is balanced, so that all subordinate divisions are the same size, then there is a bound on the size of any of the root's subordinates. Then the total size of the hierarchy can be large only if the root

8. In any tree with q interior nodes that all have s children, there are a total of qs children, $q - 1$ of which are interior nodes. Hence, there are $q(s - 1) + 1$ terminal nodes.

has many subordinates. However, the root manager's per-subordinate value of information goes to zero as the number of her subordinates increases, given the bound on the total amount of the root's disaggregate information. Hence, it is better to take a very large hierarchy, in which the root manager is essentially irrelevant, and divide it among two root managers.

6. Decentralized Computation in Hierarchies

In the model of GM91, the limitations on the information that any manager can have are exogenous. Furthermore, the likely source of some of the managers' information, through an upward aggregation of information in the hierarchy, is not modeled.

The next approach instead starts with raw data and managerial processing capacities as the primitives. Any information that a manager may end up with comes through explicitly modeled information processing.

6.1. A Model of Decentralized Batch Processing

The nature of information-processing constraints is that people are bounded in the amount they can process in a given amount of time. It is possible to suppress the temporal aspect of these constraints and simply bound the total amount of processing an agent can do, as in Geanakoplos and Milgrom (1991) and Marschak and Reichelstein (1995, 1998). However, we focus on models that emphasize this temporal aspect.

One approach that emphasizes computational delay is decentralized batch processing, known in computer science as parallel or distributed batch processing (see Zomaya 1996). Kenneth Mount and Stanley Reiter, starting in 1982, have advocated this as a model of human organizations. Models of organizations based on decentralized batch processing include Malone and Smith (1988), Mount and Reiter (1990, 1996), Radner (1993), Bolton and Dewatripont (1994), Friedman and Oren (1995), Reiter (1996), Meagher and Van Zandt (1998), Van Zandt (1998), Beggs (2001), and Orbay (2002). The value of decentralizing information processing in these papers is typically that it reduces delay; in the periodic models of Radner (1993), Bolton and Dewatripont (1994), and Van Zandt (1998), it also increases the rate (throughput) at which problems can be computed.

The first part of a decentralized batch-processing model is a function $f: Y \rightarrow Z$ to be computed. The input domain Y is typically multidimensional, in which case all data in the vector $y \in Y$ are available when the computation starts. The other part of a decentralized batch-processing model is a decentralized computational model, which consists of the following components:

1. a set of elementary operations—functions that, when composed, can yield f ;
2. a description of how the processing activities of agents are coordinated and how information is communicated between agents—this may include a communication protocol;
3. a set of potential information-processing agents, each of whom is characterized primarily by the time it takes the agent to perform each elementary operation and each operation in the communication protocol.

Given a decentralized batch-processing model, a *procedure* (algorithm) specifies how one or more agents calculate $f: Y \rightarrow Z$ by performing elementary operations and sharing information.

For the resource allocation problem in Section 4, the function to be computed is $f: \mathcal{U}^n \times X \rightarrow X^n$, where $f(u_1, \dots, u_n, x_R)$ is the solution to (11), and $\mathcal{U}$ is the set of potential payoff functions. Assume that $\mathcal{U}$ is a set of strictly convex and differentiable payoff functions such that $\mathcal{U}$ is closed under the operation $\oplus$ and such that the resource allocation problem (11) has a solution for all $\{u_i \in \mathcal{U}\}_{i=1}^n$ and $x_R \in X$.

As explained in Section 6.2, we have some discretion in choosing the set of elementary operations. The following suit the objectives of this section:

1. (aggregation of two payoff functions) $f_1: \mathcal{U}^2 \rightarrow \mathcal{U}$, where $f_1(u_a, u_b) = u_a \oplus u_b$;
2. (derivative of a payoff function) $f_2: \mathcal{U} \times X \rightarrow \mathbb{R}$, where $f_2(u, x) = u'(x)$; and
3. (inverse derivative of a payoff function) $f_3: \mathcal{U} \times \mathbb{R} \rightarrow \mathbb{R}$, where $f_3(u, p) = u'^{-1}(p)$.

These elementary operations are sufficient to compute $f(u_1, \dots, u_n, x_R)$ as follows.

1. The aggregate payoff function $u_R := u_1 \oplus \dots \oplus u_n$ can be calculated with $n - 1$ operations f_1 .
2. The shadow price $p_R := f_2(u_R, x_R)$ of the resource can be calculated with one operation f_2 .
3. The allocation of each shop i can then be computed by setting the shop's marginal payoff equal to the shadow price: $x_i := f_3(u_i, p_R)$. A total of n operations f_3 are needed.

Table 1 summarizes the elementary operations and the number that are performed to calculate $f(u_1, \dots, u_n, x_R)$.

Next we specify the means by which agents communicate and are coordinated. We choose the simplest specification:

1. Agents are coordinated by synchronously executing instructions (the organization's managerial procedures).
2. There are neither individual nor network communication costs or delays.

Table 1. Elementary operations and serial and parallel delay for the resource allocation problem

Calculation	Elementary operation	Number of operations	Parallel delay
$u_R := u_1 \oplus \dots \oplus u_n$	$f_1(u_A, u_B) = u_A \oplus u_B$	$n - 1$	$\lceil \log_2 n \rceil$
$p_R := u'_R(x_R)$	$f_2(u, x) = u'(x)$	1	1
$\{x_i := u_i'^{-1}(p_R)\}_{i=1}^n$	$f_3(u, p) = u'^{-1}(p)$	n	1
Total:		$2n$	$2 + \lceil \log_2 n \rceil$

Note: $\lceil \cdot \rceil$ denotes the round-up operation.

Finally, we specify the capacities of the potential information-processing agents. We have already assumed that they are unconstrained in their communication abilities. We also assume the following:

1. Agents have identical computational abilities and wages.
2. Each elementary operation takes the same amount of time (a *cycle*).
3. Each agent is paid only when performing an operation, at a fixed wage per operation.
4. Each agent has unbounded memory.

Overall, we have the simplest possible specification of the communication among and coordination of agents. The lack of communication costs and delays means that agents have equal access to all raw data and partial results. Therefore, it does not matter which agents perform which operations each cycle—as long as no agent performs more than one operation at a time. Such a model is called a “parallel random access machine” in computer science.⁹

6.2. Discussion of the Computational Model

We have chosen a very simple model in terms of both the decomposition of the problem into elementary operations and the interaction among information-processing agents. In this section, we explain some of the options and considerations.

Consider first the selection of elementary operations. One of the reasons for decomposing the computation problem into elementary operations, whether processing is serial or parallel, is to compare the delay and processing costs of different types and sizes of problems. To do so, we must decompose the different problems into a common set of operations. Van Zandt (2003b), for example, compares the information processing for different numbers n of shops. Therefore, the aggregation $u_1 \oplus \cdots \oplus u_n$ of all the payoff functions should not be a single elementary operation, because this operation is different for different values of n . This is why the elementary operations we defined are all independent of n .

However, there are many sets of elementary operations that satisfy this invariance condition and that are sufficient to calculate $f: \mathcal{U}^n \times X \rightarrow X^n$. We must balance other goals when choosing among the possible specifications. On the one hand, a coarse decomposition is simpler. On the other hand, a fine decomposition permits more decentralized processing (the assignment of different elementary operations to different agents) and a more complete and realistic description of the actual activities of the agents.

The other simple features of this computational model suppress some potentially interesting issues, such as the problem of economizing memory and communication costs, the coordination of agents who are not synchronized, the scheduling of tasks when agents must be paid even when idle, and the assignment of tasks to agents with heterogeneous computational abilities and wages.

Note, however, that the computational delay could be due either (i) to human delays in reading, understanding, and interpreting information or (ii) to human delays in calculating with

9. See Zomaya (1996) for an overview of the parallel random access machine and other models of parallel computation. Our model is also a special case of the one in Mount and Reiter (1990). Their formalization deals with certain technical issues related to real-number computation and to the measurement of communication costs, which our model suppresses.

information they have already “loaded” into their brains. (In a model with “reading delays,” there would be an implicit communication cost: the managerial wages for the time it takes agents to read messages.)

Communication costs are important for two themes in much of the economics literature on decentralized batch processing:

1. Decentralizing information processing entails a trade-off between delay and communication costs. As more administrators share the operations and hence more operations are performed concurrently, delay is decreased but communication costs increase.
2. The pattern of communication among individual administrators, which has been interpreted as an organization’s structure, also affects costs. Without communication costs, this microcommunication is indeterminate; when all agents have equal access to all information at all times, the identities of the agents who perform the operations each cycle are not relevant to the performance of the procedure. However, Van Zandt (2003a) contends that organizational structure should be derived from the macrostructure of decisionmaking more than from the microstructure of message exchange among individual agents.

6.3. Decentralization and Delay

This section describes two batch-processing procedures and illustrates how decentralization reduces delay. In the first procedure, a single agent (the “entrepreneur”) calculates the resource allocation. The $2n$ operations listed in Table 1 must be performed sequentially by this agent, so the delay is $2n$.

Compare this procedure with decentralized information processing, in which potentially many agents compute the resource allocation jointly. In the first stage, $u_R := u_1 \oplus \cdots \oplus u_n$ is calculated. The efficient algorithms for associative computation with a parallel random access machine are illustrated in Figure 4. In the first cycle, the payoff functions are divided into pairs, and each pair is assigned to a different agent, who calculates the aggregate of the two payoff functions. In each subsequent cycle, the aggregate payoff functions computed in the previous cycle are grouped into pairs, and again each pair is assigned to an agent who calculates the aggregate. The number of partial results is reduced by half in each cycle, so there is a single pair in cycle $\lceil \log_2 n \rceil$, whose aggregate is u_R . (The brackets $\lceil \cdot \rceil$ denote the ceiling or round-up operation.) Hence, the delay is $\lceil \log_2 n \rceil$ rather than the $n - 1$ cycles it takes a single agent to compute u_R . However, the computation of u_R still requires $n - 1$ operations.

The next step is to compute $p_R := f_2(u_R, x_R)$, which one agent does in one cycle. Finally, the n operations $\{x_i := f_3(u_i, p_R)\}_{i=1}^n$ can be assigned to n different agents and executed concurrently in one cycle. As summarized in Table 1, the total delay when the computation is decentralized is $2 + \lceil \log_2 n \rceil$, compared to $2n$ when a single agent calculates the allocations. This reduction in the delay is the benefit of decentralization.

The only administrative (computational) costs in this model are the wages of the agents. These are proportional to the total number of operations, which is $2n$ whether the computation is performed by one agent or many. Hence, there is no administrative overhead incurred by decentralization. This is because we assume that there are no communication costs and that agents are paid only for the operations they perform. Under different assumptions, such as in Radner (1993), increasing the number of agents who jointly calculate f reduces the delay but increases the administrative costs.

Figure 4. Associative computation by a parallel random access machine.

How does this batch-processing model relate to Figure 3? The aggregation of payoff functions in Figure 3 is similar to the decentralized aggregation of payoff functions in our batch-processing model. However, the disaggregation of resource allocations in Figure 3 has no analogue.

Consider first the aggregation of payoff functions. If we treat each interior node in Figure 3 as an information-processing agent in our computational model, then it takes an agent $j \in J$ who has s_j immediate subordinates a total of $s_j - 1$ cycles to compute her aggregate payoff function. Agents b , c , and d can start this calculation at the same time; they finish after two, one, and two cycles, respectively. Then agent a computes $u_a := u_b \oplus u_c$ in the third cycle, and agent R computes $u_R := u_a \oplus u_d$ in the fourth cycle. The total delay of 4 is less than the delay of 7 for a single agent. This result is similar to the parallel computation of u_R that is shown in Figure 4. (Although the nodes in Figure 4 are operations, it is possible to assign each operation to a different agent, in which case the nodes in Figure 4 correspond to agents.)

In contrast, there is no analogue in this batch-processing model to the hierarchical disaggregation of resource allocations. In the computational procedure described in this section and shown in Table 1, resources are allocated to all shops in a single step, once the shadow price p_R is calculated. Suppose instead that, as in Figure 3, there is a recursive disaggregation of resource allocations. Starting with the root, each agent j receives the allocation x_j for its division, calculates its shadow price $p_j := u'_j(x_j)$, and then allocates resources to each subordinate $k \in \Theta_j$ by setting x_k so that $u'_k(x_k) = p_j$. With such a procedure, the shadow price is the same at every node, and the only useful operations are the calculation of the overall shadow price $p_R := u'_R(x_R)$ and of the individual shops' allocations $x_i := u_i'^{-1}(p_R)$. The calculations of intermediate shadow prices and allocations increases not only the number of operations (by twice the number of intermediate nodes) but also the delay (by twice the number of intermediate tiers).

7. Real-Time Decentralized Information Processing

7.1. Measuring the Cost of Delay

For the moment, ignore the question of why resource allocations might be disaggregated hierarchically. Instead, motivate the next step by supposing that we have a batch-processing model with

communication costs and that we have derived the set of efficient procedures, in which there is a trade-off between delay and administrative cost (as is done, e.g., in Radner 1993; Van Zandt 1998). To determine which procedures are optimal or to study how information-processing constraints affect economies of scale, we need to measure the administrative cost and the cost of delay. Administrative cost is easy to measure—for example, by managerial wages. Delay, however, is not an input that we can buy at a constant unit price. Instead, it has a decision-theoretic cost—higher delay means that decisions are based on older information.

To quantify the cost of delay, we need a temporal decision problem in which current decisions are computed from lagged information. A decision procedure is then a decision rule together with a computational procedure for computing the decision rule. The computation of the decision rule must adapt to the timing of the arrival of information and that of the decision epochs. This problem is one of real-time or on-line control.

We obtain a simple temporal version of the resource allocation problem in (11) by assuming there are discrete time periods $t \in \{\dots, -1, 0, 1, \dots\}$ and that, at the beginning of each period t , new payoff functions $\{u_{1t}, \dots, u_{nt}\}$ are realized and observed and a deterministic quantity x_{Rt} of the resource must be allocated. That is, the payoff in period t when the allocation of x_{Rt} is $\{x_{1t}, \dots, x_{nt}\}$ equals $\sum_{i=1}^n u_{it}(x_{it})$. We are assuming that the resource constraint must be satisfied each period; hence, there is no intertemporal allocation of resources. However, the informational structure is dynamic, because allocations are computed from past observations of the payoff functions.

We can use the same computational model as in Section 6 for the computation of the decision rules, but we need to specify the relationship between a cycle (the unit of time in the computation model) and a period (the unit of time in the decision problem). We assume that a cycle and a period are the same; this assumption simplifies notation but is not important for the qualitative results.

We measure the net performance in each period by the expected payoff of the decision rule minus the administrative cost of the computational procedure, and we call it the “profit.” To determine the expected payoff of a decision rule, we need assumptions about the stochastic process $\{u_{1t}, \dots, u_{nt}\}_{t=-\infty}^{\infty}$. However, for the purpose of this section—which is to derive a qualitative rather than quantitative value of decentralized decisionmaking—the reader should simply imagine that we have imposed statistical assumptions such that decision rules that use old information tend to have a lower expected payoff than those that use recent information.

In this real-time setting, the following stationary procedures resemble batch processing and compute the allocation for each period from data of homogeneous lags. The resource allocation for each period t is calculated, in the manner described in Section 6, from the payoff functions $\{u_{1,t-d}, \dots, u_{n,t-d}\}$ collected in period $t-d$.¹⁰ The lag d is the delay in performing these computations, which is given in Table 1. With serial processing (one agent), the allocation in each period is calculated from the payoff functions from $2n$ periods ago, whereas with decentralized computation, each allocation is calculated from the payoff functions from $2 + \lceil \log_2 n \rceil$

10. With specific statistical assumptions, as in Van Zandt (2003a), we could allow the decision rule to take into account the expected change in the payoff functions between periods $t-d$ and period t .

Because the shadow price is calculated from $\{u_{i,t-d}\}_{i=1}^n$, the final step in which the marginal payoff is set equal to the shadow price must use these same payoff functions (rather than more recent ones) to balance the allocation.

Figure 5. A two-tier centralized hierarchy.

periods ago. Such decentralization leads to lower delay and hence more recent information and a higher payoff.

We consider this decision procedure to be a two-tier hierarchy, as shown for $n = 9$ in Figure 5. The single administrative node, which is the root node R or center, is an office in which reside the agents who compute the decision rule. Each period, this office collects the current payoff functions from the shops and sends the current allocation to the shops. In period t , the organization is busy computing the allocations for periods $t + 1, \dots, t + d$. Although these computations overlap temporally, they are independent and do not use common data. As in Section 6.3, there is decentralized information processing in the central office, because the procedure is computed in parallel, but decisionmaking is not decentralized, because, in each period, all the shops' allocations are computed from the same data. In particular, there is no hierarchical disaggregation of resource allocations.

7.2. A Procedure with Decentralized Decisionmaking

In this real-time model, we are not restricted to procedures, such as those of Section 7.1, in which each period's decisions are calculated from data of the same lag. We now specify a procedure without this property.

We first present the hierarchical structure that we ascribe to the procedure. Assume there are integers $s_1, s_2 \geq 2$ such that $n = s_1 s_2$. Consider a balanced three-tier hierarchy in which the span of an office in tier $h \in \{1, 2\}$ is s_h . Thus, the root (in tier 2) has s_2 immediate subordinates, which are offices in tier 1, and each of these offices has s_1 immediate subordinates, which are shops in tier 0. There are thus $s_1 s_2 = n$ shops. Such a hierarchy is shown in Figure 6 for $n = 9$ and $s_1 = s_2 = 3$.

In this decision procedure, each office calculates resource allocations in much the same way as the center does in the procedure defined in Section 7.1. However, an office in tier 1 uses as its quantity of resources an amount that is sent by the center. The center uses as its payoff information the aggregate payoff functions calculated by the tier-1 offices. These aggregate payoff functions are also used by the tier-1 offices to determine the suballocations of resources to their subordinate shops.

Figure 6. Information flow at the beginning of period t in a three-tier hierarchy.

Disregard the root of this hierarchy and imagine that we have simply divided the organization into s_2 independent units, which we call “divisions,” even though they are independent. Each division contains s_1 shops. Because these divisions operate independently and resource allocations to the divisions are not coordinated, each division allocates a fixed fraction of the total resources. For example, if the allocations represent net trades, then the total amount of the resources available to the whole organization and to each division is 0. Denote division j ’s available resources in period t by x_{jt} .

Each of these divisions allocates resources using a two-tier hierarchy as described in Section 7.1, but with s_1 shops rather than n shops. These calculations are shown in the left column of Table 2. The delay is denoted by d_1 and is equal to $2 + \lceil \log_2 s_1 \rceil$. The aggregate payoff function and shadow price calculated by division j for the purpose of allocating resources in period t are denoted by $\hat{u}_{jt}$ and p_{jt} and are equal to $\bigoplus_{i \in \theta_j} u_{i,t-d_1}$ and $\hat{u}'_{jt}(x_{jt})$, respectively.

These divisions and their decision procedures correspond to the three subtrees under the center in Figure 6. The advantage of splitting the organization this way is that the delay $2 + \lceil \log_2 s_1 \rceil$ of each division is smaller than the delay $2 + \lceil \log_2 n \rceil$ of the unified two-tier organization in Section 7.1. However, gains from trade (coordination) among the divisions are lost.

To exploit some of these gains from trade, we add the central office, shown as the root node R in Figure 6. The center also uses a decision procedure like the two-tier procedure described in Section 7.1, but the center’s immediate subordinates are the division offices instead of the shops. The data that the center uses are the aggregate payoff functions $\{\hat{u}_{jt}\}_{j \in \Theta_R}$ of the divisions, which are partial results of the divisions’ decision procedures. The center’s delay is $d_2 \equiv 2 + \lceil \log_2 s_2 \rceil$. Its calculations are shown in the right column of Table 2.

Table 2. Calculations by the divisions and the center in the three-tier hierarchy

	Division j	Center
Begin, . . . , end	$t - d_1, \dots, t - 1$	$t - 2 - d_2, \dots, t - 3$
Delay	$d_1 = 2 + \lceil \log_2 s_1 \rceil$	$d_2 = 2 + \lceil \log_2 s_2 \rceil$
Data	$\{u_{i,t-d_1}\}_{i \in \theta_j}, x_{jt}$	$\{\hat{u}_{j,t-d_2}\}_{j \in \Theta_R}, x_{Rt}$
Aggregation	$\hat{u}_{jt} := \bigoplus_{i \in \theta_j} u_{i,t-d_1}$	$\hat{u}_{Rt} := \bigoplus_{j \in \Theta_R} \hat{u}_{j,t-d_2}$
Shadow price	$p_{jt} := \hat{u}'_{jt}(x_{jt})$	$p_{Rt} := \hat{u}'_{Rt}(x_{Rt})$
Allocation	$x_{it} := u'^{-1}_{i,t-d_1}(p_{jt})$	$x_{jt} := \hat{u}'^{-1}_{j,t-d_2}(p_{Rt})$

Note: $\lceil \cdot \rceil$ denotes the round-up operation.

As information is recursively aggregated and passed up the hierarchy, it becomes older. As one might guess, the cumulative lag of the raw data that goes into the center's decisions equals $d_1 + d_2$.

For example, toward the end of August a division office finishes aggregating information about its immediate subordinates' resource needs and sends this information to its immediate superior. At the same time, it receives a budget for September, which in the next few days it disaggregates in order to assign a September budget to each of its subordinates. The center calculated the division's September budget using information sent by that division and the other divisions at the end of July, but the division office disaggregates the budget using more recent information, which it aggregated during August.

7.3. The Benefits and Costs of Decentralized Decisionmaking

In Section 7.2, we presented the three-tier hierarchy as a comparison of (i) independent two-tier hierarchies, between which there is no coordination, and (ii) a three-tier hierarchy, in which these two-tier hierarchies are coordinated by a central office. Now we compare (iii) a two-tier hierarchy that has no hierarchical disaggregation and (iv) a three-tier hierarchy with the same number of shops. That is, we compare Figures 5 and 6. To simplify this comparison, assume that s_1, s_2 , and n are powers of two, so that the round-up operations in the formulas or the delay in the previous sections can be ignored.

It may appear that one difference between the two- and three-tier hierarchies is that, in the latter, the aggregation of payoff functions is hierarchically decomposed and hence more decentralized. However, remember that each node in these hierarchies is an office containing multiple information-processing agents, and the aggregation of payoff functions is always maximally decentralized in each node. Thus, the hierarchical decomposition of the aggregation of payoff functions, which is explicit in Figure 6, also exists in the center in Figure 5. In particular, observe that in a three-tier hierarchy, the center finishes calculating in period $t - 4$ the aggregate payoff function $\hat{u}_{Rt}$ that it uses to allocate resources for period t . Furthermore, $\hat{u}_{Rt} = \bigoplus_{i=1}^n u_{i,t-d_1-d_2}$. Hence, the aggregate payoff function is calculated in

$$d_1 + d_2 - 4 = (2 + \log_2 s_1) + (2 + \log_2 s_2) - 4 = \log_2 n$$

periods in the three-tier hierarchy. This delay is exactly the same as that in the two-tier hierarchy.

The actual difference between the two- and three-tier hierarchies is the disaggregation of resource allocations. The center in a three-tier hierarchy, after calculating its aggregate payoff function $\hat{u}_{Rt}$ and then its shadow price p_{Rt} , does not allocate resources directly to the shops in one step. Instead, it calculates allocations for the divisions, whose offices then calculate suballocations for the shops. We interpret this procedure as decentralized decisionmaking. Its advantage may be summarized as follows.

When a division receives x_{jt} from the center in period $t - 2$, it does not have to allocate x_{jt} using the information $\hat{u}_{j,t-d_2}$ that the center used to compute x_{jt} . Instead, it uses its most recently calculated aggregate payoff function $\hat{u}_{jt}$. That is, the data used to allocate resources in each division in a three-tier hierarchy are $2 + \log_2 s_1$ periods old, and hence $\log_2 n - \log_2 s_1 = \log_2 s_2$ periods more recent than the data used to compute allocations in the two-tier hierarchy.

The intermediate disaggregation of resource allocations adds two extra steps: the calculations of the divisions' allocations and the divisions' shadow prices. This leads to two disadvantages of the three-tier hierarchy compared to the two-tier hierarchy:

1. In the three-tier hierarchy, gains from trade among shops in different divisions are exploited by the center. The cumulative lag of the center's data that it uses to allocate resources is

$$d_1 + d_2 = (2 + \log_2 s_1) + (2 + \log_2 s_2) = 4 + \log_2 n.$$

This delay is two periods greater than the center's lag in the two-tier hierarchy. The extra lag is a *decision-theoretic cost* of decentralized decisionmaking.

2. The three-tier hierarchy also has higher managerial costs. The center's calculations in the three-tier hierarchy involve $2s_2$ operations per period. Each division's calculations involve $2s_1$ operations per period. Hence, the total number of operations is $2s_2 + s_2(2s_1) = 2s_2 + 2n$. In contrast, the number of operations in the two-tier hierarchy is only $2n$. The wages paid for the $2s_2$ additional operations in the three-tier hierarchy are a *managerial cost* of decentralized decisionmaking.

The benefits and costs are summarized in Table 3.

We have now described real-time decision procedures that correspond to two- and three-tier hierarchies that are balanced (each node in the same tier has the same number of subordinates). Van Zandt (2003a) generalizes the real-time procedures to arbitrary hierarchies. Increased decentralization of decisionmaking corresponds to additional intermediate tiers. The benefits and costs of three- versus two-tier hierarchies arise again as additional tiers are added.

7.4. Optimal Hierarchies and Economies of Scale

To go beyond this qualitative treatment of the benefits and costs of decentralization, we need to make concrete assumptions about the functional forms and shocks affecting payoffs. Van Zandt (2003a,b) develops a model with quadratic costs. Although the possibility of decentralizing

Table 3. The benefits and costs of decentralized decisionmaking (three-tier versus two-tier hierarchies)

Two-tier	delay	$2 + \log_2 n$
Three-tier	delay of each division	$2 + \log_2 s_1$
Difference	decrease in division's delay	$\log_2 s_2$
Two-tier	delay	$2 + \log_2 n$
Three-tier	center's cumulative delay	$(2 + \log_2 s_1) + (2 + \log_2 s_2)$
Difference	increase in center's delay	2
Two-tier	operations of center	$2n$
Three-tier	operations center and divisions	$2s_2 + s_2(2s_1)$
Difference	increase in operations	$2s_2$

decisionmaking in these hierarchical organizations allows for larger hierarchies, organization size is still bounded. This is because the combined effect of cumulative delay and administrative costs means that in large enough hierarchies, the value of the root office's information processing is less than the office's administrative costs.

Furthermore, as the environment changes more rapidly, optimal hierarchies become smaller and more internally decentralized. A speed-up of managerial processing, such as through improved information technology, has the opposite effect.

8. Equilibrium Assignment of Talent to Teams and Hierarchies

8.1. Introduction

We have studied hierarchies that exist in isolation—organizations devised optimally to process information, acquire knowledge, and monitor individuals. But hierarchies exist in the market. The assignment of individuals to positions and jobs in a hierarchy is the other side of the occupational distribution in the labor market. For example, changing skill quantities in the job market due to offshoring or immigration will affect equilibrium wages, the assignment of individuals to teams, and the hierarchical organization of firms. Thus, an understanding of hierarchy can help us arrive at a better understanding of the impact of technology on the labor markets, as it will allow us to introduce in the analysis the changes in the organization of firms that result from a new technology or from the impacts of offshoring, brain drains, or different skill training and selection mechanisms in different countries. In sum, although decisionmaking and how it is affected by hierarchy are the focus in most of this chapter, we now move to exploring how hierarchy helps us understand more macro- or market-level facts—notably, the distribution of earnings, the distribution of firm sizes, trade patterns, the relation between growth and talent allocation, and so forth.

Neoclassical models of production, which use a variant of the generic form $Y = f(K, H)$, where K is physical capital and H is human capital, do not take a stand on the organization of production. That is, what matters is the total amount of physical and human capital employed;

no attention is paid to decisionmaking, information flows, and the allocation of responsibility. The internal organization of the firm is meant to be a separate object of study. But in fact, labor market and firm organization are the two sides of the same coin. The link between the two is the scale of operations effect: the marginal value of a worker's ability is given by the amount of resources he manages, as we discuss below. More broadly, the productivity of each individual is determined by other individuals with whom he works in a team. Thus, a worker's position in a hierarchy determines his marginal value of ability, and as a result determines labor and goods market outcomes, such as wages and productivity. Knowing the aggregate value of the human capital employed does not tell us its productivity; we need to know how and with whom these units of human capital are used. The firm size distribution and the earnings and productivity patterns in industries are jointly determined by the same underlying mechanism—the equilibrium assignment of individuals to firms and hierarchical positions.

The first two accounts of the scale of operations are by Mayer (1960) and Simon (1976). Their aim is explaining the skewness in the distribution of income. Specifically, as Mayer put it, how does a normal distribution of ability generate such a skewed distribution of income? The answer he provided (verbally) is that it must be the result of a scale of operations effect, through which those with higher ability are assigned more resources. This scale effect affects, in turn, the marginal value of ability. For example, a better concert pianist has higher earnings not only because consumers are willing to pay more for better performances but also because she plays in larger halls (scale).¹¹ Similarly, a more able lawyer wins more cases, and is assigned the largest ones; finally, earnings of entrepreneurs are skewed, because only the more talented agents have a positive span, and the differences in ability are multiplied by that span.

Simon (1976) first develops a model of hierarchy with the purpose of explaining the salaries of CEOs. The stylized fact that motivated his quest was the finding that the elasticity of CEO pay to firm size was around 0.37. (The survey by Rosen (1992) on CEO pay finds it to be 0.25.) There is no assignment or equilibrium aspect in his mechanical model. However, it does suggest some of what may be underlying these regularities. Specifically, Simon assumes that the span of control s is exogenous and fixed at all levels and that the exogenous salary multiple between levels is $b > 1$. Then the size of an L -level firm, as measured by the number of employees, is given by $N = 1 + s + s^2 + \dots + s^{L-1} = (s^L - 1)/(s - 1) \simeq s^L/(s - 1)$. Similarly, the salary of the CEO is $w_{\text{CEO}} = w_0 b^{L-1} = w b^L$, where $w = w_0/b$. Letting the elasticity of compensation to size be $\varepsilon_{wN} = d \log w_{\text{CEO}}/d \log N$, simple computations imply that $\varepsilon_{wN} = \log b / \log s$. Empirically, ε_{wN} is about 0.35. For example, with $b = 2$ and $s = 7$, we have $\varepsilon_{wN} = 0.3572$; with $s = 5$, and $b = 1.75$, $\varepsilon_{wN} = 0.35$. Of course, these simple calculations produce more questions than they answer—most notably, where do b and s come from?¹²

11. The “superstar” model of Rosen (1981) provided a formal model and a complete analysis of this scale of resources effect in the market.

12. Some more recent work in the spirit of Simon (1976) on CEO pay, notably Gabaix and Landier (2008), estimates a matching model with exogenously given firm sizes to empirically characterize the size-pay elasticity and to study whether the change in firm sizes may have caused the explosion in CEO pay. To do this, they use extreme value theory to estimate the earnings function that is derived from CEO-firm matching process. This work falls outside of the scope of this survey, as the size and the internal organization of firms are exogenously given.

8.2. Distribution of Income and the Allocation of Talent

Papers by Lucas (1978), Rosen (1982), Waldman (1984), and Garicano and Rossi-Hansberg (2006) aim to provide microeconomically founded models of the assignment of agents to positions in a neoclassical world. Essentially, the starting point of all this literature is the observation that the economy wide problem of assigning resources to talent generates skewness through the scale of operations effects. We briefly discuss these papers in what follows; the discussion is necessarily somewhat superficial, and, as in our previous sections, the reader is directed to the primary sources for a full account.

Some of the questions that these papers aim to deal with are: What determines the matching of individuals with positions and teams? What determines the salaries associated with those positions? How do changes in labor markets interact with changes in the organization of teams and/or firms? Four observations motivate this literature: (i) the distribution of firms' size is skewed to the right and is remarkably stable; (ii) the distribution of earnings is also quite stable and skewed to the right; (iii) earnings of top executive officers are enormous in magnitude and positively correlated with firm size; (iv) earnings within firms are positively correlated with rank.

8.2.1. *Heterogeneous Managers of Homogeneous Workers*

The first formal treatment of firms in equilibrium is Lucas (1978). Lucas argues that the observed size distribution is a solution to the problem: allocate productive factors over managers of different ability so as to maximize output. He departs minimally from the neoclassical production model in that, essentially, a manager is required to run a firm formed by a set of undifferentiated workers and capital. A manager with skill α shifts up the production that can be obtained by combining that labor and capital. Lucas' aim is not so much to have a theory of organization as a theory of why organization matters.

We present here the simplest possible version of Lucas's model, one that is considerably simpler than his but captures its essence. The resource allocation problem is essentially to divide the workforce, formed by N agents, into managers and workers, and to allocate the factors of production (labor N and capital K) across managers. To simplify the exposition, we ignore capital K . Managerial ability q is distributed according to a distribution ϕ of talent, $\phi : R^+ \rightarrow [0, 1]$, with cumulative distribution function Φ . Ability is defined and measured by how much an agent can raise the output of a team: a manager who has ability q and is allocated n workers produces $y = qf(n)$. Larger teams produce more, $f' > 0$, but there are decreasing returns to managerial talent, $f'' < 0$, and this results in limits to firm scale.¹³ The firm's profits are then given by

$$\pi = qf(n) - wn, \quad (20)$$

where w is the wage of a worker. The first-order condition for the choice of firm size n is given by:

$$qf'(n) = w. \quad (21)$$

13. We apologize for changing the notation in the Lucas (1978) paper. We change it to ensure consistency with the notation of other papers we survey later. Also, Lucas's analysis focuses on the planners' problem, whereas our presentation focuses on the competitive equilibrium. There are no externalities or other factors, and the two formulations are equivalent, although the competitive one is simpler.

The solution of this first-order condition is a function $n(q)$, with $n'(q) > 0$ and possibly $n(q) = 0$, which describes the number of workers managed by agent q . The most skilled agents will choose to be entrepreneurs, because they benefit from their higher ability in two ways. First, for a given firm size n , they earn more. Second, the most skilled individuals hire a larger team $n(q)$ to leverage their ability or spread it over more agents. Note that the assumption $f'' < 0$ is key; if there are no decreasing returns to scale, the most able entrepreneur can manage all workers. Of course, the model is silent as to what leads to such congestion; the literature on hierarchies surveyed to this point addresses the source of these diseconomies.

Optimal occupational choice requires that an agent become an entrepreneur if

$$\pi = qf(n(q)) - wn(q) > w.$$

Thus, there exists a cutoff skill level q^* such that those with $q > q^*$ are entrepreneurs and the rest are workers. Finally, equilibrium requires that markets clear—that is, the supply and demand of workers must be equalized. The supply of workers is $\Phi(q^*)$, and the demand of workers by all available managers, $\int_{q^*}^{\infty} n(q)d\Phi(q)$. Thus we have

$$\Phi(q^*) = \int_{q^*}^{\infty} n(q)d\Phi(q). \quad (22)$$

Solving the model involves finding two constants, the cutoff level q^* and the equilibrium wage w . If, for example, the returns to scale shift up, then each entrepreneur wants to have a larger team, and $n(q)$ shifts up; equilibrium requires that both w and q^* move up. From the model we can obtain three interesting empirical distributions: of wages in the economy, of firm sizes, and of occupations.

Beyond the pathbreaking theoretical contribution that this simple model represents,¹⁴ Lucas (1978) derives some interesting results. There is obviously a scale of operations effect ($n' > 0$ in equilibrium, as smarter managers manage larger firms). Moreover, there is a close connection between talent distribution and firm size distribution; for example, if one is Pareto, the other one is also Pareto. Also, under some restrictions on the productivity of talent, the model is consistent with Gibrat's law. Finally, there is a tight relation between managerial rents (or earnings) and firm size. However, the model has some problems. First, the relation between size and earnings obtained from the model is linear in n , that is, $R(x) = Cn(x)$. However, empirically, managerial compensation varies with the log of the number of employees, leading to the conclusion that multiple layers are needed to fit the data. Moreover, workers are undifferentiated, when in fact we know that talent is heterogeneous and thus the matching of workers to managers matters. Finally, contrary to the spirit of the rest of this chapter, the managerial technology is a black box—What are managers actually doing in these firms? Why do they raise workers' productivity?

14. Because of its tractability, the model has been widely used in macroeconomics. For example, the literature relies on Lucas (1978) to back up productivity heterogeneity from firm size heterogeneity. See Hopenhayn and Rogerson (1993: 928) and Atkeson and Kehoe (2007: 73).

8.2.2. *Homogeneous Managers of Heterogeneous but Perfectly Substitutable Workers*

Rosen (1982) expands on the Lucas technology by introducing heterogeneous workers. He adds an extra stylized fact to be understood—the within-firm correlation between pay and rank. Rosen argues that the way to explain the skewness of the earnings distribution is to combine a recursive productive technology with an assignment model like that of Lucas. From Rosen's perspective, the critical factor in the production technology must be that management makes discrete, indivisible decisions (“a great soldier is useless if in the wrong war”) and thus, managerial talent filters down—a better decision benefits all workers. However, the technology must recognize that supervision involves scale diseconomies and congestion, which limit the scope of managerial ability and, eventually, firm size. The scale economies of management require that the most able people go to top positions in large firms. The diseconomies of supervision limit management effectiveness and allow the coexistence of many firms. Thus, the technology must capture three components: decisionmaking, supervision, and production. As we shall see, the model is essentially like the Lucas model, except that now workers are heterogeneous—it is not just the size of the team but the total efficiency units that matters. The model also has multiple numbers of layers. To capture this aspect, Rosen lets the output of one layer be intermediate output that is then aggregated by an upper level, so recursively, all layers actually have the same production function. Although this assumption is convenient, it again blackboxes what is going on at different levels.

To simplify the analysis, Rosen (1982) treats skill as one factor—all supervisory and worker skills are a linear transformation of the same underlying skill—and assumes the production function has constant returns to scale. As a result, output is simply a function of the efficiency units of labor (quality-adjusted quantity) controlled by managers; there is no matching, and who works with whom is not identified. Instead, the analysis determines the quality-adjusted span of control. Under these assumptions, the technology of Rosen in a two-layer world is a generalization of the Lucas technology:

$$\pi = q_m f(Q) - wQ, \quad (23)$$

where q_m is the ability of the manager, and Q is the efficiency units of labor managed by a manager with skill q_m . Everything proceeds as in Section 8.2.1, except that now workers with skills q_i earn wq_i . As a result, the wage schedule now increases in skill (it was flat in Lucas). The output of level-2 agents is an input to the level-3 agents, and thus, multiple layers can be built.

The occupational choice conditions are analogous to those of Lucas: $q_m f(Q(q_m)) - wQ(q_m) > wq_m$. The supply and demand are somewhat different: now we count efficiency units of labor, as one worker has q units. The market clearing condition becomes

$$\int_0^{q^*} q d\Phi(q) = \int_{q^*}^{\infty} Q(q) d\Phi(q) \quad (24)$$

(note the difference in the left-hand side, adding up over units of skill, rather than over agents). Some of the results in Lucas are again delivered here: more talented people command more resources as production and labor controlled rise more than proportionally with skills, and so does the reward for skill; earnings are skewed to the right, relative to the underlying skill distribution;

and the presence of multilevel firms tends to skew the distribution of rewards even more. In addition, whereas Lucas failed at matching the elasticity of pay to firm size, Rosen's model can match any constant empirical elasticity. Moreover, the microfoundation of the analysis is more extensive. What is missing from the analysis, however, is a full characterization of the equilibrium, as the multilayer firm problem is sketched but not solved. Further, the introduction of "intermediate-layer output" as the output of middle-layer managers is somewhat unsatisfactory. This is a black-box modeling device that obscures more than it clarifies.

Thus, as in Lucas (1978), only the quantity of resources, and not the quality of which they are composed, matters. But absent an element of imperfect substitutability between workers of different skill, these models do not allow for a full analysis of either the equilibrium assignment of individuals to one another or of earnings distributions. If skilled and unskilled workers are perfect substitutes, in equilibrium, then managers should be indifferent between working with a few relatively skilled workers or many unskilled workers. Assignment patterns between individual managers and workers would then be indeterminate. A more complete analysis of assignment patterns requires introducing production with imperfect substitutability. Kremer (1993) provides a building block for this improvement.¹⁵

8.2.3. Matching: Teams of Heterogeneous Workers

The starting point of Kremer's (1993) analysis is the observation that strong complementarities are common in production, as many production functions have a "weak link" aspect to them, so that output is given by the output of the least productive worker. For example, a space shuttle is as strong as the weakest of its O-rings. This type of production function can easily rationalize the common observation that (contrary to what happens in Rosen's (1982) hierarchy) even a large number of low-skill workers cannot substitute for one high-skill worker—100 bad lawyers are not better in dealing with a divorce filing than 1 excellent lawyer. There is no consideration of managerial skill, however, in this model, as all the matching takes place (as in Becker's 1973 marriage model) between similarly placed agents.

Production in Kremer's (1993) model requires n tasks, all of which must be correctly performed. Each worker's talent q_i determines the probability of success on her task; workers are further combined with k units of capital; productivity is B units of output per worker. The firm's problem is then

$$\max_{k, q_i} k^a n B \prod_{i=1}^n q_i - \sum_{i=1}^n w(q_i) - rk,$$

where $a \in (0, 1)$.

Clearly, positive sorting holds in equilibrium, as $\frac{d^2 y}{dq_i dq_j} > 0$, where y is output as given by the profit function. Firms with high-ability workers at the first $n - 1$ positions choose able

15. In the more general model of Waldman (1984), no restrictions on the interaction between managers' and workers' skills are imposed, but that only allows him to characterize the correlation between ability levels and hierarchical position and the skew of the wage distribution to the right with respect to the ability distribution. The specific model he analyzes rules out complementarities between worker and manager skills and as a result has equilibria where workers are more skilled than managers.

workers for the last one. When workers of the same skill are matched together, the first-order conditions are

$$\frac{dw}{dq} = q^{n-1} n B k^a,$$

$$a k^{a-1} q^n n B - r = 0.$$

Substituting the second equation into the first gives a differential equation in w' , which can be solved to obtain the wage schedule, $w(a) = (1 - a)q^n B k^a + c$. It is clear that $nw(q) = (1 - a)Y + nc$; because capital reward is aY , zero profits implies $c = 0$. This is an equilibrium: firms are indifferent to hiring workers of different skills as long as the labor force in each firm is homogeneous.

Thus, when tasks are symmetric and complementary, an extreme form of segregation emerges in equilibrium, where individuals work only with others like themselves. This mechanism rationalizes large productivity differentials between rich and poor, as complementarities expand on the initial ability differentials across countries, regions, or firms. Moreover, different firms occupy different rungs in the quality of talent distribution; there is thus a positive correlation between wages of workers within firms (which is indeed observed empirically). Also, better quality workers must be used at later stages of production, where the impact of mistakes is larger. Finally, teams with more skill must be engaged in more complicated production processes, because a mistake is more likely in them.

8.2.4. *Hierarchical Teams of Heterogeneous Workers*

A further step in integrating the theory of hierarchy into an analysis of labor markets involves having workers who are not perfect substitutes for one another, so that matching is necessary, as in Kremer (1993). This refinement involves pinning down the specific talent of the specific worker who occupies a particular job and matches with one specific manager.

Kremer and Maskin (1996) first present a framework with matching and allocation of agents to different positions. However, there is no mechanism through which managers can exploit scale effects associated with their human capital: by definition, one agent is in the more productive position and one in the less productive one, so production is not hierarchical.

Imperfect substitutability is natural in a context like the problem-solving knowledge-based hierarchy in Garicano (2000). A hard problem can only be solved (or a hard decision taken) by a highly knowledgeable agent. Having multiple less-knowledgeable agents does not help, in the same way that several good high school students cannot deal with a hard topology problem if none of them has learned topology. Garicano and Rossi-Hansberg (2004, 2006) embed the model of knowledge-based hierarchies in Garicano (2000) in a context where workers are heterogeneous. In this model, workers are involved in production and managers in problem solving. From the result in Section 3, we can easily obtain the following elements of this production function. First, individuals of different skills are not perfect substitutes for one another; unlike in Rosen (1982), this extends to individuals acting as workers as well as managers. Second, managers' and workers' skills are complementary. Third, output is asymmetrically sensitive to managerial and worker skill; the asymmetric sensitivity follows naturally from the fact that

teams are formed by workers and a manager, whose skill increases the productivity of all workers to which this skill is applied.

The model in Garicano and Rossi-Hansberg (2006) has multiple levels and endogenous knowledge. We present here a simpler version with only two layers and exogenous knowledge or skill, following Garicano and Rossi-Hansberg (2004), and discuss later the broader model's implications. This simpler version amounts to specializing the production technology in Section 3 to a case with heterogeneous, but given, z , but limiting the analysis to a two-layer set-up. We label this exogenous skill or knowledge q to make it consistent with the rest of the section.

Suppose for now that organizations can only have one or two layers, so that agents can choose either to work on their own or with other agents. Teams are formed by managers, who specialize in problem solving, and production workers, who know only the routine tasks and specialize in production. Hence, a team of $n + 1$ agents, where n of them are production workers with knowledge q_p , has n units of production time. We normalize q so that skill is indexed by the percentile in the distribution of agents; that is, the population q is distributed according to a uniform distribution in $[0, 1]$.¹⁶ The task distribution is $F[q]$, so that an agent with skill q can solve a fraction $F(q)$ of the problems that come up in the course of production.

The output produced by a team is then simply $F(q_m)n$, where q_m is the knowledge or skill of its manager. This is subject to the time constraint of the manager: the manager spends a fraction of time h communicating with each worker in his team when she cannot perform a task, which happens with probability $1 - F(q_p)$. The time constraint of managers is then given by $hn(1 - F(q_p)) = 1$. Thus, the span of the manager is limited by the knowledge of production workers; if production workers are more knowledgeable, they will need help less often, and managers will be able to supervise larger teams.¹⁷

A manager with skill q_m maximizes his earnings $\pi = F(q_m)n - w(q_p)n$ subject to his time $hn(1 - F(q_p)) = 1$. Substituting in the constraint yields

$$\pi = \frac{F(q_m) - w(q_p)}{(1 - F(q_p))h}. \quad (25)$$

Solving for an equilibrium in this economy is a continuous assignment problem (Sattinger 1993) with two twists relative to standard assignment problems. First, who is assigned to whom is not a given but is an equilibrium outcome. In standard assignment models, this identity of the agents is assumed. In contrast, here we are matching a mass of workers with a mass of managers—where those roles and masses are not given by assumption. Second, agents can decide not to be matched and produce on their own; their output is $F(q)$ in this case.

16. This normalization is not in the original Garicano and Rossi-Hansberg (2004), as they were not aware that the model could be simplified in this manner.

17. Note that there are no decreasing returns to scale directly in this production function, but only through the congestion in the time constraint of the manager. We thus have a trade-off between congestion and skill: a manager can increase team size if he so desires, but he needs to hire more skilled workers to do so. Thus, matching matters: having more agents does not, in fact, help to increase production, because they need extensive supervision. The only way to increase output is to hire more skilled agents who need less help.

Optimality requires positive sorting; that is, workers with more knowledge must be assigned to managers with more knowledge. Formally, $y = F(q_m)n = F(q_m)/((1 - F(q_p))h)$, and $\partial^2 y / \partial q_m \partial q_p > 0$. A more knowledgeable manager must spread his higher knowledge over a larger number of workers, and that requires workers to be more knowledgeable, so that they can deal with more problems on their own.

To characterize the equilibrium in this economy, we need to describe three objects: the allocation of agents to occupations (i.e., production workers, specialized problem solvers, and self-employed), the team composition (i.e., the matching between workers and managers, and the optimal spans of control of managers), and the earnings function.¹⁸

The slope of wage equation must be such that the first-order condition holds:

$$w'(q_p) = \frac{f(q_p)(F(q_m) - w(q_p))}{(1 - F(q_p))h}, \quad \text{for all } q_p \leq q^*. \quad (26)$$

This equation, as in Kremer's (1993) O-ring production function, results in a wage function $w(q)$ that uniquely determines the wage of each individual q for a given match q_p, q_m .

The wage slope for those agents who do not join in a hierarchy (independents) is given by $w'_I(q) = f(q)$, and it is clear that $w'(q_p) < w'_I(q_p)$ for all workers (because for agents who are workers, $w(q_p) < F(q_p)$, and $(F(q_m) - F(q_p))/(1 - F(q_p)) < 1$). Using the Envelope Theorem, we have that the earnings function of managers is

$$\pi'(q_m) = \frac{f(q_m)}{(1 - F(q_p))h} > f(q_m) = w'_I(q_m).$$

For optimal occupational choice, it is necessary that for a marginal worker $w(q^*) = F(q^*)$ and for a marginal manager $\pi(q) = F(q)$. An equilibrium will be characterized by a pair of thresholds (q^*, q^{**}) , such that all agents with skill $q < q^*$ become production workers, all agents with skill above q^{**} become managers, and those in between are self-employed.

Consider now the market clearing condition. Again, it is significant that worker-manager matching takes place in equilibrium. Instead of summing over all workers and managers, we need pointwise equalization of supply and demand:

$$\int_0^{q_p} d\Phi(q) = \int_{q^{**}}^{m(q_p)} n(m(q))d\Phi(q), \quad q_p \leq q^*, \quad (27)$$

where $m(q_p)$ denotes the skill of the manager assigned to workers with skill q_p . Because (27) holds for all $q_p \leq q^*$, $n = 1/((1 - F(q_p))h)$ and $\Phi(q) = q$ by normalization, we can differentiate with respect to q_p to obtain $m'(q_p) = h(1 - F(q_p))$. This result, together with $m(0) = q^{**}$ and $m(q^*) = 1$, determines the equilibrium assignment function $m(q)$.

18. Two of these objects, occupational choice and optimization, are as in Lucas (1978) and Rosen (1982), but the matching and wage functions are now pinned down in the equilibrium.

The model provides all the implications in Lucas (1978) and Rosen (1982), and some more. Among the common ones are the correspondence between firm size distribution and wage distribution and the fact that managerial wages grow faster than ability thanks to the scale effects (although workers' wages grow more slowly). Among the new results are that, the model pins down, for the first time, the occupational distribution in the economy: the less-skilled agents are workers, the medium-skilled agents are independent or self-employed, and the most-skilled agents are managers or problem solvers. Moreover, the team composition is specific. It is not merely that more skilled managers have more subordinates; those subordinates are also of better quality. Finally, the model's microfoundation in a hierarchical production function allows for comparative statics with respect to information costs. Specifically, as shown in Garicano and Rossi-Hansberg (2004), better communication costs increase firm size, wage inequality, and the share of workers and managers in an economy where the three types of agents coexist.

8.3. Economywide Applications

We discuss the implications of these models for broader economic issues, such as the impact of outsourcing, information technology, or rent seeking for the structure of wages, firms, and occupations in the economy. The discussion is necessarily brief, but with it we hope to illustrate a key point of this chapter and of the entire handbook: a better understanding of the "inside the firm" economics improves our understanding of broader economic questions.

8.3.1. *Information Technology and Wage Inequality*

Garicano and Rossi-Hansberg (2006) analyze the implications of information and communication technology for occupational distribution, firm size distribution, and wage distribution. Their framework is similar to the one discussed in Section 8.2 except that it allows for both acquisition and communication of information and also for multiple layers. They find that better information access and better communication technology have different implications for wage inequality and occupational distributions. Improvements in communication technology lead teams to rely more on problem solvers. As a result, wage inequality among workers decreases, but wage inequality among top managers and between managers and workers increases. Organizations also change as spans of control and the number of layers increase. Conversely, reductions in the cost of accessing information increase the number of problems solved by agents in all layers. This increases the marginal productivity of talent at all levels, and thus wage inequality in any particular occupation; it also reduces the number of layers in firms but also increases spans. They find empirical support for this hypothesis in the covariation of the patterns of information and communication technology over the past 30 years (first information technology and then communication technology advanced) and the patterns of wage inequality (first growing within worker classes and then between).

8.3.2. *Trade and Offshoring*

Grossman and Maggi (2000) study how different talent distributions in different countries affect patterns of international specialization and trade. They show that countries with more homogeneous talent distributions specialize in O-ring style production functions (i.e., activities with strong complementarities and for which all talents matter), and countries with more

heterogeneous talent distributions specialize in the Lucas (1978) type of production functions (“superstar” functions, where only the talent of those most talented matters). They use this insight to rationalize the U.S. and Japanese specialization and trade patterns.

Antràs et al. (2006) apply a production function similar to the one in Garicano and Rossi-Hansberg (2004) discussed above to study the impact of the appearance of international production teams (offshoring) on wages and occupations. They show that the matches of all workers in the South improve when teams can be formed by production workers and problem solvers from different countries, while only the matches of the best workers in the North improve. As a result, wage inequality among workers increases in the South. In the North, overall wage inequality also increases when communication technology is sufficiently cheap and managerial skill is, as a result, particularly scarce (so that economizing on managerial skill through the use of talent is particularly important).

8.3.3. Growth

Murphy et al. (1991) present a dynamic version of the Lucas model (1978) to analyze the allocation of talent and its consequences for growth. There is a sector that works just like the Lucas sector, where entrepreneurs can leverage their abilities. The key departure from Lucas is that the technology in the next period increases with increasing ability of the entrepreneur allocated to the sector in the previous period—that is, growth depends on the talent allocated to each sector. There is an alternative sector that is pure rent seeking—its members earn a share of what rent seekers earn. Rent seeking leads to three distortions: it absorbs labor; it causes less-able entrepreneurs to become workers; and it causes the most-able entrepreneurs to become rent seekers. They show that a reduction in the share of profit extracted by rent seekers leads not only to higher levels of output (as fewer agents rent seek) but also to higher growth rates, as the talent of the most talented entrepreneurs increases.¹⁹

9. Conclusion

In this chapter, we have surveyed a literature that makes substantive progress toward explaining some empirical regularities of first-order importance: hierarchies are a crucial way to organize the division of labor in all organizations and present quite similar features across functions, sectors, and countries. We have argued that these striking regularities have to do with the large advantages that, given boundedly rational agents, hierarchies provide due to parallel information processing and aggregation and management by exception. Hierarchies allow managers to process and integrate very large amounts of information and knowledge in undertaking production tasks, and to coordinate large numbers of agents. As we have shown in this chapter, this is true *even if agents are angels* and have the best interests of the organization in mind, simply because hierarchies can bring to bear more knowledge and information on the production problems than any single manager can.

To focus on these bounded rationality issues, this chapter has abstracted from the monitoring and incentive functions of hierarchy. Mookherjee (this volume) takes the complementary view and studies managers as supervisors when agents’ incentives are misaligned.

19. Garicano and Rossi-Hansberg (2012) also present a growth model, but it is more in the spirit of the models discussed in Section 3, as it has no a priori talent heterogeneity.

Clearly, both literatures are incomplete and focus only on half of the problem. Agents are boundedly rational, yes, but they also have different preferences and interests than the principal. As a result, hierarchies do facilitate the division of knowledge, process information, and ensure the smooth disaggregation of decisions, but they also serve to ensure the enforcement of rules of behavior by large groups of individuals. The literature to this point has failed to study how these two roles of hierarchy interact and what the implications of solving coordination and motivation problems together are for organizations. This is probably one of the most promising and exciting areas for future research in the economics of organizations.

Internal Capital Markets

Robert Gertner and David Scharfstein

1. Introduction

Resource allocation is at the core of economics. Economists mostly concern themselves with resource allocation across organizational boundaries mediated through contracts or markets. Yet a great deal of resource allocation occurs within organizations. Businesses allocate capital and other scarce resources across and within business units, including production capacity, R&D capabilities, physical inputs, and human capital.

The most extensive research on internal resource allocation is by financial economists. These studies largely focus on the differences between internal and external capital allocation. Indeed, the insight that the key feature of conglomerates is the replacement of external capital markets with internal capital allocation has led to a large literature, including theoretical work that predicts differences in investment behavior between conglomerate and single-business firms and empirical work that tests these theories. The empirical work on internal capital markets is arguably the most fully developed body of empirical work in organizational economics, and it is the focus of our chapter.

In Section 2 we present an example to motivate the importance of studying internal capital markets. We then proceed to a richer discussion of the institutional literature on internal capital allocation in Section 3. We follow with a detailed survey of the theoretical and empirical literature on internal capital markets (Sections 4–6). This review includes the early empirical work in the area, as well as more granular studies of particular industries, relationships among managers, and the functioning of business groups. We conclude the chapter by discussing models of the capital allocation process, including capital budgeting rules, the shape of hierarchies, and communication (Section 7).

Despite our focus on internal capital allocation, it is important to keep in mind that firms allocate more than just capital. Firms allocate workers who have specialized firm-specific know-how and cannot be easily replaced with outside hires. Price does not appear to be the principal means by which firms allocate workers to jobs. Goods and services are also allocated in firms.

Vertically integrated firms differ greatly in the mechanisms used. For example, upstream divisions may sell exclusively to internal downstream divisions, or they may also sell outside the firm. Downstream divisions may be required to purchase exclusively from the upstream division or may be able to purchase externally.¹ In the most complete study of transfer pricing practices, Eccles (1985) demonstrates the links among transfer pricing practices, performance measurement, organizational structure, and strategic planning processes. This area is ripe for future research.

2. An Example

We begin with an example of a start-up biotechnology firm whose sole asset is a drug compound, SF-920, discovered by its founder-scientist. The firm is ready to begin early stage clinical trials but has little financial or physical capital, few employees other than the founder-scientist, and no contracts for the provision of goods or services. The firm needs to raise financial capital to fund the clinical trials, hire additional employees, and enter into contracts for goods or services. The difficulty of raising capital to fund investment is the subject of much theoretical work in finance. This literature has focused on the problems arising from asymmetric information and agency, and the contractual and governance responses to these problems.²

The founder may know more than outside investors about the likelihood that SF-920 will succeed in clinical trials. There are a number of market responses to this asymmetric information problem. First, the firm will likely raise capital from a relatively more informed capital supplier, most likely a venture capitalist or “angel” investor with special knowledge of the biotech industry. Second, the firm will not raise all the capital it needs to bring a drug from early stage clinical trials to FDA approval. Doing so would send a signal to investors that the founder was not confident that the drug would pass early stage clinical trials.

The founder’s objectives may also differ from those of outside investors, giving rise to agency problems. For example, the founder may derive nonpecuniary benefits from having a drug approved, or the founder may be overly optimistic about the likelihood the drug will succeed. As a result, the founder may be reluctant to abandon development, even when value maximization dictates that she should. There are both contractual and governance responses to this agency problem. The venture capitalist will fund only part of the cost of bringing the drug to market and will likely seek some control through board membership and contractual provisions of the financing. These market responses go some way toward resolving asymmetric information and agency problems.

Because these mechanisms help mitigate asymmetric information and agency problems, the founder may be able to raise financial capital to start her firm and hire employees, enter into contracts for goods and services, and purchase or lease equipment for scientific research.

Now suppose instead that the same scientist develops the compound in her role as an employee of an existing biotechnology firm that already has two other compounds in clinical trials,

1. Recent empirical evidence suggests that nonexclusivity is the norm. Hortaçsu and Syverson (2009) document that among vertically integrated firms, a large percentage of upstream production is sold to third parties, and a large percentage of downstream plants’ requirements of inputs they produce upstream are purchased from third parties. See also Mullainathan and Scharfstein (2001) for evidence from the chemicals industry.

2. For excellent surveys, see Harris and Raviv (1991) and Shleifer and Vishny (1997).

numerous employees (including a CEO), capital equipment, and various contracts for goods and services. The scientist would like to get the firm to fund the clinical trial. First, note that the scientist cannot just decide to raise capital from outside investors. She would need approval from her superiors to do this, as firms have the authority to prevent their employees or divisions from raising capital externally.³ Senior management can also prevent the scientist from running the clinical trial. But if they choose to go ahead and run the trial, they might choose to finance it with funds the firm already has, possibly by reallocating funds originally intended for other clinical trials, or they could seek external capital. The scientist would also need the approval of her superiors to hire people to run the clinical trials and to enter into contracts for necessary goods and services. Management might choose to reallocate employees working on other clinical trials to help in the management of the SF-920 trial and to use supply relationships they already have for the necessary goods and services.

As the example should make clear, there are stark differences in how standalone firms and divisions within larger firms obtain resources. First, authority relationships within firms provide senior management with exclusive control over people and capital. Although delegation of this authority is feasible, it only rarely occurs with respect to capital; senior management typically exercises its decisionmaking authority over large capital commitments. Furthermore, price mechanisms are not used to allocate capital resources, at least not directly. Although it is quite common to measure divisional performance net the cost of capital it employs and compensate division managers based on accounting measures that net out capital costs, the price of the capital is set formulaically, and the division managers do not choose how much capital they want as a function of its price. At most, division managers state their demands at the given price, and then senior management decides how much of the request to honor. Another common characteristic of internal capital markets is that business units do not have direct access to the excess cash flow they generate. Instead, they must upstream the cash and seek funds for capital investment through the capital allocation process. Additionally, internal capital markets often include quantity rationing through a fixed corporate capital budget. And there can be significant differences in the way information flows from divisions to headquarters compared to that in a firm with a single division.

The external capital market differs significantly from the internal capital market. In general, external capital providers have less direct control over the allocation of resources once they have been provided. Managers often have discretion over the use of cash beyond contractual obligations, enabling them to use retained earnings to invest in new projects. However, in some environments, particularly for early stage firms raising capital from one or several investors, these capital providers can exercise somewhat greater control over the allocation of resources internally through board control and possibly their power to replace management. For larger firms, where ownership is diffuse, the ability to control the use of internal resources once they have been provided is fairly limited.

3. The distinction we focus on is that the division can only go to headquarters for capital, whereas the independent firm can seek any outside source of capital. In both cases, one can think that the firm rather than the scientist owns the rights to SF-920, so the scientist could not take the compound with her if she were to quit either firm.

This distinction has been central to formal models of internal versus external capital markets, as well as to empirical analysis. But before we proceed to the recent research that attempts to explain choices between internal and external capital markets and measure their impact, we discuss the institutional literature on resource allocation that preceded it.

3. Institutional Literature on Capital Allocation

There is a rich descriptive literature on the resource allocation process and its relation to strategy. An early antecedent to the academic literature is Alfred P. Sloan's (1964) classic book, *My Years with General Motors*, in which he describes his transformation of General Motors into a multidivisional firm and the resource allocation processes the company used. The academic literature starts with Bower's (1970) classic ethnographic study, *Managing the Resource Allocation Process*. Bower's book and the work that builds on it, such as Burgelman (1983), develop and refine a descriptive model of how a company's key strategic decisions are made through the process by which capital and other scarce assets are allocated to divisions and projects. Bower characterizes internal resource allocation as a bottom-up process in which front-line managers identify investment opportunities and seek the support of middle managers, who choose which project to champion and put before senior managers for ultimate approval. Bower argues that although front-line managers may have deep knowledge of their particular areas of responsibility, the process does not readily incorporate information from other parts of the company and thereby fails to take advantage of potential synergies across business units. Given that projects are generated from the bottom up, the resource allocation process often misses new opportunities outside the limited window from which front-line managers view the world. Senior management, however, can influence the set of projects that percolate up to them for approval through communication of strategic direction, choice of organizational structure, and implementation of measurement systems and incentives.

One of Bower's (1970) most important contributions is to identify the central role that resource allocation plays in strategy. Strategy may be formulated as grand plans by senior management, but the process of resource allocation—the decisions of which initiatives to undertake and which to reject—is where strategic choices are often made. In Bower's view, a strategy formulation process that does not integrate effectively into the resource allocation process cannot be successful.

Bower's model is largely descriptive and does not try to relate differences in market outcomes with differences in resource allocation processes or between internal and external resource allocation. Nor does he try to identify and empirically document biases in the process. Furthermore, Bower's model largely abstracts from incentive problems, in effect assuming that the problem is one of aggregating diffuse knowledge within the organization. Communication is implicitly assumed to be imperfect, but the reasons for this are not explored.

Sull (1999) and Christensen (1997) go on to document some problems that can arise when firms adhere to the bottom-up process identified by Bower. Sull shows how Firestone failed to adjust to the reduced demand for nonradial tires in the 1970s. He shows that incentives can become misaligned in a bottom-up process when the capital allocation decisions involve taking away a division's resources. Lower level management did not recommend disinvestment, and senior management relied on lower management for recommendations.

Christensen (1997) documents how leading firms often fail to respond to potentially disruptive technological change because they listen to existing customers who are largely satisfied rather than learning about the market opportunities for major innovations. Christensen identifies the bottom-up resource allocation process as one of the sources for these strategic errors.

Despite the ostensible importance of resource allocation process for strategy and performance, this literature appears not to have gone much beyond case studies. And to our knowledge, the field of organizational behavior has given relatively little attention to the question of how resources are allocated in organizations. We now turn to a description of economic theories of capital allocation and the empirical work that follows from these theories. Many papers we discuss are described in Stein's (2003) excellent survey of corporate investment, as well as in a more recent survey by Maksimovic and Phillips (2007).

4. Theoretical Perspectives on Capital Allocation

The idea that firms replace price-based relationships with authority-based relationships dates back to Coase (1937). Although Coase is not specific about how these authority-based relationships work, they should have implications for how capital is allocated in firms. Williamson (1975) begins the economic literature that examines the implications for internal capital allocation. He describes the multidivisional firm as a "miniature capital market," with two main advantages over external capital markets. First, headquarters can more easily monitor its business units than external investors can monitor the companies in which they invest, "thereby securing a higher level of adherence to profit maximization than the unassisted capital market could realize." Second, headquarters is better at "assigning cash flows to high yield uses. Thus cash flows . . . are not automatically returned to their sources but instead are exposed to internal competition" (Williamson 1975: 147). Elements of these ideas also appear in Weston (1970) and Donaldson (1984).

In the context of the drug-development example in the previous section, Williamson's view amounts to saying that the headquarters of a large biopharmaceutical firm ("pharma") will do a better job allocating its drug development budget across internal projects than the capital market would do in allocating funds across smaller single-project drug-development companies ("biotech"). There are two reasons, according to Williamson. First, pharma headquarters can better assess the value of any given project and can better ensure that funds are used appropriately than can investors in a biotech firm. Second, pharma headquarters does a better job than the capital markets in choosing among competing drug-development projects; headquarters can reallocate cash flows generated by previously successful projects to fund projects with better prospects, whereas investors in biotech firms cannot redeploy cash flows from previously successful firms to other firms with better prospects.

The formal theoretical work on internal capital markets is by and large a fleshing-out of both these claims. There are two key elements of most of these models, though often both are not present: (1) agency and information problems between headquarters and external sources of capital and (2) agency and information problems between headquarters and internal users of capital (business units or project managers).

Why, as Williamson (1975) suggests, would headquarters be better than external capital markets at evaluating and monitoring projects in the firm? One possibility, suggested by Gertner

et al. (1994) is that headquarters—in contrast to a bank or noncontrolling shareholder—has unconditional control rights over the management of projects in the firm. Thus, if a CEO has an idea that would improve a project in the firm, he has the authority to have the improvement implemented by the project manager. More precisely, he has the authority to fire the manager if she does not comply, thereby giving the CEO bargaining power to have the idea implemented without having to pay the manager much in exchange for implementation. This provides the CEO with strong incentives to become informed about where to allocate resources lower down in the organization. In contrast, a bank loan officer only has control conditional on very poor performance (default), and therefore has no authority to fire a manager for not implementing his idea. Without this authority he has to pay the manager in some way to implement the idea, which in turn discourages the loan officer from coming up with ideas for project improvement. However, the greater authority of the CEO gives him the capacity to extract rents from the manager, which discourages his effort and may lead him to identify fewer valuable investment opportunities.

Stein (1997) builds on this model of a more informed headquarters to explore its implications for capital allocation across business units. In his model, business unit managers (and the managers of standalone companies) always want to invest as much as possible, because they derive private benefits from investment. Thus, the capital market, which is poorly informed about business-level investment opportunities, rations credit to protect against overinvestment. For example, each standalone firm might only be able to raise one unit of capital, even though one of the firms has much better investment prospects. However, if these standalone firms become part of a two-division firm in which headquarters makes the capital allocation decisions, the firm can raise two units of capital overall, and the well-informed headquarters can deploy more capital in the division with the better investment prospects. In Stein's terminology, the benefit of an internal capital market is that it can engage in both "winner picking" and "loser sticking," preventing divisions with poor investment opportunities from overinvesting. This idea is a formalization of Williamson's notion of the benefits of internal capital markets.

This argument would appear to hinge on the assumption that the CEO has strong incentives to maximize value. However, Stein (1997) shows that one can have an efficient internal capital market even if the managers at headquarters are empire builders, provided they prefer better projects to worse ones, controlling for the level of investment. Thus, it will be in the interest of headquarters to have a large capital budget but make sure that it is deployed in the most efficient way possible. In Stein's (1997: 131) words, "a partial solution to the agency problem of empire building managers is to take control from them and give it to an empire building supervisor, who is no more noble but has less parochial interests." Stein then uses this model to consider the optimal scale and scope of the firm.

This positive view of internal capital allocation also appears in the work of Maksimovic and Phillips (2002) but for entirely different reasons. Unlike most models in this literature, there are no agency and information problems. Instead, their model is driven by the assumptions that there are decreasing returns to scale at the business unit level, and importantly, that managers have general skills that they can apply across business units, even if they are in different industries. Under these assumptions, it is optimal for headquarters to deploy its skills across multiple, possibly unrelated, businesses rather than on one business unit with diminishing returns. In this model, it is efficient to have multiple businesses under one roof; the capital allocation process

just amounts to allocating capital to its highest value use. These authors then derive empirical implications that they argue are consistent with the data.

There are other models of the financial benefits of corporate diversification, but they are not about capital allocation, so we do not focus on them. As an example, Lewellen (1971) argues that a benefit of diversification is that asset values are less variable, which lowers the probability of financial distress and enables firms to finance themselves with more leverage, thereby allowing firms to take greater advantage of the interest tax deduction.⁴ In contrast, Hadlock et al. (2001) argue that because asset values are less variable, equity issues are associated with less adverse selection, which facilitates more equity issuance, with a less negative price impact (which they verify empirically).

The idea that internal capital markets function smoothly seems at odds with the common view espoused in the finance and strategy literature that the conglomerate form of organization—the primary purpose of which is to allocate resources—was a failure. One of the main theories behind the assembly of a conglomerate of unrelated businesses was precisely that they would allocate capital more efficiently than the external capital market (Hubbard and Palia 1999). ITT, which in its prime had acquired more than 350 businesses in industries as diverse as insurance and baking, was a leading example of such a conglomerate. However, beginning in the 1980s, with concerns rising about whether conglomerates had become too large to be effectively managed, conglomerates began paring themselves down. Many conglomerates were subjected to hostile takeovers and leveraged buyouts, with acquirers appearing to reap large gains by disassembling them and selling the parts off to industry and financial buyers (Bhagat et al. 1990). Many of the acquisitions that were done to assemble the conglomerates were, in the end, unsuccessful (Porter 1987; Kaplan and Weisbach 1992). Conglomerates appeared to be valued at less than the sum of their parts (e.g., Berger and Ofek 1995). Scholars attributed these difficulties to incentive problems in conglomerate divisions, as compensation was only loosely tied to divisional performance, and to failures of the internal capital allocation process (Baker and Wruck 1989; Baker 1992; Kaplan et al. 1997). It is against this backdrop that theories of the dark side of internal capital markets were developed. Rajan et al. (2000), Scharfstein and Stein (2000), and Wulf (2009) are early attempts to model inefficiencies in capital allocation. All the models are based on some sort of rent-seeking behavior on the part of divisional managers, which headquarters responds to by distorting the allocation of capital away from the first best. Meyer et al. (1992) also model rent-seeking behavior by division managers who try to get headquarters to allocate more capital to their divisions. But in equilibrium they are unsuccessful, and even though the rent-seeking activities are in themselves inefficient, they do not result in a distorted capital budget.

In both Rajan et al. (2000) and Scharfstein and Stein (2000) capital allocation is distorted toward poorly performing divisions at the expense of the better divisions. In Rajan et al. (2000) this distortion is an attempt by value-maximizing managers at headquarters to encourage cooperation among divisions. This result follows from a set of assumptions in their model that imply that when capital budgets and investment opportunities are very diverse, divisional managers have increased incentives to engage in the types of investments that benefit only their own divisions. These incentives are reduced with more equalized capital budgets.

4. Inderst and Mueller (2003) present an optimal contracting model in which diversification reduces cash flow variability and enables firms to pledge more cash flows to debt investors.

In contrast, Scharfstein and Stein (2000) rely on two tiers of agency problems—between headquarters and division managers (as in Rajan et al. 2000) but also between headquarters and shareholders. Division managers, particularly those in poorly performing divisions, have incentives to engage in activities that enhance their bargaining power with headquarters. Headquarters, in turn, can try to prevent this sort of behavior through cash compensation. However, if divisional managers obtain private benefits from a larger capital budget, headquarters may choose to compensate divisional managers with more capital instead of cash. As an agent of shareholders, managers at headquarters may perceive this approach as a less costly form of compensation, because they do not bear the full cost of the distortion. To the extent that the managers of the divisions with poor investment opportunities need more compensation to discourage rent-seeking activities, the capital budget will be distorted in their favor.⁵

Rajan et al. (2000) and Scharfstein and Stein (2000) both hinge on some very particular assumptions that are hard to verify empirically. In the main, these papers have been cited to motivate a set of empirical tests that examine whether the better divisions of conglomerates receive too small a share of the capital budget relative to the efficient level. An important distinction between the models, which we discuss further in our review of the empirical literature in Section 5, is that Scharfstein and Stein (2000) predict that capital allocation will be more distorted in firms in which there are greater agency problems between top management and shareholders.

Rotemberg and Saloner (1994), De Motta (2003), Brusco and Panunzi (2005), and Ozbas (2005) also present models in which an internal capital market with winner picking creates problems. Rotemberg and Saloner (1994) and Brusco and Panunzi (2005) show that if a divisional manager is concerned that the fruits of her innovative efforts will not be rewarded because capital will be allocated to other divisions, then she may not exert much effort in the first place. De Motta (2003) highlights an alternative mechanism through which an internal capital market could reduce managerial incentives while doing an effective job of winner picking among projects. In his model, managers try to signal quality to the external capital market through greater effort. If there are multiple divisions, there is a free-rider problem among divisions; it is less important for any one division manager to boost the market's impression of firm quality through its effort. Moreover, if headquarters is relatively informed about manager quality, there is less incentive to signal to headquarters through greater effort.⁶ Ozbas (2005) presents a model in which winner picking encourages divisional managers to overstate the value of their projects, and he considers various ways that headquarters can reduce this incentive through, for example, more rigid (less information-sensitive) capital allocations and job rotation across divisions.

Matsusaka and Nanda (2002) and Inderst and Mueller (2003) analyze models in which internal capital markets have both costs and benefits. In Matsusaka and Nanda (2002) the benefit of an internal capital market is that firms can use the excess cash flows of one division to fund those of another without having to bear the deadweight costs of going to the capital market to raise funding. The cost of an internal capital market is that empire-building managers may

5. Bernardo et al. (2006) also present a model of “socialistic” capital allocation that fully endogenizes incentive compensation, effort, and the allocation of capital.

6. This idea is related to the model of Gromb and Scharfstein (2002), which analyzes the costs of internal entrepreneurship (“intrapreneurship”) versus new firm formation (entrepreneurship).

overinvest excess cash flow. This cost is the same as in Inderst and Mueller (2003), whereas the benefit they model is that the reduced variability of cash flows in a multidivisional firm enables it to commit to pay out more cash to debtholders and thereby increases its ability to raise debt financing. Neither of these models has strong predictions about how capital will be allocated across divisions.

Finally, there is a line of theoretical work developed in the mainstream organizational economics literature that considers the resource allocation process of multidivisional firms. Athey and Roberts (2001) study a model in which division managers choose effort (which impacts the performance of the manager's own division) and projects (which affect other divisions' performance). They study the implications for incentive schemes and the allocation of decision rights over project selection. Dessein et al. (2010) develop a model of organizations with both business-unit managers, who choose effort, and functional managers, who identify opportunities for synergies that create externalities among business units. They study the joint choices of incentive schemes and the allocation of authority among managers. The model demonstrates the trade-offs between generating strong local incentives and taking advantage of projects that have externalities among business units.

5. Early Empirical Perspectives on Internal Capital Markets

Early empirical work on conglomerates suggests that at the time of diversifying acquisitions, the stock market perceived them as increasing value (Schipper and Thompson 1983; Matsusaka 1993). Indeed, Hubbard and Palia (1999) show that, during the 1960s, when there was an announcement that a financially unconstrained firm was undertaking a diversifying acquisition of a financially constrained firm, the acquirer's stock price rose more than the average diversifying acquisition. This phenomenon suggests that the market perceived internal capital markets as being more efficient than external capital markets, at least for the firms involved in the transactions during the 1960s. However, the poor performance of conglomerates and their disassembly during the 1980s and 1990s spawned a literature trying to understand why they appear to have failed.

The first round of empirical research tried to establish that conglomerates are indeed inefficient by documenting that firm value decreases with increasing degrees of diversification (Montgomery and Wernerfelt 1988; Lang and Stulz 1994) and that the market value of conglomerates is less than the value of a matched portfolio of standalone firms (Berger and Ofek 1995). This latter fact has come to be known as the "conglomerate discount" or "diversification discount." Berger and Ofek estimate a discount of about 13–15%, using data from the United States, and discounts of varying degrees have been documented in numerous other countries (Servaes 1996; Fauver et al. 1998; Claessens et al. 1999; Lins and Servaes 1999, 2002).

Although it is well established that conglomerates trade for less than the sum of their parts, some papers have argued that this fact is not evidence of the inefficiency of the conglomerate form of organization. In particular, Campa and Kedia (2002), Graham et al. (2002), Hyland and Diltz (2002), and Villalonga (2004a) argue that the conglomerate discount is really driven by the fact that firms that choose to be conglomerates are weaker in the first place. Indeed, Chevalier (2004) shows that single-segment firms that were acquired by conglomerates traded at a discount relative to other single-segment firms even before they were acquired. And Lamont

and Polk (2001) show that about half of the conglomerate discount does not stem from lower cash flows but rather from the market requirement for higher returns on diversified firms. Thus, some of the discount may be the result of inefficient valuation rather than inefficient management. Finally, Villalonga (2004b), using much more disaggregated, establishment-level data, shows that the conglomerate discount may not even exist on average.

Houston et al. (1997), Lamont (1997), Shin and Stulz (1998), Scharfstein (1998), and Rajan et al. (2000) are the earliest papers to look directly at the functioning of internal capital markets. Lamont (1997), though early on the scene, arrived there somewhat inadvertently. His main focus is on whether the well-documented relationship between cash flow and investment exists because of capital market imperfections or because cash flow proxies for the value of investment opportunities. This question arose in the first studies of the effect of cash flow on investment, such as Fazzari et al. (1988) and Hoshi et al. (1991). Lamont's empirical approach is to look at the investment behavior of the divisions of diversified oil firms that operate outside the oil industry. He shows that in response to a drop in the price of oil, which adversely affected the cash flow of oil divisions, firms cut the capital budgets of their non-oil divisions, even though the divisions were either unrelated to the oil industry or benefited from a drop in the oil price (e.g., the petrochemical industry). Although this finding demonstrates that corporate cash flow affects investment because of capital market imperfections, it also demonstrates that there is an internal capital market in which the cash flows of one division have implications for the investments of other divisions. In fact, Lamont showed that prior to the drop in oil prices, when oil firms were earning large profits from their oil divisions, the non-oil divisions of these firms invested more than their industry counterparts. The steep reduction in oil prices led firms to cut the capital budgets of their non-oil divisions down to the industry average, thus possibly implying that firms had been overinvesting in their non-oil divisions because of the excess cash generated by the high price of oil. This possibility is suggestive of inefficiencies in internal capital markets.

Shin and Stulz (1998) build on Lamont's (1997) study by examining the divisional investment behavior of a large sample of diversified firms. Using segment-level data reported in annual financial statements, Shin and Stulz find that a segment's investment does not just depend on its own investment opportunities (as measured by Tobin's Q) and cash flow but also depends on the cash flow of other segments, even though the segments are in different two-digit Standard Industrial Classification (SIC) codes. It is possible that this finding is part of an efficient reallocation of corporate resources as suggested by Stein (1997) and other models. However, cash flow does not appear to be more prone to be reallocated to divisions in high- Q industries. The authors suggest that this negative finding could be evidence of an inefficient internal capital market.

Rajan et al. (2000) take a different approach to examining the efficiency of internal capital allocation. Consistent with their theory, they find that diversified firms invest more in their industry segments that are below the firm average industry Q than would a standalone firm operating in that industry. Similarly, they invest less in industry segments that are above the firm's average industry Q . These differences are more pronounced in firms that operate in industries with very diverse Q values, which is also an implication of the Rajan et al. (2000) model as well as an implication of Scharfstein and Stein (2000). Moreover, the greater is the misallocation of resources according to this measure, the greater the conglomerate discount will be. Thus,

for example, we would expect that a firm that operates in a high-growth technology business would invest less than its industry peers if at the same time it owns a slow-growth consumer foods business. However, if the firm operates in two different high-growth technology businesses, the empirical results would suggest less divergence in the investment behavior of these segments from standalone industry participants. Moreover, the conglomerate discount should be smaller for the latter firm than for the former.

Scharfstein (1998) and Ozbas and Scharfstein (2010) start with a similar observation. These papers show that diversified firms tend to invest more than their standalone peers in low-Q industries and less than standalone firms in high-Q industries.⁷ Importantly, they show that these differences are more pronounced for firms in which top management has low ownership stakes. This finding is consistent with the implications of Scharfstein and Stein (2000), who argue that inefficiencies in capital allocation stem from two-tiered agency problems—those between headquarters and shareholders and those between headquarters and division managers. This paper provides direct evidence for the effect of top-tier agency problems on capital allocation. Sautner and Villalonga (2010) confirm the importance of good corporate governance for efficient capital allocation in a study of the effects of a change in German tax law that reduced ownership concentration. They find a reduction in their measure of internal capital market efficiency after the change in the tax law. Other recent work, which we discuss later in this section, examines in greater detail the effect on the capital allocation process of agency problems between division managers and headquarters, a key element of most models of internal capital market inefficiency.

A series of papers analyzes the functioning of internal capital markets by looking at what happens after a corporate restructuring. Gertner et al. (2002) document similar behavior by comparing the investment of businesses before and after they are spun off from a conglomerate. This approach has the advantage of using actual business-unit data rather than segment-level data, which may not correspond to an actual business unit. The paper documents an increased sensitivity of investment to industry Q after the spinoff. Moreover, low-Q divisions cut their investment after the spinoff, and high-Q divisions increase their investments. The effects are larger for businesses that are unrelated to the former parent, and for those whose stock price announcement effect of the spinoff is larger. Ahn and Denis (2004) also find increases in investment efficiency after spinoffs. Of course, the sample is biased toward conglomerates whose internal capital markets have likely been most problematic. These papers should be viewed as providing evidence that spinoffs may be driven by a failure of capital allocation, rather than as evidence about the average performance of internal capital markets.

7. The basic results in Scharfstein (1998) and Ozbas and Scharfstein (2010) are substantively similar; however, there are two main advantages of the latter paper, which is why we discuss it in more detail. First, it more systematically measures the relatedness of segments by measuring vertical relationships, which is done by using the input-output matrix of trade flows between industries published by the Bureau of Economic Analysis. Two industries are vertically unrelated if they do not sell (buy) more than 10% of the outputs (inputs) to (from) each other. This is an improvement over Scharfstein's (1998) subjective measure of relatedness, and the standard two-digit SIC measure of relatedness. This latter approach classifies many related industries as unrelated, and unrelated industries as related. For example, oil and gas extraction (two-digit SIC code 13) is considered unrelated to petroleum refining (two-digit SIC code 29), because they are in different two-digit SIC codes. And it considers drugs to be related to industrial inorganic chemicals, because they are both in two-digit SIC code 28. A second advantage of Ozbas and Scharfstein (2010) is that it examines a much larger sample over a longer time horizon.

Dittmar and Shivdasani (2003) examine the flip side of divestitures—the impact of the divestiture on the investment behavior of the remaining business segments. The segments that appeared to be underinvesting increased investment, whereas those that appeared to be overinvesting reduced investment. Moreover, the conglomerate discount of the remaining parent decreased following the divestiture. Peyer and Shivdasani (2001) show that when firms undertake leveraged recapitalizations (whereby they borrow to buy back a significant fraction of outstanding equity), internal capital markets appear to become less efficient. Segment-level investment becomes less sensitive to industry Q and more sensitive to segment-level cash flows.

These studies, and others like it, have been criticized by Chevalier (2004) and Whited (2001). Chevalier's main criticism is that some of the observed investment patterns of the segments of diversified conglomerates exist even before they were acquired by a conglomerate. For example, prior to a merger the investment of the target firm is sensitive to the cash flow of the acquirer, even though they are in different two-digit SIC codes. And targets tend to invest less than their industry peers if the target industry's Q is greater than the acquirer's industry Q . Shin and Stulz (1998) and Rajan et al. (2000) find the same result once the segments are part of the same conglomerate. That these patterns exist in the data prior to the businesses being part of the same conglomerate casts some doubt on the factors that drive the results in Shin and Stulz (1998), Rajan et al. (2000), and related papers. Moreover, Whited (2001), using a method she developed to correct for measurement error (relying on third- and higher-order moments of the joint distribution of the regressors), claims that the main results in the literature are not robust to correcting for measurement error.

However, as Stein (2003) points out, although these criticisms may cast some doubt on whether the average conglomerate exhibits inefficient investment behavior, they do not explain the cross-sectional findings. For example, Rajan et al. (2000) show that the cross-subsidization of investment is greater in firms with a larger conglomerate discount. And Scharfstein (1998) and Ozbas and Scharfstein (2010) relate investment inefficiencies to low managerial ownership stakes.

The early literature has been followed by three main research streams. One stream of work attempts to provide a more granular perspective on capital allocation, with more detailed investment data, a focus on a single industry, or a focus on a single firm. In particular, extensive work has been done on capital allocation in banks both domestically and across borders. The second stream of work more directly measures the effect of incentives and rent-seeking behavior at lower levels in the organization. And the third stream analyzes the functioning of internal capital markets in business groups, such as Korean chaebol and family-controlled pyramidal enterprises.

6. Granular Perspectives on Internal Capital Markets

6.1. Industry Studies

Although the main body of work on internal capital markets uses segment-level data from Standard & Poor's Compustat to examine capital expenditures of diversified conglomerates, a stream of the literature has developed that analyzes investment behavior in a particular industry. This approach has the advantage of providing a specific industry context for analysis and in some cases more detailed information on the nature of the investment.

6.1.1. Banking

Although much of the literature on internal capital allocation in banks follows the initial contributions to the literature on nonfinancial firms, Houston et al. (1997) deserves credit for being one of the founding papers in the empirical literature on internal capital markets. This paper was the first to show the existence of an internal capital market in banks by documenting that the lending behavior of banks in multibank holding companies is more sensitive to the cash flow of the holding company than it is to its own cash flow, and that a subsidiaries' lending is negatively related to the lending of other subsidiary banks of the holding company. A more recent paper by Ashcraft (2008) analyzes the "source-of-strength doctrine," whereby bank holding companies are required by their regulator (the Federal Reserve) to support troubled depository subsidiaries. He finds that bank subsidiaries of multibank holding companies are safer than either stand-alone banks or those that are subsidiaries of single-bank holding companies. This paper also points to an active internal capital market in banks, albeit one that may have been driven by regulation.

Other papers speak to the importance of internal capital markets in banking, but the authors do not position their papers as being about internal capital markets. Peek and Rosengren (1997) is a good example. Following a strategy similar to that of Lamont (1997), the paper shows that the collapse of the Japanese real estate market and the resulting large losses Japanese banks incurred in Japan induced these banks to cut their commercial real estate lending in the United States in the 1990s, while U.S. banks continued to lend. Thus, shocks in Japan were transmitted to the United States through the internal capital market of Japanese banks. Schnabl (2012) documents similar effects in Peru, where global banks reduced their lending to their Peruvian subsidiaries in response to the global banking crisis that emerged following the Russian debt default in 1998.

Transmission mechanisms of this sort were also explored by Morgan et al. (2004). In contrast to Peek and Rosengren (1997), the authors show that the internal capital market can have a stabilizing effect on lending. Their paper examines the effect of the introduction of interstate banking in the United States—state laws that allowed out-of-state banks to add branches in the state—on the variability of economic growth in the state. Morgan et al. find that it reduces the variability of economic growth: out-of-state banks stabilize lending because their own profitability is presumably less variable than that of in-state banks. Profits from banking activity outside a state provides banks with the capital they need to lend in a state subject to adverse shocks. Of course, if the shock is on a broader scale, the shock could have adverse effects on a state that was not initially impacted by the shock. This transmission mechanism is similar to the one documented by Schnabl (2012) in Peru.

Campello (2002) analyzes the effect of internal capital markets on the performance of monetary policy. He compares the response of small standalone banks to Fed monetary tightening to that of small banks that are part of larger multibank holding companies. The lending by the small banks appears to be much more sensitive to their cash flow during these periods, as they have limited access to nondeposit forms of financing to offset the decline in reserves. In contrast, larger bank holding companies can more easily raise other forms of financing and downstream the capital to their small banks. As a result, lending by these small banks is less sensitive to their own cash flows during periods of monetary tightening. Campello comes to an ambiguous conclusion about whether this allocation of capital across banks in the holding company is efficient.

Cetorelli and Goldberg (in press) undertake a related exercise by comparing the monetary policy response of U.S.-based global banks to that of U.S. domestic banks. They find that U.S. global banks are able to undo some of the contractionary effects of monetary policy tightening by borrowing from their foreign branches. Thus, lending in the United States does not decline for these banks, while it does for similarly sized domestic banks, which cannot tap foreign affiliates for funding.

6.1.2. Supermarkets

Chevalier and Scharfstein (1996) study the effect of financial constraints on the pricing behavior of supermarket chains. They argue that financial constraints will induce supermarkets to raise prices even though doing so compromises long-run market share, because raising prices increases short-run profits, given the existence of customer switching costs. Among other results consistent with this prediction, they find that when oil-producing states in the United States (e.g., Texas) experienced a recession following the large drop in oil prices in 1986, local supermarket chains increased their prices relative to national chains. Both local and national chains experienced a reduction in profits in oil states, but the national chains were able to use the profits they were earning elsewhere to avoid the pressure of raising prices to increase short-run profits. This finding is similar to that of Morgan et al. (2004) on the stabilizing effect of large multistate banks on state-level lending behavior.

6.1.3. Discount Department Stores

Khanna and Tice (2001) present evidence suggesting that in the discount department store industry, diversified firms—those with significant operations outside the discount department store industry—made more efficient investment decisions than focused firms in response to entry by Walmart. Walmart's entry reduced the value of being an incumbent. The authors argue that the efficient response to Walmart's entry was either to exit immediately or to stay and fight. They argue that this strategy was better than the in-between strategy of staying in the business for a few years and then giving up as Walmart came to dominate the local market. Diversified firms were more likely to exit early on, redeploying their capital to other, more profitable, divisions. If they did choose to stay in the market, they invested more in the markets that remained profitable despite Walmart's entry. Khanna and Tice (2001) argue that these findings are largely consistent with Stein's (1997) model in which diversified firms in related industries make more efficient capital allocation decisions because headquarters has the incentive to redeploy capital to its most efficient use.

6.1.4. Chemicals

Mullainathan and Scharfstein (2001) focus on capital investment in vertically integrated chemical manufacturers. In particular, they compare the capacity decisions of standalone manufacturers of vinyl chloride monomer (VCM), the key input in the production of polyvinyl chloride (PVC), to VCM producers that are vertically integrated into PVC production. They find that while the capacity of standalone producers of VCM is very sensitive to downstream industry demand, the integrated manufacturers' VCM capacity depends mainly on the internal demand of their upstream PVC producers. This structure could be inefficient in that integrated producers of VCM miss out on market opportunities because they are focused only on internal demand.

Or it is possible that it is efficient for these integrated producers to cater to the idiosyncratic demands of their upstream units. That integrated VCM producers are more prone to hold capacity during periods when there is excess VCM capacity suggests that there may be some inefficiency. In any case, it is clear that integration can have profound effects on the investment behavior of the units.

6.1.5. *Research and Development*

Seru (in press) analyzes whether diversified conglomerates inhibit innovative activity. He first establishes that conglomerate divisions produce fewer and less-innovative patents than stand-alone firms, but he recognizes that standalone firms might be more innovative simply because they are at an earlier stage in their development. Thus, he compares the change in patenting of the targets of successful diversifying acquisitions to the patenting of targets where the acquisition is initiated but fails to be completed. Consistent with the cross-sectional results, Seru finds that the number and novelty of the patents by the targets of completed acquisitions falls relative to the targets of the failed acquisitions. This difference is larger for conglomerates that have a more active internal capital market using the measure developed by Billett and Mauer (2003). These empirical results are consistent with theories of the firm in which the possibility that headquarters reallocates output of the division to other uses discourages effort (Gertner et al. 1994; Rotemberg and Saloner 1994; Brusco and Panunzi 2005). It is also consistent with a theory of the firm in which headquarters is not well informed about the value of innovative activity at the divisional level and therefore only funds the safest research projects because they are easiest to verify (Stein 2002; Mathews and Robinson 2008).

6.2. Direct Evidence of Divisional Rent Seeking

The early empirical work on internal capital markets documents inefficiencies in capital allocation and interprets these inefficiencies as stemming from rent-seeking behavior by divisional managers. However, it provides little direct evidence that more influential divisional managers are able to attract more capital. A series of recent papers tries to provide more direct evidence along these lines.

The findings generally support the view that the influence of divisional managers is important. The most direct evidence comes from surveys in which CFOs report that “corporate politics” plays an important role in capital allocation (Graham et al. 2011). These surveys do not explore the ways in which corporate politics matter. How they matter is the focus of much of the recent research.

Xuan (2009) finds evidence that politics matter by looking at the behavior of new CEOs. He shows that when a CEO who gets promoted from her prior position as a divisional manager (a “specialist” CEO), she tends to favor other divisions in the capital allocation process at the expense of her prior division. The investment allocations of these CEOs tend to be less efficient than those of more generalist CEOs. Xuan interprets these findings as evidence that specialist CEOs need to curry favor with politically powerful division managers.

Glaser et al. (2010) provide more direct evidence of the importance of politically connected divisional managers. Studying a single large diversified conglomerate, they show that divisional managers have more capital allocated to their divisions in response to large cash windfalls at

the corporate level if the division manager has a longer tenure in the firm or his division is geographically closer to headquarters.

Duchin and Sosyura (in press) study corporate politics using a large set of firms. They document that various measures of divisional manager connections to the CEO (e.g., membership in the same nonprofit organizations, degrees from the same universities, and previous employment at the same firm) are related to higher investment at the divisional level. These connections also reduce the sensitivity of investment to measures of divisional Q when there are greater agency problems between headquarters and management. This finding is consistent with Scharfstein and Stein (2000) who argued that capital allocation is less efficient if there are two tiers of agency problems—one between divisional managers and CEOs and the other between the CEO and shareholders.

While these papers focus on informal connections between divisional managers and CEOs as a measure of influence, Cremers et al. (2011) analyze the effect of more formal connections to headquarters. In particular, they study a German banking group, composed of 181 member banks, which each have voting rights in the management of headquarters. These voting rights can be disproportionate to the size of the member bank and could well exceed the member bank's claims on the cash flows of headquarters. They find that when a member bank has disproportionately high voting rights relative to its cash flow rights, headquarters reallocates more capital to the member bank, away from less influential banks.

6.3. Business Groups

Another stream of research focuses on the functioning of “internal” capital markets in business groups. This is not exactly an internal capital market in the sense that capital is being allocated across divisions of a single business entity; instead it is allocated across independent firms that are tied together because they are owned by a common large (possibly controlling) shareholder. This structure could take the form of a shareholder directly controlling each business through a large ownership stake and high voting rights. Or it could take the form of a pyramidal structure whereby one of the firms, which has a controlling shareholder, also owns a large (but not necessarily a 100% stake) in another firm. These structures are common around the world, as documented by La Porta et al. (1999). Much of the empirical work has been about Indian business groups and Korean chaebol.

To our knowledge, Almeida and Wolfenzon (2006) is the sole theoretical paper on the internal capital markets of business groups. They develop a model in which business groups efficiently allocate capital for the same sorts of reasons developed by Stein (1997). However, they point to a potential unintended consequence of an efficient internal capital market on the functioning of the external capital market: it could reduce the supply of funding to standalone firms with high-value projects. With weak investor protection, a business group may prefer to reallocate funds from a poor project to a mediocre internal project rather than invest in a high-return external project where its rights as an investor are poorly protected. In contrast, a standalone firm with a poor project has no alternative but to invest in the standalone firm with the high-return project. In this model, business groups appear to be efficient, given the existing structures, but could be inefficient from a broader, general equilibrium, perspective.

There are papers that point to the value of business groups in the allocation of capital and others that raise doubts about their effectiveness. Gopalan et al. (2007) analyze capital

reallocation across firms in business groups in India. These firms report interfirm loans within the business group, which tend to be quite large, thus suggesting an active market for capital within business groups. They find that most intragroup loans are made to weaker firms in the group on more favorable terms than arm's-length lending would suggest. The motive for lending seems to be more support for weak firms to avoid bankruptcy than to fund investment projects to stimulate growth. These loans are more likely to be provided to firms with higher insider holdings. The efficiency implications of this activity are ambiguous, but the authors show that when a firm in a business group fails, other firms in the group have greater difficulty raising external capital and investing.⁸

Bertrand et al. (2002) take a less sanguine view about the value of transfers among firms in Indian business groups. They examine whether controlling shareholders of these business groups engage in "tunneling," a term introduced by Johnson et al. (2000) in modeling behavior whereby profits are moved from firms where the controlling shareholder has low cash flow rights to others where he has high cash flow rights. Tunneling could happen through transfer prices or the sort of low-interest loans documented by Gopalan et al. (2007), as described above. They show that industry shocks that should increase the profits of firms where the controlling shareholder has low cash flow rights also increase the cash flow of firms where the controlling shareholder has high cash flow rights. But the opposite is not true; when positive shocks hit the industry of the firms where the controlling shareholder has high cash flow rights, there is no corresponding increase in the cash flows of the other firms.

Likewise, there appear to be somewhat competing views about the function of Korean *chaebol*. Shin and Park (1999) show that the investment of member firms of a *chaebol* is insensitive to their own cash flow, whereas independent firms' investment is sensitive to their own cash flow. This result is reminiscent of the finding of Hoshi et al. (1991) on Japanese *keiretsu*. Yet Shin and Park also find that *chaebol* firms tend to invest more than independent firms in low-Q industries, much like the finding of Scharfstein (1998) and Ozbas and Scharfstein (2010) for U.S. conglomerates. On the bright side, however, Almeida and Kim (2011) find that *chaebol* firms invested more during the 1997 Asian financial crisis than a matched sample of independent firms. This difference did not exist during noncrisis periods.

Perhaps one way to reconcile the competing views of business groups is that they may destroy value during normal times (through tunneling or inefficient investment), but during a crisis—either firm-specific or economy wide—business groups can help alleviate distress. Nevertheless, there remain many open questions about how well the business group, which is the predominant form of corporate organization around the world, functions generally and with respect to the allocation of capital.

7. The Process of Internal Capital Allocation

The functioning of internal capital markets should, in theory, depend on how the allocation of capital is organized—the layers of approval required to undertake an investment, the type of information that must be provided for an investment to be authorized, and the extent to which control over investment is centralized or decentralized. The internal capital market

8. Hoshi et al. (1990) document superior performance of distressed Japanese firms that are members of a *keiretsu* business group and those that are not.

models discussed above do not address these important questions; they essentially assume that decisionmaking is centralized and is based on information provided to headquarters.

Some work on internal capital markets has attempted to address the question of optimal design of an internal resource allocation process. Other work, although not directly addressing the design of a capital allocation process, analyzes the optimal design of organizational communication and the allocation of control rights. This work could prove useful in understanding the process of internal capital allocation.

An early paper that models the capital allocation process is that of Harris and Raviv (1996). The model is of a single division manager, who receives private benefits from investment, and of headquarters, which seeks to maximize firm value. The manager has private information about the economic value of the project. The problem is to give the manager enough latitude to incorporate her information into the investment decision, but not so much latitude that she will significantly overinvest, given the private benefits she receives from such investment. Harris and Raviv show that the optimal process involves an initial allocation to the manager, along with an option for the manager to ask for an increase in her capital allocation. If the requested increase is modest, the manager is given her request. But if it is above a certain threshold, the division is audited with positive probability to ensure that the request is warranted. If it is warranted, then the request is granted, but otherwise it is not. One implication of this analysis is that there is overinvestment in low-value projects, because managers know they can deploy the initial allocation even if the project valuation is low. There can also be underinvestment in high-value projects, because if there is a request above the initial allocation, it is not optimal to grant the manager her full request.

Dessein (2002) analyzes a similar question. A better-informed agent has interests that are systematically misaligned with those of the principal. Dessein compares delegating a decision to the agent or receiving a cheap talk report from the agent and then having the principal decide. The incentive conflict limits the amount of information that can credibly be conveyed to the principal, so the principal's trade-off is between delegation that uses all the local information but results in decisions that are misaligned or communication that incorporates limited information but avoids the misalignment. The main result in the paper is that if the incentive conflict is not too large, delegation dominates.

Marino and Matsusaka (2005) study a similar problem to Dessein (2002) in an internal capital market setting, but they allow for signaling by the agent through the size of a request for funds. Senior managers must accept or reject proposals. Larger requests signal better projects, so signaling creates a cost through excessive investment. Again delegation is typically preferred.

Malenko (2012) extends the Harris and Raviv (1996) analysis to continuous time and an infinite horizon. Like the Harris and Raviv model, the optimal mechanism derived by Malenko captures some key features of the way that capital is allocated in corporations. Malenko shows that it is optimal to give a manager a capital budget and allow him to spend freely from that budget when the projects are below a certain threshold. But if the project size exceeds the threshold, the manager is required to seek approval from headquarters to go ahead with the project, and the project is financed out of headquarters' budget.

Another issue in the design of a capital allocation process is the extent to which it should be centralized in a hierarchy or decentralized throughout the organization. Stein (2002) presents a model that is useful in addressing this important question. The model hinges on the distinction

between “hard” information, which can be documented and used to convince bosses about the value of a project, and “soft” information, which cannot be easily verified. A salient example of hard information in banking is a borrower’s credit score; an example of soft information is a borrower’s trustworthiness.

When information is soft, the disadvantage of a hierarchy with multiple layers of management is that managers may decide, based on their own information, to choose other projects proposed by other managers. This possibility reduces the incentive for lower level managers to put in effort identifying good projects based on soft information. This problem can be mitigated by designing a relatively flat hierarchy, whereby decisions over individual projects are relatively decentralized, and managers have more control over whether the project is approved.

Hierarchies may generate too little soft information, but they can result in excessive hard information production. A project is much more likely to be approved if it can be supported by hard information. Thus, even if soft information is intrinsically more valuable, managers will spend excessive time documenting their proposals with hard information. The model therefore has implications for how organizational structure affects the type of information that is gathered as well as the optimal choice between hierarchical and decentralized decisionmaking.

The Stein (2002) paper was motivated by the observation that small banks (which can be thought of as a decentralized model of decisionmaking) tend to do more relationship lending than do large banks, as indicated by Berger et al. (1999). Berger et al. (2005) present a collection of evidence indicating that large banks rely more heavily on hard information. In particular, large banks lend to firms that maintain better accounting records, operate at a greater distance from the bank, and meet with their loan officers less frequently.⁹ Liberti and Mian (2009) examine information flows within a bank rather than across banks as in Berger et al. (2005). Using detailed information from the credit dossiers of individual borrowers, they are able to show that when loans require more levels of approval, the loan approval decision is more sensitive to hard than to soft information.

A large complementary literature in organizational economics studies information flows and the allocation of control rights in organizations. Some ideas in this literature could prove useful in understanding the capital allocation process, although the empirical implications of this literature are far from clear. For example, Dewatripont and Tirole (2005) develop a model where there are misaligned incentives and communication is costly for both the sender and recipient. The more effort each one exerts, the greater the likelihood that soft information becomes hard. In other words, business-unit managers can try to explain to senior managers why they think a particular project is attractive. They can provide costly evidence, senior management can ask questions that impact the reliability of the evidence, and the like. The authors show that in these situations communication and effort can be strategic complements. It is worthwhile for the recipient to invest a great deal in listening only if the sender spends a great deal to provide useful information and vice versa. Dewatripont and Tirole also introduce the notion of cue communication—the sender conveys cues, such as his expertise, which then makes soft information credible.

9. One might be concerned that the results are driven by endogenous assignment of firms to banks, but Berger et al. (2005) do a good job of instrumenting for the size of the bank by looking at regulatory changes that affect bank size.

Several recent papers study the allocation of control rights in organizations with dispersed information. Rantakari (2008) and Alonso et al. (2008) build models with a trade-off between local adaptation and interdivision coordination. They study horizontal communication among division managers with decentralized decisionmaking and compare it to vertical communication with headquarters and centralized decisionmaking. Rantakari focuses on asymmetries among divisions in the importance of coordination and shows that asymmetric organizational structures with some divisions decentralized and others centralized can be optimal. In Alonso et al. (2008), vertical cheap talk communication is more effective than horizontal communication, because incentives are more aligned, but there is a loss in adaptation from centralized decisionmaking. As coordination becomes more important, horizontal communication actually improves, because division managers' interests become more aligned and more information is incorporated in decentralized decisionmaking. Thus, even if coordination is important, centralized control is not necessarily the optimal outcome.

Van den Steen (2010) provides one justification for centralization based on disagreements among managers of complementary projects. In his model, the combination of externalities and disagreement leads to optimal concentration of authority over projects. Common ownership (through its residual control rights) and low-powered incentives make it easier to enforce authority, thereby generating a complementarity among centralization, internal control, and low-powered incentives. The idea that lack of coordination in a decentralized firm is not simply an information problem but results from differences of opinion may be important. Communication may be insufficient to resolve such differences, and therefore, centralized authority may be required. This would be especially true if differences of opinion are coupled with differences in judgment, which could be modeled as more accurate prior beliefs. The assumption that agents have different priors may therefore also be an avenue to incorporate judgment into formal models of organizational structure.

8. Conclusion

The research on internal capital markets centers squarely on the question of how firms allocate resources. Although this issue would seem to be the central question in organizational economics, it has not received much attention from mainstream organizational economists. Instead, much of the work on resource allocation has been undertaken by financial economists, writing about the conduct and performance of diversified conglomerates. The field would be richer if there were more integration between the work of financial economists and organizational economists, as has been argued by Bolton and Scharfstein (1998). This work need not focus exclusively on the allocation of resources for investment in capital and R&D. It could also address issues related to the transfer of goods and services within firms, as well as the assignment of workers to various jobs within firms. Of course, this is no easy task, but it is one worth taking on.

What Do Managers Do?

Exploring Persistent Performance Differences
among Seemingly Similar Enterprises

Robert Gibbons and Rebecca Henderson

1. Introduction

Decades of research using a wide variety of detailed plant- and firm-level data has provided strong evidence of persistent performance differences among seemingly similar enterprises (hereafter, PPDs among SSEs). Bartelsman and Doms (2000) reviewed the sizeable initial literature on this issue, and a recent review by Syverson (2011) highlighting much new research has only strengthened the result.

As one striking example, Syverson (2004a) finds that “within 4-digit SIC [Standard Industrial Classification] industries in the U.S. manufacturing sector, the average difference in logged total factor productivity (TFP) between an industry’s 90th and 10th percentile plants is 0.651 . . . [meaning that] the plant at the 90th percentile of the productivity distribution makes almost *twice* as much output *with the same measured inputs* as the 10th percentile plant.” And the United States is not exceptional: Hsieh and Klenow (2009) “find even larger productivity differences in China and India, with average 90-10 TFP ratios over 5:1” (Syverson 2011: 326–327, emphasis in the original).

Indeed, the existence of PPDs among SSEs is so well established that recent work in trade, industry dynamics, and productivity growth has increasingly taken this fact as a fundamental starting point. For example Melitz’s (2003: 1695) celebrated paper begins: “Recent empirical research using longitudinal plant- or firm-level data from several countries has overwhelmingly

We are very grateful for help from Dan Barron, Nick Bloom, Sylvain Chassang, Eliza Forsythe, Marina Halac, Casey Ichniowski, Nico Lacetera, Ruitian Lang, Hongyi Li, Jin Li, Maria Polyakova, Mike Powell, Jan Rivkin, John Roberts, Annalisa Scognamiglio, Kathryn Shaw, Chad Syverson, John Van Reenen, Sarah Venables, and seminar audiences at Brown, Columbia, Dartmouth, Emory, Harvard, London Business School, London School of Economics, University of Michigan, University of Minnesota, Stanford, Sydney, Tilburg University, University of Toronto, Vanderbilt, Washington University, and Yale. This project would not have been possible without years of crucial support from the Massachusetts Institute of Technology Sloan School’s Program on Innovation in Markets and Organizations, especially Nancy Beaulieu, Nelson Repenning, John Sterman, and Tommy Wang.

substantiated the existence of large and persistent productivity differences among establishments in the same narrowly defined industries.”

The question of what *causes* these performance differences, however, is still wide open. Syverson (2011) offered a long list of possibilities, including differences in management practice, higher quality labor and capital, differential investment in information technology and research and development (R&D), learning by doing, firm structure, productivity spillovers, regulatory behavior, and differences in competitive regime. Here we focus on the first of these: the role of management practices as a source of PPDs among SSEs.

We choose this focus for four reasons, which we state briefly here and unpack below. First, in large-sample studies, differences in management practices are correlated with differences in productivity. Second, focused-sample studies at the plant and even the line level suggest that these large-sample results are robust to controls for many other factors that Syverson identifies as potential determinants of productivity. Third, choosing management practices as a key driver of PPDs surfaces an important question rarely asked in economics but central to strategic management: why do best practices not diffuse more readily? Finally, we hope that our specific discussion of management practices and PPDs will help shape a broader research agenda in organizational economics about what, exactly, managers do.

We begin from the observation that many competitively significant management practices cannot be reduced to well-defined action rules that can be specified *ex ante* and verified *ex post*. Instead, the implementation of these management practices is critically dependent on context. For example, for many years the singularly successful retailer Nordstrom asked its sales associates to “use their good judgment in all situations.” Similarly, Toyota’s chief request of its production workers was that they seek to “continuously improve the production process.” The state-dependent actions necessary to meet these expectations cannot be the subject of a formal contract. We therefore focus on relational contracts—roughly, understandings that the parties share about their roles in and rewards from cooperating together, but understandings so rooted in the details of the parties’ relationship that they cannot be shared with a court.

Viewed broadly, we see our perspective on management practices as consistent with decades of work on management and authority, such as Barnard (1938), Simon (1947), Penrose (1959), Cyert and March (1963), and Arrow (1974). As one crisp summary, Mintzberg (2004) separates a manager’s activities into analysis (deciding what to do) and administration (getting the organization to do it). Although both are surely important, the strong theme we see in the literature from Barnard to Arrow focuses on the latter, as do we here. In short, we see relational contracts as a key way that managers get organizations to get things done. Furthermore, we see many competitively significant management practices as relying on relational contracts that themselves are hard to build and change, leading to the slow diffusion of management practices that could improve organizational performance.

The core of this chapter is therefore (1) evidence that some important management practices rely on relational contracts, (2) evidence that relational contracts can be hard to build and change, and (3) examples of recent theories that begin to address some of these issues. To prepare for these core aspects of the chapter, in Sections 2 and 3 we briefly review the two literatures mentioned above that motivate our argument. In Section 2 we summarize evidence that PPDs among SSEs exist and are economically significant across a wide range of industries and geographies. These results have been shown to be robust to concerns that they reflect

problems of selection, or simultaneity, or the distinction between productivity in revenue versus physical terms. These productivity differences have also been shown to be persistent over time and surprisingly resistant to increased competition. That is, as we describe in Section 2, an increase in competition does tend to increase an industry's average productivity and decrease its productivity dispersion, but such dispersion is by no means eliminated, even in very competitive environments.

In Section 3 we then summarize evidence that performance differences are importantly correlated with variation in management practices. We complement the recent large-sample work in economics by drawing particularly on focused-sample research in industrial relations and human resource management that has explored the role of high-commitment work systems in driving productivity, as well as on focused-sample research in strategy and organizational studies that has studied the role of white-collar work practices in explaining competitive advantage. As we describe, such focused-sample work can offer especially sharp measures of control variables, dependent variables, and the independent variables of interest (i.e., management practices); see Ichniowski and Shaw (this volume) for more on such "insider econometrics."

In the remainder of the chapter we consider relational contracts. We begin Section 4 by sketching the basic theory of relational contracts, which is closely related to more established work on repeated games. We then describe qualitative examples of competitively significant management practices that rely on relational contracts—at Lincoln Electric and Toyota for blue-collar work and at Merck for white-collar work.

Section 5 turns to the question of why management practices associated with persistent performance differences do not diffuse more readily. We begin by reviewing the extensive literature on this topic, which has developed along four lines. First, managers may have problems of *perception*—they do not know they are behind. Second, managers may have problems of *inspiration*—they know they are behind, but they do not know what to do about it. Third, managers may have problems of *motivation*—they know they are behind and they know what to do, but they lack incentive to adopt new practices. Fourth, managers may have problems of *implementation*—they know they are behind, they know what to do, and they are trying hard to do it, but they nonetheless cannot get the organization to get it done.¹

Given the evidence from Section 4 that important management practices may depend on relational contracts, we continue Section 5 by sketching recent models in which superior performance indeed rests on relational contracts, but these contracts are either too expensive or not even feasible for some enterprises to implement. In short, in these models, bad performance is due to bad parameters among enterprises that are only seemingly similar (i.e., there is unmeasured heterogeneity in the costs of using the key relational contracts).

Our central interest, however, is in the important class of cases where practices do not diffuse even though they are widely acknowledged to be competitively significant, knowledge of how to implement them is reasonably widespread, and firms are striving mightily to adopt them. (Think of the mature phases of the Toyota Production System or total quality management, for example.) Such cases are not well explained either by the perception, inspiration, or motivation arguments for why practices do not diffuse or by relational-contract models in which the rela-

1. We thank Jan Rivkin for explaining his "four 'tion" labels to us and allowing us to adapt them here for our purposes.

tional contracts that underlie high performance are either too expensive or not feasible for some firms. Instead, for the class of cases that is our central interest, we require an implementation argument.

The remainder of the chapter therefore focuses on implementation difficulties that arise through relational contracts. In particular, we suggest two approaches to modeling such issues. We present the first approach in the remainder of Section 5. In very recent relational-contracting models, such as those where path dependence in relational contracting can produce measured performance differences among *ex ante* identical enterprises, several interesting possibilities arise: cooperation can be hard to build well, in the sense that achieving perfunctory cooperation can make it harder to achieve consummate cooperation; cooperation, once built, can be fragile; and cooperation may be difficult to build in the first place. In all these models, however, the parties play the optimal equilibrium of the game as a whole, and they understand this equilibrium from the beginning of the game. That is, although we have moved beyond explanations of bad performance based on bad parameters, now we have explanations based on bad luck.

Our second approach to modeling implementation difficulties that arise through relational contracts is much more speculative; in fact, we know of no existing models. In Section 6 we therefore draw from both case studies and lab experiments to suggest that the implementation of some relational contracts requires solving problems of not only *credibility* but also *clarity*. The credibility problem is familiar: should one party believe another's promise? The clarity problem is new: can one party understand another's promise? Furthermore, these problems seem likely to interact: for example, if one party does something unexpected, does the other attribute it to miscommunication or gaming?

We emphasize that the clarity problem is likely to be particularly acute in exactly those settings where relational contracts are needed because formal contracts are imperfect or infeasible: where parties recognize that their roles in and rewards from cooperation are not easy to articulate *ex ante* or verify *ex post*. More precisely, the existing relational-contracts literature—including the models described in Section 5 (both those focused on bad parameters and those focused on bad luck)—focuses on the credibility problem that arises when the parties' roles in and rewards from cooperation cannot be verified *ex post*. The additional issue we raise in Section 6 is the clarity problem that arises when these roles and rewards cannot be articulated *ex ante*. We conclude Section 6 with some highly speculative thoughts about how this clarity problem might be modeled. As our discussion makes clear, we view this section as a very early report on a research agenda that is promising but just beginning.

Of course, much of our argument echoes earlier work, especially outside economics. For example, there are enormous literatures on organizational culture and its potential connection to organizational performance; see Schein (1985) and Barney (1986), respectively. Even closer to our themes, Ostrom (1990) analyzed self-organized and self-governed institutions for managing common-pool resources, Rousseau (1995) studied "psychological contracts" within organizations, and Adler and Heckscher (2006) saw the firm as a collaborative community. Finally, inside economics, Leibenstein (1969, 1987) suggested that underperforming enterprises (those inside the production possibility frontier, or "X-inefficient") might be stuck in Defect-Defect equilibria, whereas superior performers might have learned to play Cooperate-Cooperate. Not surprisingly, these contributions from outside economics made little use of formal models. Furthermore, although Leibenstein's argument appealed to multiple

equilibria familiar from repeated-game models, neither his work nor subsequent models spoke directly to “stuck in” or “learned to.” Kreps (1990, 1996) pointed toward formal models of the latter issues, but the literature then went quiet.

To conclude this introduction, we return to our rationales for writing this chapter, which are encapsulated by the two parts of our title. Working backward, we begin with the existence of persistent performance differences among seemingly similar enterprises. As Syverson (2011: 326) notes, “the magnitudes involved are striking,” from which it is a short step to Lucas’s (1988: 5) remarks about analogous differences in income and growth across countries: “I do not see how one can look at figures like these without seeing them as representing *possibilities*. . . . This is what we need a theory . . . *for*: to provide some kind of framework for organizing facts like these, for judging which represent opportunities and which necessities” (emphasis in the original). In short, one needn’t aspire to move a 10th percentile firm to the 90th; moving up a quartile would be a big deal, so we need to know whether (and, if so, how) it can be done.

Continuing backward, we reach managers. In particular, we believe that a better understanding of the role of management practices in PPDs among SSEs could have significant policy implications. Since at least Cyert and March (1963), students of organizations have struggled to understand how organizations make decisions; see Gibbons et al. (this volume) for more. To put it mildly, firms do not always appear to costlessly and constantly optimize their choices from a fixed and known production possibility set, and yet the economic analyses underlying regulation and other policies often assume this to be so. We expect there to be useful analogies between how a firm struggles to improve its productivity, as considered in this chapter, and how a firm responds to regulations and incentives created by policies: in both cases, not only analysis but also implementation will be involved, and this could change the way we think about policy regarding research funding, patent law, trade liberalization, antitrust rules, and beyond. Both for these policy reasons and more generally, we hope this chapter facilitates future empirical and theoretical work on what managers actually do.

2. PPDs among SSEs Exist and Are Economically Significant

The evidence that PPDs among SSEs exist and are economically significant has been ably reviewed by Bartelsman and Doms (2000) and Syverson (2011). They describe the extensive empirical literature in the area, discussing in some depth the econometric and data quality issues inherent in accurately measuring heterogeneity in productivity across firms and plants.

This body of research establishes that there exist very significant productivity differences across plants in a wide range of industries and geographies. Furthermore, these findings on productivity differences have been shown to be robust to concerns about selection and simultaneity, as well as the distinction between physical- and revenue-based productivity. They have also been shown to be persistent over time and to be surprisingly resistant to the pressure of increasing competition.

In this section we highlight some of the central papers in the literature. Given these existing surveys, our intention is to be illustrative, not exhaustive. We complement the economics literature with some discussion of research drawn from the strategy and management literatures, including some valuable focused studies. In short, because different samples offer different advantages, we take a collage approach to summarizing the evidence on PPDs.

2.1. Firm-Level Analyses

Early work focused on the relative contribution of “firm” versus “industry” effects in explaining firm-level profitability. Building on the pioneering work of Schmalensee (1985), Rumelt (1991) and McGahan and Porter (1997, 1999) found that business unit effects were significantly more important than industry effects in explaining the dispersion of returns. More recently Hawanini et al. (2003) confirm the role of stable firm effects in explaining the variance in business performance over time and show that this result is robust to multiple measures of value creation. Intriguingly, they show that these results are driven by the performance of firms at the two tails of the distribution: when they drop the top two and the bottom two performers in each industry and re-estimate the models, firm effects fall by 35–54%, depending on the dependent variable, whereas industry effects increase by nearly 100–300%.

Some of the most compelling evidence of persistent firm effects in the data surfaced in the pioneering work of Griliches and Mairesse, who set out to study the effects of R&D on productivity at the firm level. Though not the primary focus of their research, they discovered surprisingly large between-firm heterogeneity in the data (e.g., in deflated sales, number of employees, physical plant, and R&D capital stock) even after accounting for the firm’s industrial sector and adjusting for labor inputs. This heterogeneity endured econometric analysis: estimated parameters from a simple model of the production function revealed a large amount of between-firm variability in the firm-specific intercepts and in the slope coefficient for R&D capital (Griliches and Mairesse 1981, 1982, 1985; Griliches 1986).

2.2. Plant-Level Analyses

Differences in productivity measured at the firm level immediately raise the question of the degree to which firms are similar. Research at the plant level has addressed this issue by including increasingly sophisticated controls for potential sources of heterogeneity, including product mix, capital vintage, labor quality, and market power. We begin by recounting some key accomplishments of the early literature; see Bartelsman and Doms (2000) for more. We follow this with a description of recent contributions considering the distinction between physical and revenue productivity and the econometric challenges inherent in this research.

The exploration of productivity measured at the plant level has a long history, since at least Salter (1960), who studied the pig-iron industry during 1911–1926. Salter found that labor productivity was widely dispersed and that the most productive plant was two times more productive than the average plant. Similarly, Chew et al. (1990) examined productivity dispersion across 41 operating units of a single commercial food division in a large multidivisional corporation. These 41 operating units all used essentially the same production technology, were all located in the United States, and all produced nearly identical products for very similar customers. However, even after controlling for such factors as local labor market characteristics, size of the local market, unionization, capital vintage, product quality, and local monopoly power, the top-ranked unit was still twice as productive as the bottom-ranked unit. (Figure 1 shows the raw productivities across units, where the top-to-bottom ratio is 3:1.)

Continuing with focused studies, Dunlop and Weil (1996) analyzed 42 business units in the United States that produced a narrow range of apparel products. The raw performance data on

Figure 1. Multifactor productivity index for operating units in a single commercial food division. Redrawn from Chew et al. (1990).

lead time (the total time from ordering inputs to finished products) and operating profits (as a percentage of shipments) exhibited substantial inter-unit variability (coefficients of variation of 0.80 for lead time and 0.69 for operating profits). In a similar spirit, Arthur (1994) reduced product diversity even further in a study of 29 steel mills but still found substantial coefficients of variation in labor efficiency (0.43) and scrap rates (1.0).

Turning to broader samples, more recent work, using census data from different industries and countries, suggests that the productivity dispersion found in focused-sample studies is widespread. For example, Dwyer (1998), using panel data from the U.S. census of textile plants in 21 distinct industries, documented 85-15 percentile TFP ratios ranging from 2 to 4 and showed that this dispersion did not decrease over the 1972–1987 time period. Using plant-level data from an even broader set of industries, Syverson (2004a) showed that the average 90-10 percentile labor productivity ratio for 443 (four-digit) manufacturing industries in 1977 was 7:1; whereas the average 90-10 percentile TFP ratio ranged from 2.7:1 to 1.9:1.

Moving outside the United States, Klette (1999) found significant within-industry differences in permanent plant productivity (as measured by fixed effects) in 13 of 14 Norwegian manufacturing industries studied during 1980–1990. Using similar data, Biorn et al. (2002) estimated a four-factor production function by industry on 4 years of panel data and found that 72–84% of the gross variance in productivity could be attributed to heterogeneity at the plant level. In their analyses of manufacturing establishments in the United Kingdom, Disney et al. (2003) found that establishments in the top decile are 156% more productive than establishments in the bottom decile when productivity is measured according to real gross output per

hour of manual labor; this 90-10 productivity advantage was reduced to 91% when log TFP is the productivity measure.

One might be concerned that these productivity results are measured in revenue rather than in physical product. Using a revenue-based measure of TFP, a local monopolist facing limited competition could appear to be more productive than its rival merely because it is able to obtain higher margins for its products. Idiosyncratic demand shifts could also cause high-profitability firms to appear more technically efficient than they really are. However, research controlling for these effects suggests that substantial heterogeneity in productivity remains even when output is measured in physical units. For example, Foster et al. (2008) use a Census of Manufacturers dataset for 1977, 1982, 1987, 1992, and 1997 containing measures of physical output for 11 industries with physically homogeneous goods (e.g., cardboard boxes and white pan bread). The authors document large and persistent within-industry dispersion in physical quantity-based productivity measures. In fact, dispersion in physical quantities is greater than dispersion in revenue-based TFP: after removing product-year fixed effects, the standard deviation for revenue TFP is 22 log points, and for physical productivity TFP the standard deviation is 26 log points.

These focused- and broad-sample results also appear to be robust to problems of selection and simultaneity (Olley and Pakes 1996). For example, Van Biesebroeck (2008) compared five different econometric techniques for estimating productivity. All five techniques produced remarkably similar results regarding productivity heterogeneity in Columbian clothing and apparel industries, with on average one quarter of all firms having TFP less than 45% of median productivity and one quarter of all firms having TFP greater than 42% of median productivity.

2.3. Persistence over Time and under Competitive Pressure

The research we have reviewed thus far has established the existence of cross-sectional productivity differences in many industries and countries. In this section, we review evidence that these productivity differences persist over time. We first review studies based on census data that demonstrate persistence in both the top and the bottom of productivity distributions. We then move on to describe studies that consider the effects of competition in the evolution of productivity distributions; this research suggests that heterogeneous productivity far from disappears as a result of competitive pressure.

In longitudinal data the evidence for the persistence of productivity differentials over time is very strong. In early work, Bailey et al. (1992) computed plant-level TFP for plants in 23 industries at four points in time (1972, 1977, 1982, and 1987), assigning each plant to a quintile of the productivity distribution in each of the survey years. They found substantial persistence in these distributions: 76% of plants in the top quintile in 1972 remained in the top two quintiles in 1977, and 58% of plants in the top quintile in 1972 remained in the top two quintiles in 1982.² Persistence was less strong in the bottom of the productivity distribution: 48% of plants in the bottom quintile in 1972 appeared in the bottom two quintiles in 1977, and 54% of plants in the bottom quintile in 1972 remained in the bottom two quintiles in 1982.

2. In the transition matrix, plant productivities are weighted by their employment. With unweighted data, the percentage of 1972 top-quintile plants remaining in the top two quintiles in 1977 is 62%.

Foster et al. (2006) found similar results for firms in retail trade. The authors employed quinquennial census data (1987, 1992, and 1997) to compute establishment-level productivity adjusted for four-digit industry effects. They found that “for continuing businesses these differences are highly persistent” (Foster et al. 2006: 757), although exit was also high with the entry of national chains. Similarly, Disney et al. (2003) computed the productivity dispersion of manufacturing establishments for a fixed cohort of surviving firms over time. In 1982, the 90-10 spread for the 1982 cohort ranged from 1.48 (ln TFP) to 1.62 (ln labor productivity). Five years later, the spreads for the firms remaining from the 1982 cohort had fallen to 0.81 and 1.43 (ln TFP and ln LP, respectively) but were not close to zero. Even 4 years later, in 1991, the heterogeneity among surviving firms from the 1982 cohort had fallen only a bit further, with 90-10 spreads now 0.66 and 1.28, respectively. Thus, after almost a decade, substantial heterogeneity persisted among those firms that had not exited from an initial cohort of firms.

Turning to the effect of competition, in cross-sectional data, increased competition is associated with increased productivity levels and reduced productivity dispersion. For example, Syverson (2004b) analyzes cross-sectional data on plants in the ready-mix concrete industry. Very high transportation costs in cement effectively create many distinct geographical markets, and Syverson uses the density of the local construction industry—which varies significantly across markets—as an instrument for local market competition. He finds that, in more competitive markets, average productivity is higher and productivity dispersion is lower (in particular, the productivity distribution is truncated from below). However, even in quite competitive markets, there is substantial dispersion in productivity.

There is also longitudinal evidence that productivity dispersion is highly persistent, even in the face of competitive pressure. Although increasing competition raises average productivity, as weak firms exit and strong firms expand, productivity differences are highly persistent, with some studies even suggesting that greater competitive intensity is associated with a higher degree of plant-level heterogeneity. For example, Eslava et al. (2004) use plant-level data from Columbia for 1982–1998 to study the effects of market reforms (trade, labor, and financial) on productivity, profitability, and the reallocation of market share. The authors find TFP dispersion increasing for exiting, entering, and continuing firms in each of the 17 years of their panel, and the persistence in TFP was greater in the years following market reforms. See Holmes et al. (2012) for citations to recent papers with similar findings.

2.4. Focused Studies

Further evidence that productivity differences are real and persistent comes from studies that focus on fewer firms but use much more detailed data, attempting to control at the finest level for differences in capital and labor productivity. For example, the Chew et al. (1990) study of commercial food units was discussed above. As another example, Ichniowski et al. (1997) studied 36 finishing lines in steel minimills. They included more than 25 technological controls in their analysis of the determinants of productivity, including capital vintage, computerization, learning curve effects, line speed and width, the quality of the steel input, equipment design, and scheduled downtime for maintenance. They still found very significant productivity differences across lines (which they attribute to differences in human resource management policies, so we return to this paper in Section 3).

Similarly, in a series of highly detailed field studies of semiconductor manufacturing (Ap-pleyard et al. 2000; Macher and Mowery 2003, 2009; Macher 2006) Mowery, Macher, and colleagues collected data on defect rates, yield, and cycle time. Consistent with their argument that embedded routines and processes underlie dynamic capabilities, the authors find evidence that interfirm differences in performance are greater than intrafirm differences:

The average within-firm yield coefficient of variation is 1.44, while the between-firm coefficient of variation is 4.42. Similarly, the average within-firm cycle time coefficient of variation is 0.66, while the between-firm coefficient of variation is 2.14. Our performance metrics thus appear to capture firm-specific differences that are both substantial and enduring. [Macher and Mowery 2009: S51]

In summary, the literature suggests that (1) even after the imposition of tight controls, establishment-level TFP exhibits large dispersion in many industries, countries, and time periods; (2) within-industry productivity rankings are persistent, particularly in the right tail of the productivity distribution; and (3) increased competition leads to aggregate productivity growth but not in a manner that substantially reduces productivity dispersion.

We now turn to the possible role of variation in management practices as one important cause of persistent differences in productivity.

3. PPDs and Variation in Management Practices

Syverson's (2011) review not only documents the existence of PPDs but also categorizes their potential sources into two groups: internal factors (management "levers" in organizations) and external factors (market and environmental factors beyond managerial control). An important next step is to assess the importance of these factors. However, even now a large literature argues that variation in management practices may be an important source of PPDs among SSEs, and it is to this literature that we now turn.

Perhaps the simplest way that managers could be partially responsible for measured performance differences is that some managers are just better than others. Such managerial fixed effects have been discussed at least since Walker (1887) and Mundlak (1961). See Bertrand and Schoar (2003) for recent work blending the two—that is, a study of how particular managers adopt particular practices. Our focus, however, is on management practices—that is, things that any manager (or, at least, most managers) might do, rather than on managerial ability per se.

Regarding management practices, Bloom and Van Reenen (2007) began an important research program. Their initial paper reports results from an establishment-level survey of management practices in 732 manufacturing firms located in four countries. They present data on 18 management practices (including the degree to which the firm uses high-powered incentive systems, teamwork, selective recruiting, and skills training) and show that measures of management practice are highly correlated with TFP, profitability, Tobin's Q, sales growth, and survival rate. They show that although 44% of the overall variation in management practices can be ascribed to country and/or three-digit industry effects, the remaining 56% is within country and industry. Furthermore, they demonstrate that management practices can explain a substantial portion of the variation in the permanent component of firm productivity (estimated from

longitudinal data on the production function). Finally, they find that management scores are significantly higher for firms in competitive markets; see Section 5.1.2.

Since their initial paper, Bloom, Van Reenen, and co-authors have substantially deepened this program, including expanding the dataset to include more firms, more countries, and more kinds of organizations (Bloom et al. 2012b); expanding the conception of management to include organizational structure (Bloom et al. 2012d); and exploring the connection between management and information technology productivity (Bloom et al. 2012c). In addition, they have made progress on identification issues, both through an instrumental variables approach (Bloom et al. 2010) and a field experiment (Bloom et al. 2012a). Finally, they have summarized their work in various outlets (Bloom and Van Reenen 2010, 2011).

Given all this work, one might wonder whether anything else has been or could be done. Our answer is strongly in the affirmative to both questions, for reasons like those described in the Ichniowski and Shaw (this volume) discussion of insider econometrics. Specifically, although large samples can offer important strengths, focused samples can offer complementary strengths, such as (1) more detailed controls, (2) sharper performance measures, and (3) more nuanced understandings of what managers actually do. In the econometric framework $Y = X\beta + Z\gamma + \epsilon$, these strengths correspond to Z , Y , and X , respectively. For our purposes, the first two are important, and the third is crucial: we perhaps could not have conceived of this chapter without the detailed accounts of management practices given by the kinds of focused-sample research we describe below. This is one of the chief returns that focused-sample researchers sometimes get from their days in the field talking with dozens of sources.

As a complement to large-sample research, this section describes focused-sample work. (Indeed, the field experiment by Bloom et al. [2012a] has many attributes of a focused study and so could be included here, but see Ichniowski and Shaw [this volume] for a description.) In Section 3.1 we focus on blue-collar work in general and on “high-performance work systems” in particular; in Section 3.2 we turn to studies that have explored the role of management practices in driving productivity differentials in white-collar work. Throughout this discussion, we are illustrative rather than exhaustive, and we pay special attention to studies that illustrate the benefits of focused samples in providing detailed control variables (Z), sharper performance measures (Y), and nuanced measures of management practices (X). As in Section 2, however, no sample is perfect, so we again take a collage approach to summarizing the evidence.

Any interpretation of these results in both the blue-collar and white-collar processes literature must be tempered by the recognition that the adoption of any particular configuration of organizational practices is almost certainly not a random event. On the contrary, the endogeneity of (and documented complementarity among) these organizational practices naturally limits any claims of causality. Nevertheless, we take two important findings from these carefully conducted studies: (1) there is substantial variation in internal practices and (2) there is significant correlation between internal practices and performance.

3.1. Blue-Collar Work: High-Performance Work Systems and Productivity

A long tradition among labor economists and others studying blue-collar work has suggested that high-performance work systems are closely correlated with superior organizational performance (e.g., Kochan et al. 1986, Huselid 1995, MacDuffie 1995, Huselid and Becker 1996,

Ichniowski et al. 1997, Pfeffer 1998, Appelbaum et al. 2000, Black and Lynch 2001).³ For example, a large literature has developed around the study of Toyota, a firm that was perceived for many years to be an order of magnitude more effective than its competitors.⁴ Similarly, Southwest Airlines has been widely studied as an example of best practice (e.g., see Gittell 2003). Both firms have significantly outperformed their competitors, and in both cases the difference has been widely ascribed to the ways in which they manage their blue-collar labor force.

There is no single definition of “high-performance work system,” but three overarching elements can be identified in the literature. In general, firms with high-performance work systems (1) implement effective incentive systems, (2) pay a great deal of attention to skills development, and (3) use teams and create widespread opportunities for distributed communication and problem solving. Table 1 lists some of the particular practices identified by some key studies in the field.⁵

The first of these categories, *high-powered incentives*, includes both financial incentives (e.g., employee stock-ownership plans, performance-based pay, piece rates, and group-incentive plans) and longer term psychological or cultural incentives (e.g., long-term job security; plausible promotion opportunities; reduced wage and status differentials between workers and management; and proactive conflict-resolution methods in place of autocratic, centralized control). The second, *skills development*, includes such actions as selective hiring processes, the extensive training of employees, job rotation, and more flexible job assignments. Finally, *dense communication, local problem solving* includes such practices as the widespread use of teams; the decentralization of information gathering and processing; the allocation of decision rights to frontline manufacturing employees (through self-directed teams, offline problem solving, or quality control groups); and improved communication and coordination among different employee work groups, so that they have access to resources that may assist problem solving. Several studies have found widespread variance in the adoption of such practices (e.g., see Huselid 1995).

Studies that focus on specific industries allow researchers to develop industry-appropriate productivity measures and to collect more detailed and precise data, often at the plant or even line level. Focusing on a single industry also allows researchers to control for heterogeneity, while the smaller scale of these studies mitigates selection and response-bias problems. For example,

3. Regarding this distinction between large- and focused-sample studies, it is worth noting that Huselid (1995), Huselid and Becker (1996), and Black and Lynch (2001) are in fact large-sample studies of work practices, similar in some ways to the Bloom–Van Reenen research on management practices. Huselid and Becker (1996) find that a one standard deviation increase in the use of high-performance work systems is associated with a \$15,000 increase in market value/employee. Black and Lynch (2001) find that unionized establishments that adopted human resource practices promoting joint decisionmaking coupled with incentive-based compensation had significantly higher productivity than did other similar nonunionized plants, whereas unionized establishments that maintained more traditional labor-management relations had lower productivity.

4. More than 300 books and more than 3,000 articles have been published about Toyota and managerial systems. See, for example, the international bestseller by Jeffrey Liker (2004), *The Toyota Way: 14 Management Principles from the World's Greatest Manufacturer*, and the companion book *The Toyota Way Fieldbook* (Liker and Meier 2006), which targets managers trying to implement the 14 principles in their own companies.

5. Becker and Gerhart (1996) provide a similar meta-summary of the practices included in additional studies of high-performance work systems.

Table 1. Management practices underlying high-performance work systems

Practice ^a	Huselid (1995)	MacDuffie (1995)	Ichniowski et al. (1997)	Pfeffer (1998)	Appelbaum et al. (2000)	Black and Lynch (2001)	Bloom and Van Reenen (2007)
High-powered incentives							
Incentive pay	X	X	X	X	X	X	X
Employment security			X	X	X	X	X
Merit-based promotions	X				X		X
Reduced status distinctions		X		X	X		
Performance review	X						X
Skills development							
Skills training	X	X	X	X	X	X	X
Selective recruiting	X	X	X	X	X	X	X
Flexible job assignments		X	X		X		
Dense communication and local problem solving							
Teamwork	X	X	X	X	X	X	X
Communication			X		X	X	
Information sharing	X			X	X		
Total quality management/ process control		X				X	X

Note: X indicates the inclusion of a particular practice in a study’s definition of management practices comprising a high-performance work system.

a. These practices are not necessarily mutually exclusive. For instance, some authors specifically focus on the importance of communication and information sharing in developing well-functioning teams, others directly measure the use of such teams, and still others measure a specific type of team that might be used in lean manufacturing, total quality management programs, or statistical process control. These measures may all be capturing similar successful work practices.

Lazear (2000) studied workers installing auto windshields, finding that those who were under a piece-rate system were significantly more productive than those who were not. The change to a piece-rate system led to a 44% increase in worker productivity. About half of the increase in productivity appeared to be purely an effect of the greater incentives provided by the piece-rate mechanism; the remaining increase in productivity was due to a selection effect. See Ichniowski and Shaw (this volume) and Lazear and Oyer (this volume) for details.

In a global study of automotive assembly plants between 1987 and 1990, MacDuffie (1995) contacted 90 assembly plants in 16 countries, representing 60% of the industry’s production capacity. He found statistically significant correlations among three sets of high-performance practices and productivity and quality: work system design, corporate-level human resource management policies, and the (minimal) use of inventory buffers. Their “work systems” variables capture measures of communication and local problem solving, with additional focus on specific managerial innovations, such as total quality management and statistical process control; their “human resource management policies” variable overlaps heavily with work practices

Table 2. Sample questions used to identify the presence of teamwork and communication

Variable name	Dummy variable question
Teamwork	
High participation	Are a majority of operators involved in formal or informal work teams or other related problem-solving activities?
Multiple teams	Do operators participate in more than one problem-solving team?
Formal team practice	Are operators organized into formal work teams either on the line or for the purposes of problem-solving activities according to an established policy with at least some operators involved in team activities?
Communication	
Information sharing	Are operators and union representatives, if any, provided with financial information on a regular basis?
Meet workers	Do line managers meet off-line with operators to discuss issues of concern, including issues related to performance and quality?
Meet union	Do union representatives and managers meet often to discuss concerns and cooperate in finding solutions to issues?

Source: Table 1 in Ichniowski et al. (1997).

associated with improving workers' skills and incentives; and their "inventory buffers" variable is specific to the lean manufacturing methods associated with the Toyota Production System. The nature of the capital stock, scale, model mix, parts complexity, and product design age together explained 48.3% of the variation in labor productivity, but adding their three "management practice" variables increased the adjusted R^2 to 54.3%, and adding in two- and three-way interaction effects further increased this measure to 64.9%. Subsequent work (MacDuffie et al. 1996) showed that these practices diffused only slowly: in the 43 plants common to both the 1989 and 1993 surveys, the overall 100-point work practices index increased from only 34.6 to 46.9.

Another example of an intra-industry study of the value of high-performance work systems comes from the work of Ichniowski, Shaw, and their co-authors in the steel industry (Ichniowski et al. 1997, Ichniowski and Shaw 1999, Gant et al. 2002, Boning et al. 2007). Ichniowski et al. (1997) examined the effect of human resource management practices on the productivity of integrated steel-finishing lines. The authors collected data from 36 homogenous steel-finishing lines to form a panel dataset of 2,190 monthly observations. Discussion with engineering experts and careful controls for the technology and product mix of any particular line led the authors to focus on uptime as a particularly clean measure of productivity. The study focuses on innovative practices in seven areas of personnel management: incentive pay, recruiting and selection, teamwork, employment security, flexible job assignment, skills training, and communication, each measured using a range of qualitative variables. For example, the presence of teamwork and communication were identified by asking the questions listed in Table 2.

The authors define four distinct systems of work practices. System 4 is the traditional system and lacks most of the innovative work practices. System 3 includes some low-to-moderate levels of teamwork and improved labor-management communication. System 2 includes the

innovations of system 3 with higher levels of teamwork and also introduces extensive skills training. Finally, system 1 incorporates all eight innovative work practices described by the authors. The authors find strong evidence that human resource management practices exist in bundles, and they use cross-section and fixed-effects specifications to suggest that it is bundles—and *not individual practices*—that have an economically and statistically significant effect on productivity.

Their data suggest that relative to system 4, systems 3, 2, and 1 improve line productivity by 1.4%, 3.2%, and 6.7%, respectively.⁶ Using detailed cost data from one line, the authors estimate that the 6.7% productivity difference between systems 1 and 4 implies increased profits of \$2.24 million annually. In an attempt to identify causality, the authors also use a fixed-effects specification to explore productivity changes in a particular line following the adoption of new work practices. Their data show that lines upgrading from system 4 to systems 3 and 2 improved their productivity by 2.5% and 3.5%, respectively.⁷ Controlling for selection effects (because lower performing lines are more likely to switch regimes) raises these numbers to 4.3% and 6.8%. Here again the data suggest that “better” practices are surprisingly slow to diffuse: 36% of the monthly observations in the sample used the traditional system for all 5 years, and 58% still had no teams by the end of the sample.

Hamilton et al. (2003) used weekly productivity and personnel data for employees at a garment factory between 1995 and 1997 to investigate the effects of the introduction of a team-based production system on productivity. Between 1995 and 1996, both team and individual production methods were employed side by side under the same management and union, sewing essentially identical garments. They found that the adoption of teams over a 3-year period at a single plant was associated with an average increase in productivity of 14% (4% stemming from higher ability workers more likely to join teams and 10% attributable to team-production effect).

The focused-sample studies of blue-collar work practices discussed in this section demonstrate detailed and customized controls (e.g., model mix, parts complexity, and design age in MacDuffie’s study of automotive assembly), sharp and meaningful measures of productivity (e.g., windshields installed per day in Lazear’s study of piece rates in the autoglass industry), and sophisticated measurement of organizational practices (e.g., teamwork and communication among workers in the Ichniowski et al. study of steel-finishing lines). Even in these studies, with detailed and careful measurement of the *Z*s, *Y*s, and *X*s, there is evidence of a strong relationship between management practices and productivity.

3.2. Management Practices in White-Collar Work

An extensive stream of empirical work has explored the implications of variation in white-collar work processes on productivity. However, in contrast to research on the blue-collar workforce, much of the work in this tradition abstracts from questions of incentives and skills to focus primarily on questions of decisionmaking and integrated communication.

6. These estimates come from a regression using detailed technology controls, including customer type, maximum line speed, maximum width of line, nine dummies corresponding to specific equipment used in the line, equipment age, computer control of operations, and a measure of the value of major new equipment.

7. All lines classified as system 1 are new lines and hence could not be included in analyses of line changes over time.

For example, Clark and Fujimoto (1991) and Iansiti and Clark (1994) draw on detailed data collected at the level of individual product development projects to show that product development productivity in the world automobile industry between 1981 and 1988 was strongly correlated with the use of “heavyweight project teams”—an organizational structure in which the senior team leader has finite-duration matrixed authority over the members of his or her team and is responsible for supporting rich communication and rich problem solving processes across functional groups. The authors show that the use of heavyweight project teams is correlated with higher development productivity, faster lead times, and higher quality projects. Successful firms also do simultaneous product and process engineering, and they rely on bilateral and face-to-face communication, and the constant and early release of information. For example, these authors show that Japanese firms (which were in general more likely to employ these techniques) took an average of 24 months to develop a new vehicle, whereas American firms (which were the least likely to use them) took 34.

In a study of R&D productivity in the pharmaceutical industry, Henderson and Cockburn (1994) used qualitative research methods to develop measures of management practice and study their effects on research productivity. Using data from structured interviews and internal company documents, the authors created the variable PROPUB to measure the use of incentives designed to persuade researchers to “act almost as if they were academic scientists” and to publish in the research literature. They created a second managerial variable, DICTATOR, to measure the degree to which decisionmaking about resource allocation was concentrated in a single individual. The authors show that adding PROPUB and DICTATOR to their regression predicting research productivity increased the R^2 statistic by 34% (from 0.49 to 0.66).⁸ Despite the apparent power of these practices, they diffused only slowly across their sample (Cockburn et al. 2000).

Researchers in healthcare delivery have also increasingly examined organizational factors as a potential explanation for the wide variability in the adoption of clinical best practices and organizational performance. For example, in 2000, a highly motivated anesthesiologist from the Johns Hopkins University School of Medicine named Peter Pronovost set out to reduce medical errors in intensive care units (see Pronovost and Vohr 2010). He chose to focus initially on central line catheter-related bloodstream infections. Existing research had shown that consistent compliance with a few basic safety procedures could significantly reduce the rates of this type of infection. Another contributing factor in the study choice of catheter-related bloodstream infections was the large personal cost to the patient (morbidity and risk of mortality) and medical costs associated with these events (estimated annually in the United States to be 80,000 infections, 28,000 deaths, and \$2.3 billion in additional costs). Finally, informal observation of clinicians in surgical intensive care units at Johns Hopkins suggested that these basic safety procedures were not in use.

Over time, based on his experience at Johns Hopkins, Pronovost developed a set of complementary management practices designed to reduce errors (specifically, catheter-related bloodstream infections) in hospital intensive care units. This set of management practices included (1) a checklist of five steps to be taken when inserting central line catheters, (2) organizational tools to support continuous quality improvement (e.g., performance data collection and

8. This analysis included a wide variety of program-level controls for productivity, including resources spent by program, therapeutic area, and the scale and scope of the research effort as a whole.

feedback), and (3) a culture change program that was delivered in house and was designed to foster collaborative teamwork between clinicians and nonclinicians in reducing errors. In 2003, Pronovost and colleagues entered into a research collaboration involving nearly all acute care hospitals in Michigan (108 intensive care units). They designed and executed a pre- and post-experiment involving the three-pronged intervention. Over 18 months, median (mean) catheter-related bloodstream infections were reduced from 2.7 (7.7) to 0 (1.4) infections per 1,000 catheter-days (Pronovost et al. 2006). These reductions were sustained at 36 months postintervention (Pronovost et al., 2010) and were associated with significant decreases in hospital mortality (Lipitz-Snyderman et al. 2011).

Researchers in education have similarly begun to document more systematically the role of management practices in school effectiveness. For example, a recent stream of work from Roland Fryer and co-authors has attempted to identify the key ingredients in charter school success in New York City. Several studies have previously found a significant and sizeable effect of charter school attendance on student achievement, especially in poor urban settings (e.g., see Hoxby and Murarka 2009; Angrist et al. 2012). However, it is much less common for researchers to conduct a detailed look inside the “black box” of charter schools. Dobbie and Fryer (2012) collected extensive school-level data on student outcomes and school inputs (physical and human capital), school curriculum, and several management practices from 35 New York City charter schools and found that an index of five policies explains roughly 50% of the variation in student achievement. These policies include increased instructional time, data-driven instruction, quality teacher feedback, high-dosage tutoring, and a culture of high expectations.

4. Many Important Management Practices Are Relational

The evidence that heterogeneity in management practices may be one important source of PPDs among SSEs raises an important question: why, then, do best practices not diffuse? After all, changing management practices would seem much less costly than, say, upgrading capital equipment or buying the latest information technology.

As outlined in Section 1, we believe that one possible answer to this question may be that, first, the implementation of many competitively significant management practices requires a relational contract (again, roughly, a shared understanding of each party’s role in and rewards from achieving cooperation) and, second, that such contracts are hard to build and change. Here in Section 4 we use field research and case studies to buttress the first part of this suggestion: we describe particularly successful blue- and white-collar work practices that rely on relational contracts. In Section 5 we then argue that these relational contracts can be hard to build and change, again drawing on qualitative evidence, this time partly from firms that had significant difficulty implementing competitively significant management practices.

In some sense, we have made our tasks in Sections 4 and 5 harder, because we allowed our descriptions of management practices in Section 3 to be deceptively precise, such as “commit to employment security,” “develop teamwide communication,” and so on. Such blithe descriptions can give the impression that management practices are like light switches—choices that can be easily switched on or off—so that a manager’s greatest challenge lies in designing practices, rather than in implementing them. Here we argue that this view is mistaken and that many (most?) competitively significant management practices require both managers and employees to act

in ways that cannot be fully specified *ex ante* or verified *ex post*, so organizations must rely on relational contracts to implement these practices.

One concrete example of this idea is provided by the case of Nordstrom (Spector and McCarthy 2012). For many years Nordstrom's employee handbook was a single sheet of paper on which was written:

Welcome to Nordstrom

We're glad to have you with our Company. Our number one goal is to provide outstanding customer service. Set both your personal and professional goals high. We have great confidence in your ability to achieve them.

Nordstrom Rules: Rule #1: Use good judgment in all situations.

There will be no additional rules.

Please feel free to ask your department manager, store manager, or division general manager any question at any time.

Throughout this period Nordstrom was an extraordinarily successful firm, plausibly because their employees were extremely good at "exercising good judgment in all situations." Nordstrom's sales associates have reputedly accepted the return of snow tires (Nordstrom does not sell snow tires), driven for hours to deliver merchandise so that customers can be ready to attend family occasions, and changed the tires of customers stranded in the company parking lot. These actions, and others like them, have given Nordstrom a reputation for excellent customer service that is the envy of its competitors and that has created deep customer loyalty. Notice, however, that "exercising good judgment" is not something that can be easily defined. By its very nature it is not an action rule that can be readily described *ex ante* or verified *ex post*. Instead it is a process of noticing what this particular customer needs at this particular time and then deciding to take a particular action in response. No formal contract could fully specify what it means to "exercise good judgment," and it therefore seems plausible that the firm relies on relational contracts instead.

In this section we attempt to extend this insight and build the case that many—perhaps most—competitively significant management practices rely on relational contracts. In Section 4.1, we lay some formal groundwork by describing the repeated trust game from Kreps (1990) and briefly discussing relational-contract models that have built on this intuition. We then present three qualitative examples of management practices supported by relational contracts. In Section 4.2, we discuss two blue-collar examples—the bonus system at Lincoln Electric and the use of the andon cord in the Toyota Production System. And in Section 4.3, we discuss a white-collar practice—the nature of "pro-publication" management in the pharmaceutical industry.⁹

4.1. Modeling Relational Contracts

Repeated game models of collusion among firms have been explored since at least Friedman (1971). The repeated trust game from Kreps (1990) has the same underlying intuition but is

9. These descriptions draw on Gibbons and Henderson (2012), "Relational Contracts and Organizational Capabilities," *Organization Science*, by permission from the Institute for Operations Research and the Management Sciences, 7240 Parkway Drive, Suite 300, Hanover, MD 21076, USA.

cast in a setting closer to our own and so allows us to develop some basic terminology. In Kreps's analysis, each period begins with player 1 choosing either to Trust or Not Trust player 2. If player 1 chooses Trust, then player 2 can choose either Honor or Betray; if player 1 chooses Not Trust, then the period ends. The payoffs to players 1 and 2 are (C, C) following (Trust, Honor), (S, D) following (Trust, Betray), and (P, P) following Not Trust, where $D > C > P$. That is, in the language of the prisoner's dilemma, D is player 2's payoff from defection (betraying 1's trust), C is her payoff from cooperation (honoring 1's trust), and P is her payoff from punishment (when 1 chooses not to trust). For simplicity, we assume that player 1's payoffs are the same values C from cooperation and P from punishment, but all that really matters is that 1's payoffs satisfy $C > P > S$ (where, again drawing on the prisoner's dilemma, S is 1's sucker payoff from having his trust betrayed). Finally, to focus on the case where cooperation maximizes the players' total payoffs, we assume that $2C > S + D$.

In a one-shot trust game, player 2 will choose Betray, because $D > C$, so player 1 will choose Not Trust, because $P > S$. In the repeated game, however, the parties may be able to sustain cooperation, provided player 2 is not too impatient. For example, if player 1 begins by playing Trust but switches forever to Not Trust if player 2 ever plays Betray, then it is optimal for player 2 to play Honor if the present value of the payoff sequence $(C, C, C, \dots)$ exceeds the present value of the payoff sequence $(D, P, P, \dots)$. If player 2's discount rate is r , then it is optimal for her to cooperate if $r < (C - P)/(D - C)$; in this case, one could say that the players have a shared understanding that is "self-enforcing." See Gibbons and Henderson (2012) for details, modest enrichments, and evidence from both experiments and contracts between firms that such relational considerations matter in practice.

The repeated trust game allows us to understand the basic intuition behind relational contracts, but it does not allow the parties to make payments to each other. Because employment relationships are perhaps our chief setting of interest (and because, as we will see, allowing for such payments has an important impact on the analysis), henceforth we focus mainly on models where payments are feasible. (Strictly speaking, the possibility of such payments is what distinguishes relational-contract models from repeated-game models.) The first such models were by Bull (1987) and MacLeod and Malcomson (1989), who analyzed intuitive equilibria but conducted these analyses before the literature learned from Abreu (1988) to analyze *optimal* equilibria. That is, it is one thing to determine that a particular set of strategies (say, reverting to the static Nash equilibrium after defection) can sustain cooperation if the parties are sufficiently patient, but it is quite another to determine what is the best equilibrium outcome the parties can achieve if they are not especially patient. The latter equilibrium need not have the simple form assumed in the former equilibrium. Indeed, for repeated-game models, the optimal equilibrium can involve quite sophisticated punishment strategies; see Abreu (1988) and Abreu et al. (1990).

Levin (2003) rebooted the relational-contracts literature by proving the striking result that the possibility of payments between the parties makes optimal equilibria quite simple in many relational-contract models, as opposed to optimal equilibria in repeated game models. For example, in the canonical repeated agency model, where both parties are risk neutral and have deep pockets, suppose the principal promises to pay the agent a bonus b as a function of the agent's output y . Levin showed that the optimal equilibrium is stationary, in the sense that the bonus in period t is a stationary function of only the output in period t , $b(y_t)$. Furthermore,

this bonus function $b(y_t)$ might itself be simple (as well as stationary across periods), such as paying no bonus if output is below a critical value y^* and a bonus of b^* if output is above y^* . See Malcomson (this volume) for much more on this subject.

The simplicity of optimal equilibria in the canonical relational agency model has facilitated the application of such models in many settings, including some of those described in Section 5.2. Furthermore, the rebooting of this literature has led to richer models in which the optimal equilibrium is not stationary, including some of those described in Section 5.3. Before turning to such models, however, we first illustrate the relational contracts underlying some famously successful management practices.

4.2. Relational Contracts in Blue-Collar Settings: Lincoln Electric and Toyota

Lincoln Electric is an Ohio-headquartered manufacturer of arc welders and has relied successfully on incentive pay for more than 75 years.¹⁰ Most workers earn a piecework wage and receive an annual bonus that generally averages half the worker's annual pay. The board decides on the companywide bonus pool, and individuals then receive shares according to a merit rating based on four factors—dependability, quality, output, and ideas and/or cooperation. Because of its incentive plan, and perhaps also for other reasons, Lincoln has succeeded fabulously in its industry, including driving established firms, such as General Electric, out of the market.

At first glance it might appear that Lincoln's piece rate and bonus could easily be duplicated, but our simple description again masks the presence of several nuanced relational contracts between the company and its employees that are central to the effectiveness of Lincoln's incentive plan. For instance, the company encourages workers to continuously improve piecework processes, but it reserves the right to change piece rates when there is "a change in methods." A worker who develops a faster method for a particular piecework process thus has a clear incentive to keep this knowledge concealed. If the worker's output suddenly skyrockets, managers might notice and readjust piece rates, but the worker could also produce the same amount of output in less time and with less effort while maintaining the outward appearance of constant hours and output. Both workers and managers might be better off in the long run if workers were to share possible process improvements, but workers are likely to share their knowledge only if they believe that they will receive some "fair return" from doing so. Thus arises Lincoln's relational contract about when and how to change the piece rate.

The annual bonus also has important discretionary components. Although it may be possible to develop relatively concrete measures of some aspects of any particular worker's performance, the value of each individual worker's ideas and cooperation may be quite difficult to quantify. To the degree that Lincoln wishes to encourage exactly this kind of less quantifiable behavior, any effective incentive contract will include a significant discretionary component. Furthermore, even if the merit rating on which the annual bonus is based were to be constructed from purely objective measures, the board ultimately sets the firmwide bonus pool. Although the board makes use of a bonus reserve to minimize variance in actual bonuses paid, the average bonus has still ranged from 78% to 129% of wages since 1945. In short, the board ultimately has complete discretion in setting the bonus pool, so workers must rely on a relational contract

10. This account draws on Fast and Berg (1975).

Table 3. Relational contracts at Lincoln Electric

Actor	Action		
	Cooperate	Defect	Punish
Worker	1. Work on improving piecework process 2. Share ideas and improvements	1. Shirk on process improvement effort 2. Keep improvements hidden from co-workers and managers	1. Stop or reduce process innovation effort 2. Keep ideas and innovations secret, inhibiting further innovation 3. Quit
Manager	1. Adjust piece rate only when there is a genuine change in methods 2. Credit workers for ideas in assessing merit ratings 3. Set total bonus pool for all workers large enough to reward workers' contributions	1. Claim there is a change in methods to adjust for workers who have innovated new methods 2. Deny workers good merit ratings 3. Limit the cumulative total bonus pool despite obvious contributions	1. Lower workers' merit ratings (and thus lower bonuses) 2. Fire workers

that the board will, indeed, pay the expected bonus. Table 3 summarizes some elements of the relational contracts that we believe to be in place at Lincoln.

A similar reliance on relational contracts is evident in our next case study, from the Toyota Production System, an exemplar from the automotive industry of the high-performance work systems described in Section 3.1.¹¹ As we outlined in Section 3, much of this performance differential appears to have been driven by the firm's management practices rather than by any structural advantage. Indeed, Toyota's success came in the face of competition that possessed many significant assets—including well-established brands and distribution channels, extensive technical knowledge, and in some cases local government support.

Extensive research has demonstrated that one important source of the extraordinary levels of productivity and quality obtained by Toyota in the late 1980s and the 1990s was the firm's ability to make continuous improvements to its production processes. Shop-floor workers were grouped into problem-solving teams that were encouraged to identify bottlenecks and inefficiencies in the production process and to explore potential solutions to them. Workers were asked to be alert for potential opportunities for improvement and to be creative and innovative in their search for solutions. Successful participation in these teams relied on a set of behaviors that could not be articulated *ex ante* or verified *ex post*, and hence could not be rewarded through a formal contract. The use of the andon cord as a tool to improve the production process is a particularly compelling example. Every worker on the Toyota production line has access to an andon cord, a rope that can be pulled to alert a supervisor to the fact that the worker believes there is a problem on the line. Once the andon cord is pulled, if the supervisor cannot resolve

11. This account draws on Liker and Franz (2011).

Table 4. Cooperation, defection, and punishment in the use of the andon cord at Toyota

Actor	Action		
	Cooperate	Defect	Punish ^a
Worker	1. Pull the andon cord when worker sees a problem 2. Offer suggestions on improvements to the production process (that might make worker's job redundant)	1a. Never pull the andon cord (out of fear of being punished) 1b. Pull the andon cord to stop the line and avoid work when there is no true problem 2. Keep improvements hidden from co-workers and managers	1. Sabotage the manufacturing line 2. Pull andon cord frequently 3. Engage in absenteeism
Supervisor	1. Recognize potential problem when andon cord pulled and aid in problem-solving 2. Implement improvements without necessarily cutting jobs 3. Accept authority of work teams to make some shop-floor decisions	1. Punish workers for pulling andon cord (even appropriately) 2. Cut workforce once they discover potential innovations 3. Interfere in work teams and override their decisions	1. Penalize workers (financially or socially) for pulling andon cord 2. Remove the andon cord

a. The punishment is undertaken in response to the perceived defection by the other actor (i.e., worker or supervisor).

the problem that the worker has identified in a reasonably short time, the entire production line may be brought to a halt. This event is enormously costly. Giving individual workers the power to stop the line on the basis of something as nebulous as “whenever you see a problem” implies, we believe, the existence of a relational contract between workers and the firm. Any worker pulling the andon cord must exercise considerable judgment in identifying potential problems and must believe that he or she will not be penalized for potentially stopping the line. No formal contract can specify the conditions under which stopping the line is an appropriate thing to do. Table 4 sketches some key elements that may underlie the relational contract that supports the use of the andon cord at Toyota.

4.3. Relational Contracts in White-Collar Work: Pro-Publication Management at Merck

A similarly complex relational contract has been operational for many years, we believe, in some leading pharmaceutical firms, such as Merck, that have implemented the “pro-publication” management practice described in Section 3.2.¹² For many decades, research-based pharmaceutical firms attempted to discover new drugs through a large-scale process of trial and error, so-called

12. This account draws heavily on Henderson (1994).

random drug discovery. For example, researchers might inject hundreds of compounds into rats or dogs in the hope of finding one that lowered cholesterol or reduced hypertension. If a compound showed promising activity, then medicinal chemists would synthesize large numbers of related compounds for further testing, in an attempt to find potential drug candidates that were both more efficacious and less toxic. Highly skilled medicinal chemists were the backbone of most companies' research efforts.

Beginning in the 1980s, university-based researchers working in biology and biochemistry began to uncover the biochemical mechanisms underlying many diseases. Early work exploring the causes of hypertension, for example, uncovered the fact that blocking the renin angiotensive cascade lowered blood pressure. This discovery, and others like it, enabled firms to move from animals to using chemical reactions as screens to discover new drugs. In place of "find me something that will lower blood pressure in rats," firms could now request "find me something that inhibits the action of the angiotensin II-converting enzyme."

This science-based approach promised to be—and, *ex post*, proved to be—much more productive than the approach it replaced, but it required those firms who embraced it to significantly change the ways in which they managed research. First, the firms had to hire scientists with quite different sets of skills, including molecular biologists, physiologists, and biochemists. Second, whereas random drug discovery required the firm's scientists to maintain only a cursory understanding of the current scientific literature, the science-based approach required them not only to stay current with the promising mechanisms being discovered in the academic literature but also to conduct such leading-edge science themselves, in house.

This shift required research scientists to behave almost as if they were academic scientists. On the one hand, staying current with the academic literature or, more importantly, understanding the current literature, could not be accomplished by simply reading journal articles. In a classic instance of what Cohen and Levinthal (1990) have called "absorptive capacity," researchers wishing to stay at the leading edge found that they not only needed to attend academic conferences but also to conduct leading-edge science themselves (e.g., to be invited to such conferences, or to participate in informal discussions at them). Some pharmaceutical firms even began to encourage their scientists to publish in the peer-reviewed literature—even though protecting the firm's intellectual property through patents was a substantial part of the ultimate goal.

At the same time, scientists in science-based pharmaceutical firms could not act completely like academics. They also had to actively support their colleagues in the attempted discovery of new drugs. Making a major scientific breakthrough—even winning a Nobel prize—without simultaneously generating knowledge that could be quickly applied to the search for new drugs would not constitute consummate success. Instead, those firms that chose to adopt the science-based approach—and the scientists who worked for them—had to learn how to balance the behaviors characteristic of a successful research scientist with those characteristic of a successful drug hunter.

This was not a balance that could be easily specified in a formal contract. It was widely understood that staying connected to the academic world required publishing in journals and attending conferences, but no one could specify *ex ante* exactly how many papers a scientist should publish and which conferences he or she should attend, particularly when every scientist's research trajectory was likely to be different. How could anyone tell *ex ante* exactly what the balance between fundamental research and drug hunting should be at any given moment,

Table 5. Cooperation, defection, and punishment in science-driven drug discovery

Actor	Action		
	Cooperate	Defect	Punish ^a
Scientist	Behave almost like an academic scientist, but be sure to develop useful knowledge for discovering new drugs	Either shirk (represent lack of results as unlucky research) or behave like an academic scientist (pursue problems for their own sake, build external reputation)	Behave like an academic scientist, or ignore research and become a drug hunter
Manager	Reward the scientist who displays high-science behavior even if no new drugs result	Fail to increase resources for scientists who publish; reward only those who produce drugs	Fire the scientist or cut funding

a. The punishment is undertaken in response to the perceived defection by the other actor (i.e., scientist or manager) and perhaps depends on the nature of that defection.

or develop a verifiable measure of whether a researcher was being “sufficiently helpful” to his or her drug-hunting colleagues? This uncertainty was symmetric: scientific researchers might be motivated as much by the chance to work on interesting problems and to control their own time as by money or promotion, but specifying in advance exactly what kinds of rewards would be given in response to exactly what kinds of behaviors proved to be very difficult.

In practice, those pharmaceutical firms that successfully developed “pro-publication” management (as Cockburn et al. [2000] have termed it) not only fared better in the production of major patents (Henderson and Cockburn 1994) but also appear to have developed a sophisticated relational contract with their researchers. Table 5 sketches our sense of its key elements.

Taken together, we hope that these three examples make plausible the idea that many—perhaps most—competitively significant management practices rely heavily on relational contracts for their execution. Such shared understandings ask both managers and employees to perform actions that cannot be easily specified *ex ante* or verified *ex post*, and as such cannot be enforced by formal contracts.

5. Could Relational Contracts Be Part of the Implementation Problem?

It is one thing to assert that competitively significant management practices may rely on relational contracts but quite another to suggest that this dependence is one of the reasons that such practices are slow to diffuse and hence that performance differences persist. To believe the latter, we would need to know why the relational contracts underlying key management practices might themselves be slow to diffuse. In this section and the next we discuss three approaches to exploring this possibility.

To put these three approaches in context, we begin in Section 5.1 by briefly summarizing existing explanations for the slow diffusion of management practices—without reference to relational contracts. As noted in Section 1, this existing literature has proposed four broad

answers to the question of why competitively significant management practices do not diffuse more rapidly. First, incumbent managers may have problems of *perception*—they do not know they are behind. Second, managers may have problems of *inspiration*—they know they are behind, but they do not know what to do about it. Third, managers may have problems of *motivation*—they know they are behind and they know what to do, but they lack incentive to adopt new practices. Fourth, managers may have problems of *implementation*—they know they are behind, they know what to do, and they are trying hard to do it, but they nonetheless cannot get the organization to get it done.

The first of our three approaches to understanding why some relational contracts might be slow to diffuse is related to the motivation problem: if the relational contracts that facilitate high performance in some enterprises are simply too costly or not feasible for others to adopt, then low-performing enterprises will know they are behind and know what could be done, but they will find it unprofitable or infeasible to do it. In this scenario, high- and low-performing enterprises may seem similar but actually differ in some important parameter. In short, this approach is consistent with the idea from Section 4 that high-performance management is often importantly relational, but this approach then attributes PPDs to unmeasured heterogeneity in the costs of adopting the key relational contracts.

We discuss models of this kind in Section 5.2. In particular, we describe models with four sources of heterogeneity—differences in discounting, in the competitive environment, in network structure, and in player types—that might lead to heterogeneity in the kinds of relational contracts that firms can adopt. These models offer interesting applications of the basic logic from Levin's (2003) canonical model, and they suggest further topics that could be explored with related techniques.

In contrast, the models in Section 5.2 cannot account for the important class of cases in which managers believe that the adoption of a particular management practice would improve productivity, they have a deep understanding of the nature of the practice, they are striving mightily to adopt it, and yet they still fail to implement the practice successfully. In Section 1 we mentioned the mature phases of the Toyota Production System and total quality management as examples from this class; now, after Section 4.2, we can add science-driven drug discovery, such as at Merck, to the list.¹³

Our second and third approaches to understanding why some relational contracts might be slow to diffuse both explore implementation difficulties that arise through relational contracts. In particular, our second approach includes a variety of recent models that enrich Levin's canonical model and deliver nonstationary optimal equilibria. In contrast, our third approach is more speculative and has not yet been modeled, as far as we know.

We discuss the second approach in Section 5.3 by describing models such as those where path dependence in relational contracting can produce persistent performance differences among ex ante identical enterprises. As noted in Section 1, several interesting possibilities arise: cooperation can be hard to build well, in the sense that achieving perfunctory cooperation can make it

13. For example, there have been more than 300 books and thousands of articles written about Toyota, yet until quite recently many automobile companies appeared to have great difficulty imitating its practices (Pil and MacDuffie 1996). Similarly, the practice of science-driven drug discovery diffused only slowly across the pharmaceutical industry despite widespread agreement about its effectiveness (Cockburn et al. 2000).

harder to achieve consummate cooperation; cooperation, once built, can be fragile; and cooperation may be difficult to build in the first place. In all these models, however, the parties play the optimal equilibrium of the game as a whole, and they understand this equilibrium from the beginning of the game. Thus, although we have moved beyond the bad parameters that cause bad performance in Section 5.2, now we have explanations of bad performance based on bad luck—that is, from path dependence or other events over the course of the relationship, among enterprises that were identical *ex ante*.

Finally, because our third approach is more speculative, with no relational-contract models we know of, we discuss it separately, in Section 6. Indeed, we begin not with theory but instead with brief descriptions of cases in which firms had difficulty building or changing relational contracts. Based in part on these cases, we suggest that the implementation of some relational contracts requires solving problems of not only *credibility* but also *clarity*. The credibility problem is familiar: should one party believe another's promise? The clarity problem is new: can one party understand another's promise? In fact, the clarity problem is tougher than this statement, for the usual reasons associated with common knowledge: I need to understand that you understand my promise, and so on.

We emphasize that the clarity problem is likely to be particularly acute in exactly those settings where relational contracts are needed because formal contracts are imperfect or infeasible: where parties recognize that their roles in and rewards from cooperation are not easy to articulate *ex ante* or verify *ex post*. More precisely, the existing relational-contract models described in Section 5 (both those focused on bad parameters in 5.2 and those focused on bad luck in 5.3) share the focus of the entire relational-contracts literature on what happens when the parties' roles in and rewards from cooperation cannot be verified *ex post*. This literature's focus on what happens without verifiability *ex post* has been very productive; we think it is now time to start studying what happens when these roles and rewards cannot be fully articulated *ex ante*. We say more about how one might do this in Section 6.

5.1. Existing Explanations for the Slow Diffusion of Management Practices

An extensive literature has attempted to account for the fact that many competitively significant management practices do not diffuse rapidly. As noted above, four major lines of argument involve the perception, inspiration, motivation, and implementation problems. For ease of exposition, we proceed from perception to motivation and then to inspiration and implementation.

5.1.1. The Perception Problem

A first stream of work hypothesizes that significant heterogeneity in management practices persists because managers are subject to problems of perception. It argues that managers may literally not be aware that heterogeneity in management practices exists or that these differences shape productivity. For example, Henderson and Clark (1990) suggest that in the photolithographic alignment equipment industry, incumbent firms failed to recognize the threat posed by the next generation of products, because their employees focused their attention on the components of each technology, failing to understand that their competitors had developed the ability to understand the performance of the system as a whole. Christensen (1997) suggested that incumbent firms in the disk-drive industry invested their attention and resources in satisfying the

needs of their existing customers, and in doing so failed to appreciate the ways in which their competitors had developed skills that allowed them to meet new customer needs using new technology. Tripsas and Gavetti (2000) drew on a detailed history of the competition between Polaroid and Kodak to show that the two firms conceived of photography in very different terms, which led them to make very different investments. More recent work has amplified and extended these results, suggesting that both the cognitive frames of individual managers and the ways in which information processing is structured in the firm may lead firms to have quite different perceptions of their environments and the capabilities of their competitors (Kaplan et al. 2003; Kaplan 2011).

5.1.2. The Motivation Problem

A second stream of explanation has focused on the degree to which heterogeneity in the adoption of management practices persists because managers have motivation issues, either because of differences in competitive intensity across industries or because of differences in agency costs in firms. This perspective has most recently found support in the work of Bloom and Van Reenen (2007); see also Reinganum (1989) and Bresnahan et al. (2011) for alternative formulations. Bloom and Van Reenen report statistically significant correlation between the adoption of their measures of management practices and competition, measured by three separate proxies: import penetration, the Lerner index, and self-reported survey results on the level of competition. After controlling for firm and market characteristics, firms with five or more competitors have management *z*-scores 0.140 higher than firms with fewer competitors. Bloom et al. (2012e) find even stronger results for estimates with industry-country fixed effects in panel data.

5.1.3. The Inspiration Problem

The third stream of explanation for persistent heterogeneity in management practice flows from the seminal work of Sidney Winter and his collaborators. It suggests that many competitively significant management practices fail to diffuse because, even though managers may be aware that their competitors have developed practices that it would be valuable to adopt, they are hampered in adopting new practices by an inspiration problem: much of the knowledge fundamental to building management practices is tacit, or deeply embedded in individuals or organizational routines, so it is simply unclear how to mimic a high performer (e.g., see Nelson and Winter 1982; Winter 1987, 1988, 2006; Zollo and Winter 2002).

Winter (2006: 131) likens the problem of transferring organizational knowledge to the difficulty of baking a cake from a recipe: “‘Knowing how to bake a cake’ is clearly not the same thing as ‘knowing how to bring together in one place all of the ingredients for a cake.’” As to the sequence of actions required to turn the ingredients into cake, he notes that even though it is technically feasible to write out these tasks in great detail, hands-on experience under an experienced chef is a much easier and more effective way to learn to cook than any amount of book learning. This idea has been explored empirically by several researchers. For example, Anand and Khanna (2000) suggested that one of the reasons some banks are much better at making acquisitions than others is because there is a great deal of “causal ambiguity” in the knowledge required to make good acquisitions, and because some banks have greater absorptive capacity (i.e., more knowledge of the area in question) and so are better equipped to understand new ideas. Similarly, various studies have shown that both access to knowledge

and performance are correlated with the movement of key individuals (e.g., see Almeida and Kogut 1999; Lacetera et al. 2004; Breschi and Lissoni 2009), suggesting that management practices are much easier to “learn” if one has access to individuals who have experienced them first hand.

Detailed studies of particular management practices confirm the idea that many practices have important “sticky” or causally ambiguous elements. For example, Gant et al. (2002) conducted a study of the drivers of innovation across four steel-finishing plants. They find that more innovative plants are characterized by an emphasis on worker-level decisionmaking, team-based work, and greater communication in general, with particular emphasis on horizontal communication among workers on the shop floor. Their detailed diagrams of communication patterns show that innovative plants have more horizontal communication and denser interaction networks than do other plants and suggest that once we examine communication at a sufficiently fine-grained level, it turns out to be a highly complex set of behaviors that might indeed be hard to reproduce.

5.1.4. *The Implementation Problem*

Finally, introducing the implementation problem (and to some extent blending it with an inspiration problem), a fourth reason it might be difficult to imitate a high performer is based on the idea that effective management practices are subject to strong complementarities; for example, see Milgrom and Roberts (1990, 1995) and Brynjolfsson and Milgrom (this volume). When the elements of a management practice are highly interactive, there can be little return from getting most elements right but large return from getting them all right. As a result, a firm could know that it is behind, know what it needs to do, be trying hard to do it, and yet not be able to coordinate the many pieces of the organization sufficiently to get the job done.

As evidence in this spirit, recall from Section 3.1 that the work of Ichniowski et al. (1997) suggests that high-performance work practices are most tightly correlated with productivity when they are bundled together. Similarly, Pil and MacDuffie (1996) find that firms are more likely to adopt what they deem high-involvement work practices (use of teams, problem-solving groups, and job rotation) when they previously had in place certain complementary human resource practices (selective hiring, contingent compensation, training, and reduced status barriers between management and production workers). Finally, Bresnahan et al. (2002) find evidence of complementarities among workplace organization (a measure of teamwork and decentralized work practices), information technology, and more skilled workers.

Levinthal, Rivkin, and Siggelkow, among others, build on these observations to develop models of bounded search over rugged landscapes consistent with the idea that firms that search locally may find it very difficult to adopt new bundles of practices even under quite weak assumptions as to bounded rationality and costly search (Levinthal 1997; Rivkin and Siggelkow 2003; Siggelkow and Rivkin 2005). Rivkin (2000), for example, suggests that it can be exceedingly difficult to search through a space of strategies with numerous elements that are highly interactive, and that imitators may suffer large penalties from even small errors in attempting to match a particular combination of practices. Similarly Brynjolfsson and Milgrom (this volume) suggest that the existence of complementarities plausibly makes changing management practices—when change must occur simultaneously across the entire bundle of practices if it is to improve performance—costly or infeasible.

5.1.5. Summary

Taken together, these four streams of research—on the perception, motivation, inspiration, and implementation problems—offer compelling explanations for why management practices may not readily diffuse. But none of these research streams has paid much (if any) attention to relational contracts. Given the suggestion from Section 4 that competitively significant management practices are often relational, in the rest of this chapter we begin to explore how relational-contract models might complement existing work in these research streams. In particular, in Section 5.2 we explore models related to the motivation problem: if the relational contracts that facilitate high performance in some enterprises are simply too costly or not feasible for others to adopt, then low-performing enterprises will know they are behind and know what could be done, but they will find it unprofitable or infeasible to do it.

In Sections 5.3 and 6, we then shift to our main focus—implementation difficulties that arise through relational contracts. We see our approach to the implementation problem as importantly complementary to the rugged-landscape models of Levinthal, Rivkin, and Siggelkow. More specifically, a firm that can engage in only local search may have difficulty on a rugged landscape, perhaps getting stuck at a local peak, whereas any firm that can hill-climb locally can find the global peak of a landscape, where all monotonically increasing paths lead to the top. But our canonical setting—say, something like Levin’s relational agency model—is just such a smooth landscape, so local search would suffice. Instead, in our approaches, relational contracts pose implementation difficulties because the enterprise may have trouble moving at all (not to mention searching locally): getting the organization to move requires the right relational contracts, and these may be hard to build.

5.2. Unobserved Heterogeneity in the Costs of Using Relational Contracts

One relational explanation for persistent performance differences is that some enterprises find it too costly or infeasible to use the relevant relational contracts.¹⁴ Here we draw from recent literature to explore four potential sources of such heterogeneity: differences in discounting, in the intensity of competition, in network structure, and in the types of managers or employees. This literature is making nice progress; our summary is designed not to be a comprehensive listing but rather to be suggestive of the potential fruitfulness of this approach.

Perhaps the most intuitive source of variation in the effectiveness of relational contracting is variation in discounting: impatient players are more tempted to defect. (Of course, a player’s discount rate need not reflect her personal rate of time preference; it could instead reflect, say, the frequency of repeated interactions.) As one of many recent papers that produces this comparative-static result but is otherwise focused on different issues, consider Board (2011), where a firm builds a group of suppliers over time and then, once the group is established, sources each period from the low-cost provider from the group. A more patient firm optimally

14. By focusing here and hereafter on models of PPDs sustained by relational contracts, we are certainly not rejecting alternative theories, including those related to the perception or inspiration problems. Indeed, we cannot resist noting some of the fascinating learning theories that could be seeds for the latter models, such as Smith and Sørensen (2000), Jeitschko and Taylor (2001), Bar-Isaac (2003), Bonatti and Hörner (2011), Callander (2011), and Ali and Kartik (2012).

builds a larger group of suppliers and thus has lower expected procurement cost per period. An econometrician who could not control for the size of the supplier group or the firm's discount rate would therefore measure persistent differences in the firm's input costs that are created by the quality of its relational contracts with its suppliers.

As an illustration of how variation in competitive intensity could affect relational contracting, consider Powell (2012), who explores the interaction between relational contracts inside an organization and competition in the market outside. In particular, Powell builds on the MacLeod and Malcomson (1989) result that the key to sustaining a relational contract is the net surplus that the relationship creates over and above the parties' outside opportunities (for details, see Malcomson, this volume). Powell embeds many firms in one market, where each firm consists of a principal-agent relationship in which the principal creates incentives for the agent through a relational incentive contract. For a given firm, the net surplus from its principal-agent relationship depends on the market price of output, which in turn depends on the aggregate output produced by the other firms in the market. Loosely speaking, competition in the market may thus be bad for productivity in a firm, if a lower market price of output reduces the net surplus in the firm's agency relationship. More specifically, if market 1 consists of firms 1a and 1b and market 2 of firms 2a and 2b, then firms 1a and 2a might be internally identical and yet able to sustain different relational contracts—because of differences in the productivities of firms 1b and 2b.¹⁵

As illustrations of how variation in network structure could affect relational contracting, consider the emerging literature on repeated games in networks. This literature suggests that the network structure of interactions, the network structure of information, optimal network structures, and endogenous network structures may shape the kinds of relational contracts that can be constructed (e.g., see Lippert and Spagnolo 2011; Fainmesser 2012; Jackson et al. 2012; Wolitzky 2012). This emerging literature may also allow important connections to empirical work, such as the Gant et al. (2002) paper described in Section 5.1, which relates work-group networks to productivity. Our point here is simply that differences in network structure in firms might be hard to measure and hence may be a source of PPDs among enterprises that are only seemingly similar. A further step would be to see network structure as not only endogenous but perhaps also responsive to management practices.

Finally, as an initial illustration of how private information about a player's type can affect relational contracting, consider Halac (2012), who adds persistent private information to Levin's (2003) analysis of relational contracting by endowing the principal with private information about her outside option (and hence about the value of the relationship, from which follows the maximum feasible strength of incentives for the agent). Unlike Levin's case of complete information, where it is immaterial whether the principal or the agent has the bargaining power, Halac derives different reneging temptations and hence different (and possibly testable) time

15. See also Board and Meyer-ter-Vehn (2012) for more on how industry equilibrium might affect relational contracting in individual firms. In particular, identical firms hiring identical workers in a given labor market may offer different relational contracts in equilibrium. Workers accept inferior contracts only until high performance gets them an offer from a firm offering a superior contract. Firms offering inferior contracts eventually lose their workers, but they profit in the short run from the high effort the workers supply in the attempt to generate an outside offer.

paths for incentive strength and termination probability, depending on which party has the bargaining power. In particular, when the principal has the bargaining power, in the efficient equilibrium, incentives strengthen gradually, as the agent becomes convinced of the principal's type. Consistent with persistent performance differences, both of the principal's types in Halac's model value the relationship enough to stick with it, so after the bad type reveals herself, the relationship may not terminate but rather settle into perfunctory rather than consummate cooperation. See Watson (1999, 2002) for other models where relationships start small to screen types.

Another set of models endows the agent, rather than the principal, with persistent private information. For example, in MacLeod and Malcomson (1988), workers know their own abilities, but initially firms do not. The technology of production is such that, under full information, it would be efficient for higher ability workers to exert more effort. The result is akin to heats in a track meet. In the first round, only the least-able workers fail to qualify for the second round (i.e., fail to get promoted); all other workers work just hard enough to qualify. Of those in the second round, the least able fail to qualify for the third, and the others work just hard enough to qualify. Eventually, the continuous distribution of ability is broken into intervals, corresponding to the groups of workers who failed to qualify for each successive round. Having reached its steady-state level, each such group is playing an efficiency-wage continuation equilibrium—where the firm pays a high wage each period but will fire the worker if output is below a critical value. Of course, different groups of workers are playing (appropriately) different efficiency-wage continuation equilibria: a group with high average ability receives a higher wage and produces greater output than does a group with low ability, so an econometrician will measure persistent productivity differences if ability is not a control variable. See Malcomson (2012) and Yang (2012) for further models in this spirit. As with variation in network structure, a further step in this literature would be to see the distribution of workers' types as responsive to management practices—whether via screening during hiring or skill development during employment.

5.3. Consummate Cooperation Can Be Hard to Build and Sustain

We turn next to our second approach to understanding why some relational contracts might be slow to diffuse. Whereas the relational-contract models in Section 5.2 bear some resemblance to the motivation problem—in that the relational contracts that facilitate high performance for some enterprises are simply too costly or are not feasible for others to adopt, so underperformers know they are behind and know what needs to be done but are not trying to do it—the models we describe here are our first stab at our main interest: implementation difficulties arising from relational contracting.

In this section we focus on path dependence and other events during a relationship that can cause *ex ante* identical enterprises to perform differently. As will become clear, this literature is very recent but also very exciting. We hope it continues to grow.

In Section 5.3.1 we describe how learning about persistent private information potentially causes a principal-agent relationship to settle for perfunctory cooperation, when the principal knows that consummate cooperation is feasible but too expensive to discover. This model thus produces persistent performance differences among *ex ante* identical enterprises. In Sec-

tion 5.3.2 we describe how learning about independent identically distributed (iid) private shocks can cause nonstationary dynamics if the shock persists. In particular, in this model short-run shocks can produce long-run or even permanent distortions. Finally, in Section 5.3.3 we describe several models in which cooperation, once built, is nonetheless fragile. Of course, a publicly observed change in the payoffs can cause initial cooperation to collapse, but interesting recent models explore much more subtle threats to cooperation involving learning in various ways.

In all these models, the parties play the optimal equilibrium and have a shared understanding of this equilibrium from the beginning of the game. In Section 6 we discuss our third approach to why some relational contracts might be slow to diffuse, this time exploring how clarity problems might hamper the parties' attempt to develop a shared understanding.

5.3.1. Persistent Performance Differences among *ex ante* Identical Enterprises

We now consider Chassang's (2010a) model of building a relationship. As in the type models in Section 5.2, such as Halac (2012) and MacLeod and Malcomson (1988), persistent private information inspires an initial learning phase. The key difference between the Chassang and type models, however, is that here the agent's private information is about production possibilities, not about an aspect of the agent himself, such as his ability. Our interest in this seemingly slight difference in modeling is that now the principal's attempt to learn and utilize the agent's information can produce persistent performance differences among *ex ante* identical enterprises (i.e., among enterprises with the same production possibilities) as follows.

Chassang shows that in the optimal equilibrium of the game as a whole, play converges to one of several heterogeneous steady states, based on the stochastic results of the initial learning phase. Furthermore, these steady-state continuation equilibria correspond to equilibria of the underlying game without private information. In this sense, Chassang's model can be interpreted as an equilibrium theory of equilibrium selection, potentially rationalizing Leibenstein's (1969, 1987) conjecture that underperforming enterprises might be stuck in Defect-Defect, whereas superior performers might have learned to play Cooperate-Cooperate.¹⁶

Formally, in each period, the principal first chooses whether to invest or not, where investing imposes a cost k on the principal but delivers a benefit b to the agent. Not investing delivers zero to both parties and means that no further actions are feasible that period. If the principal does invest, then the actions $a \in A$ might be feasible for the agent: each period, each action is feasible with (independent) probability p . Both parties observe which actions are feasible, and the principal observes the action the agent chooses.

There are two kinds of actions, unproductive and productive: $A = A_U \cup A_P$. An unproductive action costs nothing for the agent to take but produces no output for the principal, whereas a productive action costs c to take and produces output $\tilde{y}(a)$, where $\tilde{y}(a) = y(a) > 0$ with probability q and $\tilde{y}(a) = 0$ with probability $1 - q$. It is common knowledge that the number of productive actions is $\#A_P$ and that a given productive action produces $y(a_p)$ when it produces positive output, but initially only the agent knows which actions are productive.

16. The remainder of this description of Chassang (2010a) draws on Gibbons (2010) with permission from the *Annual Review of Economics*, Volume 2, © 2010 by Annual Reviews, <http://www.annualreviews.org>.

As a simple case, suppose it is common knowledge that there are two productive actions, a_0 and a_1 , with $y(a_0) < y(a_1)$. In the first period, a_0 might be feasible but a_1 not, or the reverse, or both might be feasible, or neither. To induce the agent to take a productive action that has not been revealed as such, instead of an unproductive action, the principal threatens not to invest in several future periods if this period's output is zero. Note that this punishment will occur on the equilibrium path, because a productive action could produce zero output. In this sense, learning (i.e., identifying a new action as productive) is expensive. In contrast, if an action has produced a positive output then the principal knows that the action is productive, so if the agent takes this action in a later period and it produces zero output, then the principal does not need to punish the agent.

Because learning is expensive (and all the more so after at least one productive action has been identified), it can be optimal to stop learning before all productive actions are identified. Because opportunities to learn arrive randomly, otherwise identical dyads may stop learning after identifying different sets of productive actions. Thus, this model can produce persistent performance differences among ex ante identical dyads because of path-dependence in building a relationship.

5.3.2. *Long-Run Distortions from Short-Run Shocks*

In this section we consider Li and Matouschek's (2011) relational-agency model. The key feature of their model is that the principal's opportunity costs of paying the agent are stochastic and privately observed by the principal. Even though the principal's opportunity costs are iid, the optimal relational contract generates periodic conflicts during which effort and expected profits decline gradually. To manage a conflict, the principal uses a combination of informal promises and formal commitments that evolves with the duration of the conflict.

More specifically, suppose that the principal promises the agent a bonus if he provides the agreed-upon effort level, but she makes this promise contingent on her privately observed opportunity costs being low. If the principal does not pay the bonus, then the agent has to punish her. The challenge is to structure the punishment in the most efficient way.

Consider a period in which effort and expected profits are at their highest level and suppose that the principal then faces high opportunity costs in a number of consecutive periods. In the first phase of the conflict, the agent punishes the principal by gradually reducing effort. Since the production function is concave, these effort reductions become increasingly costly. At some point, it becomes more efficient for the agent to punish the principal by insisting on a contractible wage that is not contingent on the principal's opportunity costs. In the second phase of the conflict, effort is therefore constant but contractible wages are increasing over time. Finally, contractible wages reach their highest sustainable level and the conflict enters its third and final phase during which effort and wages are constant. This final phase lasts until there is a period with low opportunity costs. In that period, the principal pays her debts to the agent with a single large bonus payment and the agent returns immediately to the efficient-effort level.

Li and Matouschek also consider an extension of their model in which the principal is liquidity constrained: the payments she can make in any period are constrained by the amount of effort provided in that period. They show that such liquidity constraints slow down recoveries, since the principal can no longer pay her debts to the agent with a single bonus payment and instead spreads this payment over multiple periods.

Li and Matouschek find support for their predictions from two cases we discuss in Section 6.1: Credit Suisse First Boston (CSFB) and (further history from) Lincoln Electric. For example, at CSFB, in line with this model, management's response in the first year of a shock was to promise superior bonuses when times got better, but their response in the second year was to offer guaranteed pay raises immediately. During this evolution of management's responses, the bankers did not switch abruptly from cooperation to defection, but they might well have decreased their effort, again in line with the model.

5.3.3. *Might Cooperation Be Hard to Sustain, Even Once Initiated?*

As a stark example where cooperation collapses, imagine enriching the repeated trust game from Section 4.1 so that player 2's payoffs begin as (C, D, P) , but in each period there is a probability that 2's payoffs are publicly observed to have shifted permanently to (C, D', P) , where $D' > D$ and $r > (C - P)/(D' - C)$. In this case, cooperation will end after player 2's payoffs shift, but cooperation can nonetheless start at the beginning of the game, provided that r is sufficiently below $(C - P)/(D - C)$, relative to the probability that player 2's payoffs shift.

Richer versions of this idea explore how cooperation can collapse from transitory shifts in player 2's payoffs, slower learning about permanent shifts in 2's payoffs, or other subtler causes. For example, McAdams (2011) models a stochastic partnership under symmetric information. There can be learning about the partnership's productivity, which can evolve, and the partners' actions can affect future productivity. A vicious cycle can arise where a negative shock bodes ill for the future, reducing the value of the ongoing relationship and possibly causing the partners to work less hard now, thereby further imperiling the relationship.

Whereas the state variable in the McAdams model is public information, Chassang (2010b) studies the effect of the global-games perturbation, where each party receives a low-noise, conditionally independent private signal of the state. In particular, Chassang analyzes a dynamic exit game, where staying is akin to cooperation and exiting is akin to defection. The extreme equilibria—those with most staying and most exiting—involve threshold strategies, where a player stays for the next period only if her noisy signal is sufficiently high. In such equilibria, each player is uncertain about the other's behavior, and this makes it difficult to coordinate their expectations about play. Even as the noise goes to zero, the conditions needed for cooperation are stricter than they would be under complete information. Moreover, these conditions now depend on new considerations: now not only the predatory incentive (to defect when one's partner is cooperating) but also the preemptive incentive (to avoid cooperating when one's partner defects) matter for whether cooperation can be sustained.

As the first of two more applied examples, in the related model of deterrence of Chassang and Padro i Miquel (2010), weapons stocks are unambiguously helpful in deterring war under complete information, but they may be harmful with vanishingly little private information if they greatly reduce the payoff from being the second party to engage in war, even if they also somewhat reduce the payoff from being the first. And in the second example, Chassang and Takahashi (2011) analyze a related model of the repeated prisoner's dilemma. Here the sucker payoff from being the victim of defection—not just the temptation payoff from being the defector—matters for whether cooperation can be sustained. Furthermore, in the Chassang and Takahashi model, grim-trigger strategies need not be the best way to sustain cooperation: selective punishment strategies that punish defectors while attempting to reward cooperators sustain higher levels of cooperation by reducing the overall cost of being the victim of defection.

Finally, cooperation can also collapse when there is private monitoring, such as in the subjective-evaluation agency models by Levin (2003), MacLeod (2003), Fuchs (2007), and Maestri (2012). A key insight of this literature is that there must be inefficiency on the equilibrium path: to provide incentives, the agent must do worse when outcomes are poor; but to induce truthful revelation of outcomes, the principal must be indifferent across alternative output reports. See Malcomson (this volume) for more on private monitoring in relational incentive contracts.

6. The Clarity Problem

In Sections 5.2 and 5.3 we explored the credibility problem in relational contracting: should one party believe another's promise? In this section we finally reach the clarity problem in relational contracting: can one party understand another's promise? Both of these problems arise naturally if formal contracts are infeasible or imperfect because the parties are unable to articulate *ex ante* or to verify *ex post* their roles in and rewards from cooperating together. So far, the relational-contracts literature has focused on the credibility problem that arises when roles or rewards cannot be verified *ex post*. Here we begin to explore the possibility that roles or rewards cannot be fully articulated *ex ante*.

As an example familiar to many, consider the tenure criteria in an academic department. In principle, a department could use solely formal criteria (here meaning objective weights on objective measures); for example, department policy could be "you get tenure if and only if you have at least three papers in *Econometrica* by the fall of your sixth year." More typically, however, a department's tenure process allows some role for judgment and discretion—perhaps for reasons similar to those that led Lincoln Electric to complement its objective piece rate with a discretionary bonus, as described in Section 4.2. At Lincoln, decades of shared experience seem to have given managers and workers a shared sense for how the bonus program is supposed to be run (although see Section 6.1.2 for an interesting twist in this story). Likewise, in many departments, senior faculty seem to have a shared sense for what their department's tenure criteria are. The issue we explore in this section, however, is the possibility that these senior faculty cannot easily communicate their shared sense to a new assistant professor, or even to an outside senior hire. Clearly, such phrases as "have an impact on your field," "publish good papers in good journals," or "contribute appropriately to the work of the department" are only a beginning.

As a second example, recall from Section 4.3 the relational contract that supports pro-publication behavior by scientists and managers at science-driven pharmaceutical firms like Merck. Notice how much shared information is required. First, there is extensive task knowledge about the state-dependent actions that constitute pro-publication behavior. Each scientist has to learn not only what kinds of knowledge are potentially useful in the search for new drugs, but also how to behave almost like an academic scientist—including subtle expertise about which conferences to go to, what kinds of papers to publish, and, most importantly, how to make trade-offs between behaving like an academic and actively engaging in drug discovery. Likewise, each manager has to learn what kinds of rewards and recognition matter to research scientists—employees who famously care more about the design and reception of their work than they do about monetary rewards. All this learning, by scientists and managers, is significantly complicated by the fact that appropriate behaviors will likely vary across fields (e.g., cardiology versus

neurology), across disciplines (e.g., chemists versus biologists), and with the particular circumstances of the firm (e.g., How strong are the firm's market and patent positions? How close is it to finding other new drugs?).

In short, as Winter and others studying the inspiration problem described in Section 5.1.3 have emphasized, task knowledge is often both extensive and difficult to communicate. We further emphasize that management practices relying on relational contracts have additional information requirements, which we call relational knowledge. Roughly, if task knowledge concerns what is supposed to happen, relational knowledge is its complement: what will happen if parties do not do what they are supposed to (i.e., in game-theoretic terminology, what is supposed to happen off the equilibrium path)? We note that, hard as it might be to communicate task knowledge, there is a sense in which relational knowledge is more difficult to communicate, because events off the equilibrium path are not supposed to happen, so there may be less opportunity for the parties to learn from experience about relational knowledge than about task knowledge.

Given the shared task and relational knowledge underlying pro-publication behaviors by scientists and managers, we find it impressive that Merck and some other pharmaceutical firms managed to succeed at this management practice. We also find it unsurprising that other firms were slower or less successful at implementing this practice; see Cockburn et al. (2000). What we ask readers to imagine here, however, is how Merck got this practice going in its early days. We find it easy, for example, to imagine a recruiter trying to explain the novel approach to a newly minted postdoc (who, let's say, would otherwise be considering academic jobs) by appealing to a rough metaphor, such as "it's almost like being an assistant professor." We return to both of these ideas—difficulties in communication and the related reliance on metaphors—in Section 6.2.

Motivated by these examples of tenure and pro-publication behaviors, we proceed in two steps. First, in Section 6.1, we provide brief descriptions of case studies that can be interpreted as examples where the parties may not have had a shared understanding of their intended relational contract. Then, in Section 6.2, we discuss recent evidence and theory about how parties might build a shared understanding. If the parties have identical interests, this work explores the resolution of the clarity problem in its pure form, without any complications from the simultaneous presence of the credibility problem that arises from imperfectly aligned interests. Exploring the interaction between these two problems is a leading issue for further research, both theoretical and empirical: if one party does something unexpected, does the other attribute it to miscommunication or gaming?

6.1. Case Studies of Imperfectly Shared Understandings

In this section we discuss the possibility that parties may not have a shared understanding of their roles in and rewards from cooperating together. In Section 6.1.1 we consider examples where the possibility of misunderstanding surfaced relatively early in the relationship. In Section 6.1.2 we turn to examples that arose after decades of a successful relationship.¹⁷

17. This section draws on Gibbons (2010) with permission from the *Annual Review of Economics*, Volume 2, © 2010 by Annual Reviews, <http://www.annualreviews.org>.

6.1.1. *Imperfectly Shared Understandings Early in Relationships*

Empirically, it seems unsurprising that parties may not have a shared understanding early in their relationship. Theoretically, however, we know of no models exploring how this possibility affects relational contracting. That is, even in relational-contract models with learning, such as those discussed in Section 5, one party may be disappointed at what the other turns out to have known all along, but the parties are never surprised to find that they have misunderstood each other. We return to this issue in Section 6.2.3.

We use two case studies to illustrate the possibility of imperfectly shared understandings relatively early in relationships. Naturally, these case studies also admit other interpretations. In particular, both case studies we describe here can be interpreted as cousins of the types models in Section 5.2, such as Halac's (2012) model, where the principal has private information about her value from continuing the relationship.

First, consider Stewart's (1993) account of how Credit Suisse, a large European bank, bought the U.S. investment bank First Boston, taking the company private under the name CS First Boston (CSFB). At the time of the deal, there was much speculation about how the new firm would handle the inevitable differences in culture and firm policies, especially with regard to bankers' compensation. Although we cannot know the details of managers' attempts to identify and resolve these differences, the events that unfolded in the years immediately following the change in ownership reveal a lack of shared understanding about the determination of the bankers' annual bonus payments.

In the first 2 years that Credit Suisse controlled CSFB, all firms in the investment-banking industry performed poorly, and CSFB bankers received bonuses that were lower than the historical average but comparable to bonuses paid at other investment banks. In the third year, however, CSFB performed better than previously and yet worse than its competitors, and Credit Suisse paid bonuses that were above bonuses at CSFB in the first two years but lower than those at other firms in the third year. A crisis ensued. In brief, CSFB bankers asserted that the bonus policy in their industry was to match the market, meaning that bonuses should be competitive with bonuses at other top-bracket firms. In contrast, the Swiss asserted that in *their* industry the bonus policy was pay for performance, meaning that a banker's bonus depended on how he and his bank performed. Note that these two policies make identical pay prescriptions when all firms in the industry have the same performance, as was broadly true in the first 2 years.

We make no attempt to adjudicate the parties' competing claims in this case. Nonetheless, we do draw two lessons from this case. First, it seems unlikely that the parties had common knowledge *ex ante* about the determinants of the bonus (since they could not then offer each other conflicting claims about what they had understood). Second, in expressing their claimed understandings, both parties use metaphors: match the market and pay for performance. That is, although one could imagine solely formal bonus plans receiving such labels (e.g., "pay the same total bonus pool as at Goldman Sachs" or "pay 30% of profits as bonuses"), such formal contracts were clearly not what the parties were saying they had understood to be in place.

As a second example, consider the Danish hearing-aid firm Oticon. In 1990 the firm launched radical empowerment of its product-development projects with a memo from CEO Lars Kolind titled "Think the Unthinkable" that envisioned project groups as akin to mini-businesses, each with its own resources, timeline, goals, and incentives. The initial results were strong and were attributed to the new organization; subsequent commentators used language like "bringing the market inside the firm" (for a discussion, see Foss 2003).

We don't know whether Oticon's executives explicitly used the market metaphor to introduce the new organization, but suppose they did (or, suppose the metaphor was used by contemporaneous commentators). Oticon's project managers could then interpret the market metaphor as an initial approximation (akin to "almost like being an assistant professor") or as something closer to a literal promise to run the firm as an open market. If the former, then they would have expected the metaphor to be refined as events unfolded, clarifying just how much autonomy project managers actually would have in the new organization; if the latter, then they may have been surprised and upset (perhaps akin to the Wall Street bankers at CSFB) when the firm's Projects and Products Committee (staffed by the CEO and three senior managers) tightened control after the firm's portfolio of projects spiraled into disarray. The reaction of the firm's employees to the change suggests that the latter was the closer to the case.

Again, the possibility we take from this case is that the parties did not have a shared understanding *ex ante*. Perhaps no one thought that the market had literally been brought inside the firm, in the sense that project managers were now identical to entrepreneurs in their control over project decisions, and perhaps everyone understood that the old way of running the firm (before "Think the Unthinkable") no longer applied. But the gap between these extremes is very large, and we find it easy to imagine that project managers might have thought or hoped that the new way the firm was to be run would be closer to the former than the latter.

6.1.2. *Imperfectly Shared Understandings in Decades-Old Relationships*

In 1981, the cover of Johnson & Johnson's annual report read "Decentralization = Creativity = Productivity" (Aguilar and Bhambri 1986: 1). For decades before and after, J&J was comprised of many disparate and nearly autonomous healthcare businesses, ranging in size from a handful to thousands of employees. Although the substantial freedom given to each business was widely believed to increase innovation and initiative, it also made coordination more difficult.

This tension is by no means unique to J&J. For example, Alfred P. Sloan's (1963: 429–435) account of his years at General Motors is similar:

It has been a thesis of this book that good management rests on a reconciliation of centralization and decentralization, or "decentralization with co-ordinated control." . . . It must be apparent that co-ordinated decentralization is not an easy concept to apply. . . . The balance which is struck between corporate and divisional responsibility varies according to what is being decided, the circumstances of the time, past experience, and the temperaments and skills of the executives involved. . . . [T]he responsibility for determining administrative organization is a continuing one.

One example of this tension between initiative and coordination at J&J arose as hospitals found it increasingly burdensome to work directly with so many separate businesses, requesting that J&J instead create a single organization that could handle sales and distribution for all its relevant divisions. Although J&J's competitors moved rapidly to this structure, the firm delayed making the change for several years, plausibly because it believed that having corporate headquarters create this new sales and distribution business would raise serious questions as to the nature of the relational contract between headquarters and the existing businesses: if headquarters was prepared to limit these businesses' historical autonomy in this way now, what would happen in the future?

Our reading of this episode in J&J's history is that there was, of course, never any doubt about whether corporate headquarters *could* make this change in the organization structure, but there was concern about whether and how it *should*—in the sense that doing so might be interpreted by some as reneging on an understanding of how the tension between initiative and coordination was to be managed at J&J. Presumably, this episode concerning sales and distribution to hospitals was not the first time this tension surfaced at J&J, nor was it the last (e.g., see Barrett 2003). As Sloan put it, the “responsibility for determining administrative organization is a continuing one.” Or, in our terms, even decades of shared experience may not fully clarify a crucial relational contract.

As a second example where decades of a successful relationship nonetheless left key decisions in doubt, we update the history of Lincoln Electric begun in Section 4.2. As Hastings (1999) describes, in the early 1990s rapid international expansion led to serious financial difficulties at Lincoln. For example, in 1992 the firm as a whole lost \$46 million, even though operations in Cleveland had an excellent year. These losses forced Lincoln to consider how large a bonus pool to pay the Cleveland workers. (Recall that Lincoln's bonus is completely discretionary and not governed by contract or formula.) Broadly similar to CSFB, there were two possible views on the bonus Lincoln should pay in Cleveland: a large bonus based on Cleveland's excellent results, or a small or zero bonus based on results for the firm as a whole. Because Lincoln's overseas expansion was recent, this distinction between Cleveland profits and aggregate profits had never arisen.

In the event, Lincoln's managers decided to conform to the Cleveland workers' interpretation of the contract and paid \$52 million in bonuses at the end of 1992, even though the firm had to take on debt of \$250 million (63% of equity). Lincoln's financial difficulties continued into the following year, while the Cleveland operation continued to excel. Lincoln's management team launched an intensive communication effort to implore the Cleveland workers to expand their efforts and hours even further to make up for the firm's aggregate losses and failed production efforts abroad and to rescue the company from violating covenant agreements. Workers responded by redoubling their efforts and raising the capacity utilization of the Cleveland plant from roughly 75% to nearly full capacity. This required current workers to work weekends and holidays and to give up vacation time. These efforts played a major role in the firm's being able to honor its loan agreements, and the firm paid out \$55 million in bonuses at the year's end despite again having aggregate losses.

We interpret these events as suggesting that in some important respects the relational contract that had developed at Lincoln was incomplete. When the company operated only in Cleveland, the question of whether the bonus should reflect plantwide or firmwide profits was immaterial; it was only after the company was operating around the world that it became clear that management and employees might have different understandings of their relational contract. Under these conditions Lincoln's decision to honor their employees' understanding of the relational contract represented a substantial investment in strengthening their relationship—an investment whose power was illustrated in the following year by the employees' continued commitment to the firm.

6.2. Toward Modeling the Clarity Problem

As noted above, this second approach to understanding implementation difficulties that might arise through relational contracts—based on the clarity problem rather than, say, path

dependence—is much more speculative; in fact, we know of no existing models. However, we are mindful of Krugman's (1995: 27) dictum that “like it or not, . . . [in economics] the influence of ideas that have not been embalmed in models soon decays.” We therefore hazard the following avenues for future research.

6.2.1. Team-Theoretic Experiments and Models

There are some fascinating laboratory studies and models of parties trying to develop a shared understanding. To date, however, most of these analyses assume that the parties have identical interests. We discuss this work here, because it gives exciting hints about what might be done with imperfectly aligned interests, as in our settings of interest.¹⁸

In a pair of beautiful laboratory investigations, Weber and Camerer (2003) and Selten and Warglien (2007) study how parties learn to communicate. Weber and Camerer show one subject 16 pictures of people in office settings, and a light goes on next to one of the pictures. The other subject sees the same 16 pictures but in a different order and without the light. After the light goes on, the first subject picks up a phone and speaks to the second; each subject gets a payoff if the second subject can touch the correct picture in a specified amount of time. After the specified time has elapsed, the second subject learns which picture had the light next to it.

Selten and Warglien conduct a parallel exercise but with a much simpler state space: instead of 16 pictures that are somewhat hard to describe, they use 6 simple figures in a cross-product structure—a circle or a triangle on the outside of each figure, and nothing or a dot or a plus on the inside. If the subjects could use a phone, the exercise would be too easy, because the first subject would simply say “circle with a dot in it.” But, having simplified the state space, Selten and Warglien also simplify the message space, allowing the first subject to send characters from a small, abstract message space, such as {7, J, &, *, \$}. The advantage of simplifying the message space in this way is that Selten and Warglien can easily capture the language used by the subjects over time. For example, the second subject might learn that 7J means a circle with a dot in it.

Formally, both these papers report on observations of players attempting to build a shared language during repetitions of a game like the following: (1) player 1 observes the state of the world, $s \in S$; (2) player 1 sends a costless message to player 2, $m \in M$; (3) player 2 chooses an action $a \in S$; (4) payoffs to each player are $U(s, a) = 1$ if $a = s$ and $U(s, a) = 0$ otherwise; (5) player 2 observes s . Thus, player 1 would like to send a message $m(s)$ that tells player 2 that the state is s (so that player 2 will then choose the action $a = s$). The problem is that, at least in the early going, player 2 has little basis for understanding player 1's messages, especially in the setting used by Selten and Warglien.

Both papers find that different pairs of players develop different languages, even though these pairs are playing in the same environment (except for the random realizations of the states of the world over time). Because these are common-interest games, we interpret the knowledge being communicated as task knowledge, not relational knowledge. In particular, there is no concern with defection or punishment in a common-interest setting. Nonetheless, consistent with the large literature on the difficulties of communicating tacit knowledge, different

18. This section draws on Gibbons and Henderson (2012), “Relational Contracts and Organizational Capabilities,” *Organization Science*, by permission from the Institute for Operations Research and the Management Sciences, 7240 Parkway Drive, Suite 300, Hanover, MD 21076, USA, as well as on Gibbons (2010) with permission from the *Annual Review of Economics*, Volume 2, © 2010 by Annual Reviews, <http://www.annualreviews.org>.

pairs of players take different lengths of time to develop a shared understanding, and different pairs hold different shared understandings once they reach them. From this lab evidence, we find it only a small stretch to imagine that similar forces could cause reasonable people to hold different understandings in situations like those at Lincoln Electric or CSFB. Of course, the issue at these two companies involved bonuses, so these were not common-interest settings; rather, the problem of credibility also arose because there was imperfect alignment of interests.

Turning to theory, in a game with Pareto-ranked Nash equilibria and zero payoff to all players out of equilibrium, a focal point may command everyone's attention. But what if multiple Nash equilibria offer the best payoff, or some of the payoffs out of equilibrium are very negative (making coordination failure very costly)? Furthermore, what if the parties cannot easily discuss the opportunities they perceive (as when an organization has congealed into functional silos, and, say, the production and marketing groups have only a rudimentary language in common)?

Crawford and Haller (1990) provide a pioneering analysis of such issues in a repeated coordination game. One of their important insights is that, absent a common language about actions (e.g., about the detailed production and marketing activities that might be useful in concert), the parties' shared experience may facilitate coordination by allowing decentralized partners to label their action spaces in terms of past play.

Blume and Franco (2007) continue in this spirit, analyzing an n -player, m -action coordination game with k "successes" (Nash equilibria paying 1 to all players) and $m^n - k$ "failures" (action-tuples where all players receive 0). The parties know the number of successes but not the action-tuples that will achieve them. Each player observes his own actions and payoffs but not the actions of other players. The optimal strategy entails mixing (until a success is reached), so that the players do not all change their actions in lock-step (which would cause the players to revisit unsuccessful action-tuples). As a result of this mixing, different groups of n players could take different durations to find a success.

Whereas Blume and Franco call their work "Decentralized Learning from Failure," Ellison and Holden (2012) take a more hierarchical approach, in which a principal instructs an agent. Each period, (1) the agent observes the state of the world, $s \in S$; (2) the agent chooses an action $a \in A$; (3) the principal sends a message $m \in M$ to the agent; and (4) both parties receive the payoff $\pi(a, s)$. A novel aspect of the model is that the principal cannot communicate about a state until that state has been realized. More specifically, the principal's message dictates that if a future state is within a specified neighborhood of this period's state, then the agent should take a specified action. When messages are of this form, there are more and less useful realizations of s that may occur in early periods; in particular, a useful realization is one that allows the principal to specify a broad neighborhood. As a result, dyads whose early realizations of s are useful will perform better.

Finally, as a first step away from common interests, there are a few papers that consider the costs that parties bear in trying to communicate with each other, focusing more on whether the parties will choose to incur these costs and what quality of communication will then occur, rather than on what language is then used to communicate. The initial paper in this spirit is Dewatripont and Tirole (2005), who treat the problem as one of moral hazard in teams: will a sender and a receiver both invest sufficiently to allow an intelligible message to be sent by the one and understood by the other?

Closer to our concerns, Li (2012) studies a setting where the clarity problem is difficult to resolve in organizations, because (1) propagation of tacit knowledge requires shared experience between individuals, and thus can diffuse only gradually across the group and (2) propagation of shared knowledge is privately costly, so self-interest may stymie the propagation of knowledge. Initial conditions in an organization may then have a persistent effect on the extent to which knowledge is propagated across the organization and thus the extent to which the clarity problem is resolved for the organization as a whole. For example, if an organization expands too quickly for the diffusion of knowledge to keep up with the expansion, the resultant incomplete propagation may persist even after the period of rapid growth has ended.

6.2.2. Categories, Metaphors, and Beliefs

We conclude this section with a speculative discussion about the sources and consequences of differing beliefs about relational contracts.

To illustrate what people might do when struggling to articulate a proposed relational contract *ex ante*, we return to the two settings discussed at the beginning of Section 6. First, in attempting to communicate tenure standards, senior faculty might cite specific examples, such as “Jane got tenure, but Joe did not.” Second, in the early days of pro-publication management at Merck, we imagined a recruiter saying “It’s almost like being an assistant professor.” We see these as complementary approaches to communicating a state-dependent action rule $a^*(s)$: the former conveys specific examples such as $a^*(s_1) = a_1$ and $a^*(s_2) = a_2$, whereas the latter offers an alternative rule $a(s)$ that is somehow close to $a^*(s)$.

Research in cognitive psychology and linguistics has explored related issues concerning categories and metaphors. Rosch (1973, 1975) departed from the view that categories are defined by a set of properties shared by all their members, showing that there can be more- and less-representative members. Later work such as Osherson et al. (1990) explored category-based induction. For example, if you are told that lions and tigers use norepinephrine as a neurotransmitter, what is your belief that rabbits do, too?

Turning to metaphors like the Merck example, Lakoff and Johnson (1980: 3) argue that “Metaphor is pervasive in everyday life, not just in language but in thought and action.” Lakoff (1987: xi) then builds on Rosch’s theory of prototypes to connect categories and metaphors to human reasoning: “categorization [is] the main way that we make sense of experience.” With both category-based induction and metaphors, two things seem plausible: first, there can be better or worse examples $a^*(s_1) = a_1$ and $a^*(s_2) = a_2$ and metaphors $a(s)$; second, reasonable people might draw different conclusions from specific examples and metaphors. See Mullainathan et al. (2008) for an initial economic model of some of these ideas.

We so far see four interesting opportunities for further work on communicating relational contracts via categories and metaphors. First, differences in beliefs about what will happen off the equilibrium path can lead to different equilibria. For example, Greif (1994) interprets the cultural origins of institutional structures governing commercial transactions as a difference in beliefs about what would happen if a trader claimed malfeasance by an agent. In Genoa, individualist cultural beliefs encouraged the use of family firms to mitigate the costs of defection, whereas among the Maghribi an expectation of community enforcement made family firms unnecessary. Fudenberg and Levine (2006) explore related issues.

Second, if multiple rules $a^*(s)$ can fit a finite history $\{a^*(s_1) = a_1, \dots, a^*(s_n) = a_n\}$, there may be a role for reinterpretation of the history to clarify the proposed equilibrium going

forward. Sabel (1993) describes something like this in industrial districts in Pennsylvania, and Bates et al. (1998) do likewise for conflicts in Zambia and the Balkans. See also Gibbons (2010: 358) for a discussion of how, in the early 1990s, Hewlett-Packard attempted to reinterpret decades without a layoff as a guiding value rather than an ironclad commitment.

Third, recall from the CSFB and Oticon cases in Section 6.1.1 that the parties began a relationship but later claimed to have different beliefs about what equilibrium they were playing. Such scenarios may be loosely related to Fudenberg and Levine's (1993) definition of self-confirming equilibrium, in which players' understandings of each other's strategies need agree only on the equilibrium path. However, in a self-confirming equilibrium, events off the equilibrium path never occur. See Ryall (2003) and de Figueirde et al. (2006) for applications to strategy and the American Revolution, respectively.

Finally, one can ask what happens after people misunderstand one another. In Ettinger and Jehiel's (2010) theory of deception, parties have only coarse knowledge of one another's strategies. Their approach connects nicely with the fundamental attribution error (Ross 1977), in which parties over-attribute another person's behavior to that person's permanent type, rather than to transitory shocks to that person's environment. Heath and Staudenmayer (2000) and Repenning and Sterman (2002) discuss related attribution errors in attempts to coordinate and cooperate, respectively. Further work on attribution errors seems likely to be one important way to explore how the problems of clarity and credibility may interact.

7. Conclusion

In this chapter we have explored the role of relational contracts in sustaining persistent performance differences among seemingly similar enterprises. We began by reviewing the evidence that PPDs among SSEs exist and are economically significant across a wide range of industries and geographies, and we summarized the evidence that these performance differences are correlated with variation in management practices. Critically, we suggested that the successful performance of many of these practices cannot be easily articulated *ex ante* or verified *ex post*, and we used three qualitative accounts to suggest that many (most?) competitively significant management practices rely on the presence of relational contracts.

We then turned to the question of why managerial practices, if they do indeed play a significant role in enabling PPDs, do not diffuse more readily. We reviewed the rich literature exploring this question and suggested that it can be complemented by a focus on the difficulties firms may encounter in building relational contracts. Here we described three barriers firms may face: bad parameters, bad luck, and bad communication. First, the relational contracts operated by leading firms may be infeasible or prohibitively costly for underperformers to implement. In this case, measured PPDs are due to bad parameters (i.e., unmeasured heterogeneity in the costs or benefits of the relevant relational contract). Second, the sequence of events during a relationship can produce measured performance differences among *ex ante* identical enterprises: achieving perfunctory cooperation can make it harder to achieve consummate cooperation; cooperation, once built, can be fragile; and cooperation may be difficult to build in the first place. Third and less conventionally, we suggested that the problem of clarity—difficulty in communicating the extensive task and relational information that underlies many relational contracts—may also play a role in making it difficult to build unfamiliar relational contracts.

At our most ambitious, we hope that our specific discussion of relational contracts, managerial practices, and PPDs will help define and encourage research in organizational economics about what, exactly, managers do. At a broad level, we find the distinction between analysis (deciding what to do) and administration (getting the organization to do it) extremely useful. Returning to our specific focus, if the impediments to building the relevant relational contracts include bad parameters, bad luck, and bad communication, we could imagine managers working to reduce each of these impediments. For example, regarding bad parameters, in Section 5.2 we mentioned models in which network structure and worker types play key roles in limiting the feasible set of relational contracts, and managers might work to change such parameters. Similarly, regarding the models of bad luck in Section 5.3, managers might work to change the likelihood of bad luck—such as building a rainy-day fund so that being liquidity constrained is less likely. Finally, regarding bad communication (i.e., the clarity problem discussed in Section 6), managers might take seriously that they and others not only talk but also think in categories, metaphors, and codes, all of which can lead first to miscommunication and then to attribution errors.

Of course, all these approaches—to changing parameters, luck, and communication—are not only possible managerial activities but also possible avenues for research. And while theoretical work on these issues would be exciting, this chapter as a whole cries out for empirical work focused sharply on relational contracting. Gibbons and Henderson (2012) give some illustrations of relational contracts in laboratory experiments and field data on contracts between firms, but there is perilously little analogous work inside organizations. One promising start, however, is Bloom et al. (2012d), who use the large-sample methodology of Bloom and Van Reenen described in Section 3, but complement it with auxiliary data on trust scores between regions. Bloom et al. find that multinational subsidiaries located in a country that the parent firm's country tends to trust will be more decentralized (measured, say, by expenditure constraints) than subsidiaries located in a country that the parent firm's country does not trust. We see this as an enormously promising start toward empirical work on the issues we have raised here, but clearly much more remains to be done.

Finally, moving from our main focus on productivity to the neighboring notion of profitability, much of what we have described can be cast in reduced form as saying that relational contracts are an investment that might improve an enterprise's productivity. But investments are costly, and there are typically many such investments a firm could make. One intriguing question is therefore whether and how investments in relational contracts might act as substitutes or complements to other more conventional assets. Both Toyota and Southwest Airlines, for example, appear to have used investment in relational contracts as routes to enter industries that had for many years been dominated by firms with harder assets—superior brands and prime geographic locations. We suspect that exploring the interaction between relational contracts and other forms of investment will be a productive target for future research.

Corporate Governance

A Critical Assessment

Benjamin E. Hermalin

1. Introduction

People invest in organizations. They invest their human capital, and they invest their physical capital. In exchange, they expect some return, and all else equal, they would like the organizations in which they invest to maximize that return. A problem arises, however, when the people who invest in an organization are not the same people who control the organization. Lack of control makes the investors vulnerable to mismanagement of the organization, misallocation of its resources, or even misappropriation of their returns. In short, investors fear that their returns will not be maximized, because their desires are not necessarily aligned with those of the controlling parties. In response to these fears, investors will wish to put in place various institutions to constrain the controlling parties to better act in their interests. In short, they will put in place some sort of governance structure for the organization.

Although this problem is endemic to all organizations (consider, e.g., the concerns of a philanthropist worried that a charitable organization will not make the best use of her money), it has proved to be of critical importance with respect to corporations (especially, for-profit corporations).¹ In the corporate setting, the parties typically deemed to have control are management and, if they exist, dominant shareholders. In some cases, the controlling parties are both (e.g., companies dominated by a single family, as the Ford Motor Company was historically by the Ford family or as many companies around the world are today).

The potential misalignments of incentives in corporations are many. For instance, managers are more inclined to tolerate their own incompetence than are shareholders. They are also unlikely to see eye-to-eye with shareholders about managerial amenities, such as lavish offices, corporate jets, and the like. The terms of an asset transfer from one firm to another could be disadvantageous to the first firm (and hence the majority of its investors), but advantageous to its dominant shareholder if the other company is one in which she owns an even greater proportion.²

1. There is a limited literature on the governance of nonprofit corporations. See, for example, Bowen (1994) and Ehrenberg (2004).

2. Johnson et al. (2000) refer to such transfers as “tunneling.”

Concerns about corporate governance,³ in particular, the issues that arise when investors and controlling parties are not one and the same, are longstanding. Smith (1776) is an early, if not the earliest, example in economics:

The directors of such companies, however, being the managers rather of other people's money than of their own, it cannot well be expected that they should watch over it with . . . anxious vigilance . . . Negligence and profusion, therefore, must always prevail, more or less, in the management of the affairs of such compan[ies]. [Book V, Part III, Article I, "Of the Publick Works and Institutions which are necessary for facilitating particular Branches of Commerce," paragraph 18]

The modern era of economic interest in corporate governance appears to have started in the 1920s, when initially the focus was on financial reporting.⁴ Berle and Means (1932) was perhaps the most important early modern work, and it directly influenced a number of reforms undertaken by the New York Stock Exchange (NYSE).⁵ Berle and Means were among the first to note that the stark separation of ownership and control, common to the modern corporation, created a number of potentially serious problems. The 1950s and 1960s saw economists looking at issues of executive compensation and starting to model the divergence of interests between owners and managers (see Lewellen 1968 as an example and survey of the former; Williamson 1963 is a noteworthy example of the latter). An article of great importance in the evolution of the field was Jensen and Meckling (1976), which, in addition to surveying some of the literature to that point, identified many of the issues that have continued to occupy economists working on corporate governance to this day. As with much of life, good timing is essential, and the renewed interest in corporate governance generated by Jensen and Meckling occurred just as the tools of information economics, game theory, and contract theory were coming to the fore in economics. These tools led to an explosive growth in the literature on organizations generally (as this handbook attests) and on corporate governance specifically. For instance, Becht et al. (2003) cite more than 550 works in their survey of corporate governance, almost all of which are dated 1980 or later; surveying just the literature on boards of directors, Adams et al. (2010) cite approximately 170 works, with the overwhelming majority having been written after 2000.⁶

This vast literature has generated many survey pieces. In addition to the two just mentioned, a sample of such surveys includes Shleifer and Vishny (1997), Tirole (2001), Farinha (2003), and Zingales (2008) on the literature overall; John and Senbet (1998) and Hermalin and Weisbach (2003) on boards of directors; Bertrand (2009) on CEOs; Devers et al. (2007) and Edmans and Gabaix (2009) on executive compensation; Bhagat and Jefferis (2002) on econometric issues; Denis and McConnell (2003) on international governance; and Durisin and Puzone (2009) on the intellectual structure of governance research. One can rightly ask whether another survey

3. Becht et al. (2003: 5) suggest that the term "corporate governance" was first used in 1960. The field is obviously considerably older.

4. An important work in this regard was Ripley (1927), which was initially a series of articles in the *Atlantic Monthly*. Baskin and Miranti (1997: 197) describe Ripley's work as a "widely read polemic." Scholz (1928: 178) discusses "the commotion which was aroused in financial and official circles" by its publication.

5. See Baskin and Miranti (1997: 200) for a discussion of the influence of Berle and Means on policy.

6. Adams et al. (2010: 64) report that more than 200 papers on boards—not all of which they cite—were written in 2003–2008 alone.

is needed; in particular, given the existence of the aforementioned surveys, the social benefit—even accounting for my egotistical exaggeration of my writing's value—is modest, and given the huge literature, the cost—to me at least—immense. Consequently, I propose a different course of action: this chapter presents an overarching framework from which to assess the issues of corporate governance and a means of framing the existing literature, both empirical and theoretical. Such an approach will, I believe, also be more conducive to suggesting future lines of research than a more traditional survey chapter.

Briefly, the chapter is organized as follows. The next section considers the scope of corporate governance, arguing that it is primarily the study of what happens when investors seek to protect themselves against mismanagement, misallocation, and misappropriation of their investments by those who control the corporations in which they wish to invest. The section thereafter seeks to tie these three Ms to the various economic literatures that have explored these contract and agency problems. Section 4 deals with the fact that governance institutions are arrived at *endogenously*. This has important implications for how empirical work needs to be conducted. Perhaps more importantly, it also has important implications for how that work is interpreted. This second point is explored further in Section 5, where the consequences of the fact that different governance structures govern different firms are discussed. Section 6 focuses on the dispersion of ownership and its consequences. The last two sections are essentially conclusions. The first of these suggests that both the literature and policy have placed too great an emphasis on improving shareholder control. The second sketches directions for future research.

2. What Is Corporate Governance?

I suggested in the previous section that corporate governance is concerned with protecting the interests of investors when they are not the ones wholly in control of the organization. Such a view echoes Shleifer and Vishny (1997: 737):

Corporate governance deals with the ways in which suppliers of finance to corporations assure themselves of getting a return on their investment. How do the suppliers of finance get managers to return some of the profits to them? How do they make sure that managers do not steal the capital they supply or invest it in bad projects? How do suppliers of finance control managers?

For companies in which a few dominant shareholders have control, one could replace “managers” in this quote with “dominant shareholders.” One could, and perhaps should, also extend it to cover all suppliers of capital, including human capital. That said, the economic literature has been almost exclusively focused on the suppliers of finance (Roberts and Van den Steen 2003 and Tirole 2001 are notable exceptions).

One could, following Tirole, take an even more encompassing view: Corporate governance is the means by which the externalities that controlling parties generate are regulated.⁷ With respect to the very largest corporations, we are all affected to some degree by the actions of those in control. Typically, however, the set of individuals affected is more compact: its employees,

7. Tirole (2001: 4) writes “I will . . . define corporate governance as the design of institutions that induce or force management to internalize the welfare of stakeholders.”

customers, suppliers, local community, and, of course, investors—a set typically referred to as the firm’s “stakeholders.”

Although one might properly be concerned with stakeholders’ welfare, such a broad view is not, in my opinion, the best way to look at corporate governance. First, the potential externalities of the controlling parties’ actions are many and include such matters as environmental degradation, the health and safety features of the products and services provided, and even the contribution to rush-hour congestion through transportation decisions. Further, these externalities may generate subsequent effects, so like the proverbial butterfly that triggers a hurricane, everyone is potentially affected by each corporate decision. This is simply too broad a perspective to be workable in terms of analysis or policy setting.

Second, even if one limits the set of externalities at issue, the set of those affected is not necessarily clear. If a firm closes a plant, who would we say has been affected? The workers, certainly, and, perhaps, their local community as well. But what about the workers of companies that supplied the plant and who now face reduced hours or layoffs? What about their communities? Or what about a distant community whose economy is, in part, reliant on remittances from those who work at the plant? In this regard, a plus for focusing on investors is that they are readily identifiable.

Third, if the focus is on externalities, broadly defined, then what distinguishes corporate governance from other forms of environmental or health and safety regulation? Even a cursory examination suggests that there is some value in studying corporate governance apart from the general study of state regulation of economic activity.

One way in which corporate governance stands apart from state regulation generally is that corporate governance involves, to a great extent, the way private parties choose to regulate their own dealings. In contrast, the only way in which all stakeholders, broadly defined, can have a say is if the state intervenes on their behalf. Hence, the focus in the chapter is on the institutions that the private parties—investors and managers—wish to put in place to govern their relations. Although corporate governance is highly regulated by the state, at least in most of the world and in all OECD countries, it is possible to consider corporate governance independently of any state action. Indeed, there is much to be gained by studying corporate governance assuming away state regulation. Only by knowing what private parties would otherwise put in place can we properly assess the wisdom—or lack thereof—in state regulation of firms’ governance structures. To be sure, one cannot wholly ignore the state—or at least the law—with respect to corporate governance; in particular, some institutions could not be created privately absent certain features of corporation law or political institutions.⁸ Nevertheless, the relevant parties still possess considerable freedom in designing the institutions that govern their relation.

8. See, for instance, Hansmann and Kraakman (2000a,b) and Kornhauser and MacLeod (this volume) on this topic. Hansmann and Kraakman argue that private contracting could not replicate the corporation’s legal personhood. The ability of the corporation to own property in its own name—as opposed to having said property owned collectively by the shareholders—is essential for a corporation to function. Beyond simplifying the sale of shares, it also simplifies the corporation’s ability to sell and acquire assets. Perhaps most importantly, legal personhood prevents a shareholder from selling his or her portion of the assets or pledging them as collateral, and similarly, it prevents any creditor of a shareholder from seizing the firm’s assets as a form of recovery should the shareholder default on his or her debts. This is what Hansmann (this volume) refers to as “entity shielding.”

Fligstein (2008) discusses some of the political and societal structures necessary for a corporate governance regime aimed at maximizing firm value to be acceptable.

3. Threats and Responses

Investors fear losing returns due to mismanagement of the organization, misallocation of its resources, or even outright misappropriation. Of these, the last is arguably the biggest threat, at least as measured in terms of the response. A moment's reflection plus some quick back-of-the-envelope calculations will show that expenditures on procedures and methods to detect and discourage misappropriation are the lion's share of resources devoted to the control of the corporation. Every large organization has numerous procedures and methods to detect theft. Examples include auditing of transactions, requiring multiple levels of approval for transactions, and direct monitoring of employee activity. A nontrivial portion of various governance regulations, such as Sarbanes-Oxley, are concerned with these processes.⁹

Misappropriation can occur at any level of the organization. In economics, the study of misappropriation mitigation at the lower levels has been essentially indirect, with the focus on such matters as management of hierarchies, budgeting, and collusion.¹⁰ With respect to misappropriation at the top, the literature has focused on how securities should be designed to mitigate the threat of misappropriation—of nondisgorgement of funds, more specifically. For example, one topic has been how debt can induce those in control to disgorge the returns due investors. Townsend (1979), Jensen (1986), and Hart and Moore (1998) are some examples of this literature.¹¹

A related concern is that a dominant shareholder may engage in self-dealing in one form or another. As Johnson et al. (2000), among others, observe, there is a danger that a controlling shareholder could engage in transfer pricing between companies she controls in a manner that is self-enriching (e.g., she has a firm of which she owns 50% buy inputs from a firm of which she owns 75% at an inflated price). If she is an executive, she could also approve excessive compensation for herself. There are other abuses of minority shareholders that could arise, such as freeze-outs (i.e., effectively compelling them to sell at less than true market value).¹² Here, the principal response to this threat has been legal: it is laws on the protection of minority-shareholder rights that mainly serve to limit such behavior.

Although the distinction between misappropriation and misallocation is fuzzy—has the CEO stolen from shareholders when he has the company purchase a corporate jet?—we can view misallocation as a catch-all for various agency problems that arise because management and investors have differing preferences concerning the use of corporate resources, including managerial time. If we treat management's allocation choices as a hidden action,¹³ then basic agency theory (e.g., Holmström 1979; Shavell 1979; Grossman and Hart 1983) provides a sense of the responses. In particular, we would postulate that companies would provide executives

9. The accounting literature on auditing is vast. A few notable contributions are Baiman and Demski (1980), Fellingham and Newman (1985), Antle and Demski (1988), and Demski and Sappington (1989).

10. See, for instance, Williamson (1975), Tirole (1986), and Mookherjee and Reichelstein (1997).

11. See also Tirole (2006: 132–144) for a survey and discussion of the relevant literature.

12. For more on freeze-outs, see Hermalin and Schwartz (1996) and the citations therein. There is also considerable cross-country variation in the law governing minority-shareholder protections; see La Porta et al. (1997).

13. If allocation decisions are observable to investors, then presumably management and investors will bargain to an efficient agreement concerning these decisions; that is, misallocation will not occur.

with various forms of incentive compensation. (Although it is important to note that incentive compensation is not the only way to respond to the threat of moral hazard; a point to which I return later.)

Executive compensation has been much studied (for two recent surveys, see Bertrand 2009; Edmans and Gabaix 2009). Although I will return to the topic later for a more critical discussion, it is worth mentioning some of the more important work in this area. The popular press and others (e.g., Bebchuk and Fried 2004) have bemoaned the seemingly endless rise in executive compensation. For historical perspectives on this phenomenon, see Hadlock and Lumer (1997) and Frydman and Saks (2010). The literature has also sought to empirically test whether compensation practices are consistent with basic agency theory, with mixed results. For example, agency theory predicts that the optimal compensation scheme should seek to eliminate noise from the performance measure. Bertrand and Mullainathan (2001) find that CEO compensation schemes fail to do so. In contrast, Gibbons and Murphy (1990) do find evidence of relative-performance compensation, a means of reducing noise. As Bertrand (2009) observes, one reaction to the rapid run-up in CEO compensation and the poor record of basic agency theory has been the development of new models of compensation based on changes in the executive labor market or other trends. A partial list of these include Murphy and Zabojnik (2003); Murphy and Zabojnik (2004), Hermalin (2005), Gabaix and Landier (2008), and Terviö (2008).¹⁴

The third investor concern, mismanagement, deals with the competence of the managers. Managers or would-be managers vary in ability. If talent were known *ex ante*, then some market mechanism would allocate managers to firms (for such models, see, e.g., Gabaix and Landier 2008; Terviö 2008). In equilibrium, investors are happy with their manager's ability in the sense that they are unwilling to effect an alternative outcome.

Alternatively, managerial ability could be unknown, including, possibly, by the manager. This is the approach taken in Holmström's (1999) seminal article on career concerns.¹⁵ How well a newly appointed CEO will do is uncertain, but if his previous record is publicly known, then everyone should hold the same beliefs about his ability at the start of his tenure as CEO.¹⁶ In addition to Holmström (1999), other articles adopting a career-concern approach include Holmström and Ricart i Costa (1986), Stein (1989), Hermalin and Weisbach (1998), and Hermalin (2005).¹⁷ In these models, players learn information that improves their estimate of

14. Bertrand (2009: 136–138) offers a critical assessment of the Gabaix and Landier (2008) model with respect to its fit with the empirical evidence.

15. The article first appeared in 1982 in a now out-of-print *festschrift* for Lars Wahlbeck.

16. The underlying logic of career concerns models does not rely on the CEO's being equally ignorant of his ability as other players. Provided there is no scope for him to clearly signal his type, the CEO will still have incentives to engage in the signal-jamming activities discussed here. The technical difficulties that would, however, arise are daunting, which is why the equal-ignorance assumption prevails in these models.

Another variation—unexplored to the best of my knowledge—would be for the CEO to hold a biased estimate of his ability, consistent with some of the excessive optimism and overconfidence models in the behavioral economics literature. See, for example, Malmendier and Tate (2005). Bertrand (2009: 142–144) contains a nice survey of the literature on “cognitively challenged CEOs.”

17. The paper by Gibbons and Murphy (1992) is an empirical study of career concerns. It finds evidence to support the idea that firms increase explicit compensation to compensate for the reduced career concerns CEOs have toward the ends of their careers.

the CEO's ability. Because the CEO is rewarded if his estimated ability increases (e.g., he receives higher salary offers) or punished if his estimated ability falls (e.g., he gets fired), the CEO has an incentive to manipulate what information is learned by the other players. This manipulation can be beneficial to the firm (the CEO works harder, as hypothesized by Fama 1980), but it can also create agency problems (see, in particular, Stein 1989). For instance, the CEO may boost signals of his ability in the short term in ways that have long-term adverse effects that outweigh the net present value of any benefit the boost might create. An example of this is a CEO who behaves in a myopic fashion to boost performance in the short term at the expense of long-term value (see Stein 1989). Alternatively, the CEO may choose actions based on how much or little they reveal of his ability rather than based on the investors' best interests (see Holmström and Ricart i Costa 1986). In other words, investors' desires to limit mismanagement can create costly agency problems.

Another feature of these models is that improving the estimation of CEO ability exposes the CEO to risk.¹⁸ Under certain circumstances, he will require compensation for bearing that risk, which in turn could motivate investors to limit that risk even at the cost of reducing the probability that a bad CEO will be fired. Hermalin and Weisbach (1998) and Hermalin (2005) consider, in different contexts, what the consequences of this tension are for the design of governance structures. In particular, these last two articles examine, among other issues, how the choice of corporate directors—the people who actually dismiss the CEO—balances the desire to be able to get rid of low-ability CEOs against the potential agency problems and compensation demands that monitoring induces.

Monitoring is another response to agency problems. Generally, the job of monitoring top management has been seen as a responsibility of a company's board of directors (although the takeover market and proxy contests can also take on this role). Directors are also supposed to guard against misappropriation and misallocation. As noted earlier, the literature on directors is voluminous (for surveys, see Hermalin and Weisbach 2003; Adams et al. 2010).

This section has briefly considered the various threats investors face and the range of responses they may take (more precisely, the economics literature that considers how to respond). What it has ignored is what determines the choice and degree of response. In particular, because those in control naturally do not wish to be constrained, they can be expected to push back against the various responses, seeking to modify or limit them. This is the topic of the next section.

4. The Determination of Responses: Corporate Governance in an Equilibrium Framework

As noted, investors wish to limit the ability of controlling parties to behave contrary to the investors' interests. Such limits are not in the controlling parties' private interests, and the

18. This can be seen intuitively by imagining that the estimate of ability was based on a signal that is complete noise. Consequently, the posterior estimate would equal the prior estimate. Given there is no change in the estimate, there is no uncertainty and, hence, no risk. In contrast, if the signal is informative (not noisy), then the posterior estimate will put considerable weight on it, meaning, from an *ex ante* perspective, that the posterior estimate is quite variable, which translates into risk for the CEO.

controlling parties can, thus, be expected to resist their imposition. Or, if they cannot block their imposition, then controlling parties will seek compensation for them. This suggests that the corporate governance institutions we observe are the consequence of some—perhaps implicit—bargaining game between investors and controlling parties.

In economics, the standard presumption is that if the private parties are symmetrically informed *at the time* they bargain, they will typically reach an efficient outcome.¹⁹ Because the optimal solutions to agency problems are almost always second best, the efficiency standard is second-best efficiency; a standard often referred to as “constrained Pareto optimality.” Specifically, given the constraints inherent in dealing with agency issues, the outcome is optimal only in the sense that money has not been left on the table. That is, there is no alternative contract or institution the parties could adopt that at least one party favors more than the original and the other no less than the original. Moreover, if we assume—as seems reasonable in this context—an ability to make transfers between the parties, then there is no alternative contract or institution that would generate greater total welfare in equilibrium than the one the parties put in place.

Admittedly, the view that governance institutions could be constrained Pareto optimal is not without controversy. It is a perspective that is certainly at odds with how many commentators on corporate governance see corporate governance.²⁰ How can one use the adjective “optimal” with regard to practices—such as apparently impotent boards and apparently undeservedly huge executive compensation—that seem so suboptimal? Where is the optimality in spectacular governance failures such as Enron, WorldCom, and Parmalat? These commentators are overlooking one or more the following:

1. Even if there were no constraints, this does not imply that investors would get everything they want. As noted, there is bargaining between investors and management, which presumably reflects relative market position. If capital is plentiful but managerial talent scarce, then the returns generated by combining capital and talent will tend to flow disproportionately to the talent.²¹
2. Even if there were no constraints, there are costs to governance, and some amount of failure should occur even in the first-best solution. By way of analogy, auto-related fatalities can be reduced by requiring automobiles to travel more slowly. But there is an opportunity cost to the extra time spent traveling. Hence, society accepts some failures (auto-related fatalities), because eliminating or reducing them would be too costly.
3. There are constraints and they are not trivial. As an analogy, we would not say that Henry Aaron, Babe Ruth, and other Hall-of-Fame hitters were failures because more than 65% of their at-bats ended in failure.²² Major-league pitchers, backed up by major-league fielders, represent a serious constraint with respect to hitting safely.

19. See Hermalin et al. (2007: especially 21–46) for a survey of the relevant literature.

20. As examples of work suggesting current governance is highly suboptimal, see Lorsch and MacIver (1989), Bebchuk and Fried (2003, 2004), and MacAvoy and Millstein (2003).

21. In this regard, it is worth speculating about the extent to which the run-up in executive salaries at the beginning of this century was due to the availability of cheap capital. Did the relative bargaining positions of talent and capital tip toward talent?

22. Henry Aaron's career average was .305. Babe Ruth's was .342.

4. Finally, the corporation is not the only way to organize an enterprise. Alternatives include sole proprietorships, partnerships, cooperatives, and state-owned enterprises.²³ For more than 400 years, at least, the corporate form has successfully competed with these other forms and has, economically, come to dominate all alternatives.²⁴ Hence, there is a limit on just how bad corporate governance can be.²⁵

I am not, however, suggesting one adopt a panglossian approach to governance. It is doubtful that we live in the best of all possible worlds; that is, there could be scope for improvement via regulatory action (more on this point later). My point is rather that the efficacy of regulatory action is more limited than many commentators would suggest.

Investors and management choose the institutions by which their relation is governed. Hence, governance institutions are *endogenous*. As such, any regression analysis that attempts to determine the effect of one or more of these institutions on firm performance—for instance, a regression of return on assets (ROA) on the proportion of the board of directors who are outside directors—needs to control for the joint endogeneity of the dependent and independent variables.²⁶ Although researchers have not always been careful in this regard, the better work does attempt to deal with this endogeneity (for a more complete treatment of this issue, see Bhagat and Jefferis 2002).

A more fundamental issue, though, is the following: how should one interpret a regression of financial performance on governance attributes? A common presumption in the literature, for example, is that outside directors are better monitors of management than are inside directors. Naïvely, one might seek to test this hypothesis by regressing a measure of financial performance on a measure of the relative number of outside directors. The “rationale” is that, if the hypothesis is correct, firms that score higher on the measure of outside directors will tend to score better

23. See Hansmann (this volume) for a survey of the literature on why different organizational forms are chosen.

24. The East India Company is often taken to be the first corporation, chartered on December 31, 1600, by Queen Elizabeth I (Baskin and Miranti 1997). Another early corporation was the Vereenigde Oost-Indische Compagnie (usually referred to in English as the Dutch East India Company), which was established in 1602. Neither is as old as Stora Kopparberg, a Swedish mining company that sold its first share in 1288 and was chartered by King Magnus IV of Sweden in 1347. Malmendier (2009: 1077) argues “the earliest predecessor of the modern business corporation was . . . the Roman *societas publicanorum*.” *Societates publicanorum* rose to prominence in the last two centuries BCE.

25. This is not to claim that corporate governance is better than the governance of other forms of enterprise. Rather, it is the observation that it cannot be so bad as to outweigh whatever benefits the corporate form offers over these other forms. In this regard, it is worth noting that one of the benefits of the modern corporate form, limited liability, cannot be what has made the corporate form survive. Limited liability did not come into being until the British enacted the Limited Liability Act of 1855, roughly 255 years after the first corporation was chartered there (for further discussion and detail, see Diamond 1982).

26. The outside directors of a corporation are those directors who are not current or former officers of the corporation (i.e., part of its management team). Inside directors are directors who are current or former officers. In the literature the two groups are often referred to as “outsiders” and “insiders,” respectively. It is generally assumed that outsiders’ interests are more aligned with investors than are insiders’; in particular, the presumption is that outsiders exercise some control over management. See, for example, Hermalin and Weisbach (2003) and Adams et al. (2010) for a discussion of the relevant literature.

Figure 1. A hypothetical regression of financial performance against a measure of outside director presence on the board.

in terms of financial performance.²⁷ That is, if the data resemble those in Figure 1, then there is support for the hypothesis.²⁸

A problem with such an interpretation is that if more outside directors really mean better financial performance, why does firm A in Figure 1 choose to have a low measure of outside directors? That is, if the hypothesis is true, then it would appear firm A is leaving money on the table. Surely the investors and management of firm A would have had a larger “pie” to divide had they emulated firm B in terms of outside directors. In short, one cannot accept both the hypothesis that governance structures are constrained Pareto optima and the hypothesis that the regression in Figure 1 is a valid test of whether more outside directors improves financial performance.

Furthermore, as Demsetz and Lehn (1985) and others have noted, if one accepts that the observed governance structures are constrained Pareto optima, then it is no longer clear that any

27. Baysinger and Butler (1985), Rosenstein and Wyatt (1990), Brickley et al. (1994), and Dürkin et al. (2009), among others, find evidence that measures of outside directors are positively correlated with firm performance. Hermalin and Weisbach (1991) and Yermack (1996) also study the issue but find little evidence that firm performance is related to board composition. Other studies have investigated the relation between other attributes of the governance structure and firm performance: Yermack (1996) and Eisenberg et al. (1998) find a negative relation between board size and firm performance (Coles et al. [2008], however, find that firm performance is increasing in board size for certain types of firms); Stulz (1988) and Morck et al. (1988) find a positive relation between managerial stock ownership and firm performance (up to a certain threshold of ownership, at which point the relation reverses; see Becht et al. 2003: 63 and Section 6 for a more detailed appraisal of the managerial stock ownership literature); Jarrell and Poulsen (1987), Mahoney and Mahoney (1993), and Bebchuk and Cohen (2005) find having directors serve staggered terms of multiple years (as opposed to all serving annual terms) has a negative effect on firm performance. See some of the aforementioned survey articles for additional studies of the relation between governance attributes and firm performance.

28. To be more precise, imagine in Figure 1 that the dependent variable is the residual of financial performance regressed on the relevant controls other than the measure of outsiders.

Figure 2. Given firms choose governance optimally, should governance and performance be correlated? Parabolas illustrate the indicated firms' optimization problems.

relation should exist in the data between governance structures and performance. If the relevant parties are solving an optimization program unique to their firm, then, as Demsetz and Lehn observe, we could readily expect to see data like that shown in Figure 2. In this second figure, in addition to the scatter plot of the "data," I have also drawn parabolas to indicate, heuristically, the different optimization programs faced by the investors and controlling interests of these three firms.²⁹

Consistent with the idea that the parties achieve constrained Pareto optima, each firm in Figure 2 is shown resting on the top of its respective hill; that is, no set of parties could do better. Clearly, a regression should reveal no relationship between the variables in question. Yet many carefully executed empirical studies find evidence of correlation; moreover, this correlation tends to be positive: measures that arguably indicate stronger governance (e.g., smaller boards, or higher governance indices) go hand-in-hand with better firm performance and vice versa.³⁰ Why, in a world of constrained Pareto optimal governance structures, do we observe these positive correlations?

29. See Adams et al. (2010) for a survey of models that seek to explain the optimal mix of outside and inside directors. In this literature, there are three basic explanations: (1) bargaining between management and investors (directors) results in a compromise (see, e.g., Hermalin and Weisbach 1998; Cyert et al. 2002); (2) getting management (the CEO) to reveal information or otherwise take actions risky to their careers (see, e.g., Almazan and Suarez 2003; Dominguez-Martinez et al. 2008); or (3) as a means of inducing efficient information sharing among directors (see, e.g., Adams and Ferreira 2007; Harris and Raviv 2008). In all these models, restricting the proportion of outside directors is essentially a means of committing the board to future actions that cannot be contracted on formally.

30. See, for example, Bhagat and Jefferis (2002), Becht et al. (2003), and Adams et al. (2010), among others, for surveys covering this empirical literature. Examples of articles finding a negative correlation between board size and performance (i.e., that small boards are associated with better performance) include Yermack (1996) and Eisenberg et al. (1998) (but for partially contradictory evidence see Coles et al. 2008). Examples of articles finding a positive correlation between indices of good governance and performance include Gompers et al. (2003) and Bebchuk et al. (2009).

Could the view that Figure 1 is showing something causal be resuscitated by assuming that firms sometimes get out of equilibrium or that there are large adjustment costs? The problem with an out-of-equilibrium explanation is the following. If firms are truly seeking to be at the peaks of their respective parabolas but get knocked off the peak for various reasons, why aren't they equally likely to land to the right of the peak as to the left? That is, an out-of-equilibrium explanation of the data in Figures 1 must posit that firms are more likely to slip to the left—have less than the optimal measure of outside directors—than to the right—have more than the optimal measure. To be sure, such a bias is possible. Indeed, the Hermalin and Weisbach (1998) model predicts that corporations will “drift to the left” over the tenure of a CEO.³¹ The Hermalin and Weisbach model does not, however, also predict that financial performance will fall as the corporation drifts to the left.

Adjustment costs would seem to offer another explanation for why firm A does not emulate firm B in Figure 1. But then one is left with the puzzle of how firm A came to be so far from the optimum board structure in the first place. Perhaps L was, at some point in the past, the optimal measure of outside directors. But if so, then H was suboptimal, and we are left wondering how firm B came to be so far from the optimum. An evolutionary twist might help: a greater percentage of outsiders on the board is a “mutation” largely enjoyed by new firms, such as B. Older firms, such as A, see that this is a positive mutation, but find it hard to adjust. Evolution and organizational adjustment are important phenomena (see, e.g., Hermalin, “Leadership and Corporate Culture,” this volume), but it seems unlikely this could be the explanation, given the long time such heterogeneity has existed. (For example, Hermalin and Weisbach [1988] find considerable variation as far back as the 1970s, and such variation continues to exist to this day.)

Where, then, does this leave us? The fact that many studies do find a significant and positive relation between governance and performance suggests there could be something in the data that cannot be dismissed. But what is in the data, and how do we reconcile it with the previous discussion? One answer is that we are thinking about the data backwards: Rather than good governance causing good performance, perhaps it is good performance—more specifically, the potential for or likelihood of good performance—that is causing good governance.

To have a tangible framework in which to explore the idea that good governance is the consequence of the potential for good performance, consider the following model. Investors deal with a single manager. The manager's utility is

$$u = D + v(R - D, g),$$

where R denotes the firm's resources, D denotes the amount the manager diverts to uses he desires but that are unproductive from the firm's perspective, $v : \mathbb{R}^2 \rightarrow \mathbb{R}$, and g is a measure of the strength or effectiveness of governance. The variable g could represent the percentage of independent directors on the board or on key board committees, a measure of the directors' diligence, a measure of the effectiveness of the monitoring and auditing systems in place, some

31. There is also empirical evidence for a leftward drift; that is, for the proportion of outside directors to tend to decrease with the length of the CEO's tenure. See Hermalin and Weisbach (1988), Baker and Gompers (2003), Ryan and Wiggins (2004), and Boone et al. (2007).

measure of the strength of the incentives given the manager, or perhaps some index of governance strength (e.g., that proposed by Gompers et al. 2003). One interpretation, in particular, is worth considering: given the many dimensions of governance, think of g as the firm's total expenditure on governance. Provided the owners set the dimensions of governance optimally, spending more on governance must correspond to stronger governance.

As with all exogenous functions in this chapter, $v(\cdot, \cdot)$ is assumed to be twice continuously differentiable. The function represents the benefit the manager derives from behaving in a manner desired by the investors (i.e., not diverting funds or assets for private use). This benefit is, in part, a function of the level of governance.³² All this simply reflects the idea that governance structures operate to reward the manager for good behavior. Consistent with the view that better performance is better rewarded, assume $v_1(\cdot, g) > 0$ for all $g > 0$.³³

To keep the analysis straightforward, assume that, for any g , there is a unique value of D that maximizes the manager's utility. That is, it solves

$$\max_D D + v(R - D, g).$$

This maximization has a unique solution if the manager's utility exhibits diminishing marginal return to diversion (i.e., if $v_{11}(\cdot, g) < 0$ for all g). Let $D(g)$ denote that solution. Again to keep the analysis straightforward, corner solutions are ruled out.³⁴

Stronger governance means an increase in the governance parameter that results in a reduction in agency behavior; that is, it leads the manager to choose a smaller D . Formally, assume the following.

Assumption 1 *Let g and g' be two different levels of governance, $g > g'$, and let D and D' , respectively, be the levels of private use chosen by the manager in response to those governance levels. Then $D < D'$.*

A sufficient condition for Assumption 1 to hold is that the marginal utility of not diverting resources is increasing in the level of governance; that is, $v_{12}(\cdot, \cdot) > 0$. That more governance then leads to better behavior follows from well-known concepts in comparative statics (see, e.g., Topkis 1978; Milgrom and Roberts 1990), which in this context can be summarized by the following lemma.

Lemma 1 *Let $f : \mathbb{R}^2 \rightarrow \mathbb{R}$ be at least twice differentiable in its arguments. Suppose that $f_{12}(\cdot, \cdot) > 0$. Let $\hat{x}$ maximize $f(x, z)$, and let $\hat{x}'$ maximize $f(x, z')$, where $z > z'$. Then $\hat{x} \geq \hat{x}'$. Moreover, if $\hat{x}'$ is an interior maximum, then $\hat{x} > \hat{x}'$.*

32. Of course, because a cost is just a negative benefit, this formulation also incorporates specifications in which the governance structure punishes the manager for behaving at odds with the shareholders' preferences.

33. I am employing the convention that subscripts on functions denote partial derivatives; that is, f_n denotes the derivative with respect to the n th argument of function f , and f_{nm} denotes the second derivative with respect to the n th and m th arguments.

34. Specifically, if $g > 0$, we want $D(g) < R$. Hence, assume $v_1(0, g) > 1$ for all positive g . However, to avoid dealing with corner solutions in the level of governance, assume $v_1(0, 0) = 1$; hence, the absence of governance implies $D(0) = R$. To assure $D(g) > 0$ for R great enough, assume $\lim_{R \rightarrow \infty} v_1(R, g) < 1$ for all g . An example of a v function satisfying all assumptions given so far is $v(R - D, g) = 2g\sqrt{R - D}$.

Suppose that the corporation's returns r are distributed on the interval $[\underline{r}, \infty)$, $\underline{r} > -\infty$, according to the conditional distribution function $F(\cdot|R - D, \tau)$, where $\tau \in \mathbb{R}$ is the corporation's type (more on τ below). Assume $\mathbb{E}\{r|R - D, \tau\}$ exists for all possible values of $R - D$ and τ . Using integration by parts, observe that

$$\mathbb{E}\{r|R - D, \tau\} = \underline{r} + \int_{\underline{r}}^{\infty} (1 - F(r|R - D, \tau))dr = \underline{r} + \int_{\underline{r}}^{\infty} S(r|R - D, \tau)dr,$$

where $S(r|X, \tau) \equiv 1 - F(r|X, \tau)$ is the survival function. It is natural to assume that the more net resources utilized, the greater the expected return. In fact, let us make the somewhat stronger assumption that an increase in net resources improves the distribution of returns in the sense of strict first-order stochastic dominance; that is, $\partial S(r|X, \tau)/\partial X > 0$ for all $X, r \in (\underline{r}, \infty)$, and τ . Finally, as our definition of corporate type, assume that this improvement is stronger the greater is τ . In other words, the marginal expected return from an increase in net resources utilized is greater for higher type corporations than lower type corporations. In terms of calculus, this definition of type can be written as

$$\frac{\partial^2 S(r|X, \tau)}{\partial \tau \partial X} > 0 \quad (1)$$

for all $X, r \in (\underline{r}, \infty)$, and τ .

The realized profit of the corporation is return less the cost of governance, $C(g)$. Writing $X(g)$ for $R - D(g)$, the investors' choice of governance will be the solution to the program

$$\max_g \underline{r} + \int_{\underline{r}}^{\infty} S(r|X(g), \tau)dr - C(g). \quad (2)$$

The cross-partial derivative of (2) with respect to g and τ is

$$\int_{\underline{r}}^{\infty} \frac{\partial^2 S(r|X(g), \tau)}{\partial X \partial \tau} X'(g)dr > 0, \quad (3)$$

where the inequality follows from (1) and from the fact that $D(\cdot)$ is a decreasing function, and thus, $X(\cdot)$ an increasing function. Expression (3) and Lemma 1 imply the following proposition.

Proposition 1 *The level of governance a corporation has is nondecreasing in its type (i.e., in its marginal expected return from net resources).*

By imposing more structure on the model, it is possible to ensure that the solution to (2) is always an interior solution. This would allow us to conclude as follows.

Corollary 1 *If the level of governance that maximizes the investors' expected net returns is an interior solution within the space of feasible governance levels, then the level of governance a corporation has is increasing in its type.*

Proposition 1 and its corollary explain the difference between firms A and B in Figures 1 and 2. An additional dollar of net resources is more valuable to firm B than firm A; that is, B is a higher-type firm than A. What has not yet been explained is why the data resemble Figure 1 and not Figure 2. Explaining that requires an additional assumption: a corporation that employs no net resources will enjoy a zero return (one typically does not get something for nothing). Hence, the distribution of returns when no net resources are employed is independent of type. In terms of calculus, this means $\partial S(r|0, \tau)/\partial \tau \equiv 0$ for all r and τ . This insight and expression (1) imply

$$\frac{\partial S(r|X, \tau)}{\partial \tau} = \frac{\partial S(r|X, \tau)}{\partial \tau} - \frac{\partial S(r|0, \tau)}{\partial \tau} = \int_0^X \frac{\partial^2 S(r|x, \tau)}{\partial \tau \partial X} dx > 0 \quad (4)$$

for all r and $X > 0$. Observe that (4) demonstrates that an increase in type, holding net resources constant, improves the distribution of returns in the sense of first-order stochastic dominance.

Let $g(\tau)$ be the solution to program (2). Utilizing the Envelope Theorem, it follows that

$$\frac{d}{d\tau} \left(\underline{r} + \int_{\underline{r}}^{\infty} S(r|X(g(\tau)), \tau) dr - C(g(\tau)) \right) = \int_{\underline{r}}^{\infty} \frac{\partial S(r|X(g(\tau)), \tau)}{\partial \tau} dr > 0,$$

where the inequality follows from (4). In words, higher-type firms have greater expected profits in equilibrium than do lower-type firms. This explains why the performance of firm B, a higher-type firm, is better than that of firm A, a lower-type firm. To summarize, I have shown that higher-type firms will have both greater levels of governance and greater profit (in expectation) than lower-type firms. Thus, governance level and profits should be positively correlated; the data should, in fact, resemble those shown in Figure 1.

Proposition 2 *In this model, in which all corporations are making optimal decisions, there will be a positive correlation between level of governance and corporate profits.*

Note the path of causation: A corporation with a high marginal return to net resources—which will therefore be, *ceteris paribus*, a corporation with greater profits on average—is a corporation with a higher marginal cost of agency. It therefore puts in place a higher level of governance than would a corporation with a low marginal return to net resources (low marginal cost of agency).

5. The Many Dimensions of Governance

Governance is the product of decisions in many dimensions: board structure, security design, incentive schemes, and the like. This observation raises another issue: if the different dimensions are substitutes and different firms face different factor-price vectors, then there could be considerable heterogeneity in the governance practices in any sample of firms. To see this readily illustrated, consider the following extreme “model.” Let $g = \max\{\gamma_1, \gamma_2\}$, where γ_i is the amount of governance on dimension i . A corporation will, therefore, set the more expensive dimension to zero. If the more expensive dimension is the first for some firms, but the second for others, then the sample will contain a subset of firms that use only the first method of governance and another subset that use only the second. This situation can create complications

Figure 3. The empirical consequence of governance structures having many dimensions.

for empirical work, because empirical work often focuses on the effect of governance on a single dimension only. Because the firms that elect to have zero of the dimension under study are not necessarily poorly governed firms (they could have invested heavily in the other, unstudied dimension), the coefficient on the dimension being studied will be biased downward. Figure 3 illustrates the potential problem. In that figure, there are four data points. Firms A and B achieve their governance objectives by investing along the first dimension (e.g., proportion of outside directors); Firms C and D achieve their governance objectives by investing along the second dimension (e.g., incentive compensation). Firms B and D are high-type firms, and so perform well, whereas firms A and C are low-type firms, and so perform less well. But because firms C and D achieve their governance objectives differently than do A and B, a regression of performance on γ_1 will suggest that the relation between these variables is less strong than it truly is for those firms that invest in governance along the first dimension.

Observe that controlling for governance on both dimensions—that is, running the regression

$$\text{Performance} = \beta_0 + \beta_1\gamma_1 + \beta_2\gamma_2 + \varepsilon$$

does not correct the problem identified in Figure 3. Relative to the true relation for those firms utilizing a given dimension, the coefficients β_1 and β_2 will be biased downward.

Heterogeneity is a particularly important issue in the study of pay-for-performance incentive contracting. Agency theory (e.g., Holmström 1979; Shavell 1979; Grossman and Hart 1983) teaches us that one way to better align the incentives of investors (the principal) and managers (the agent) is to make the agent's compensation contingent on signals that are informative about the agent's action in a way that induces the agent to take actions the principal desires. Because investors desire that management takes actions that boost their returns, a natural set of signals on which to base compensation are various performance metrics (e.g., profit or ROA). The extent to which different metrics are utilized depends on their informativeness (see, e.g., Holmström 1982; Kim 1995), which could differ across different firms or industries. Consequently, one should expect variation in the incentive contracts employed across firms and industries. One should also expect variation because high-type firms will wish to provide their managers

stronger incentives than will low-type firms, as discussed above. Even with otherwise identical firms, variation in incentives can arise in equilibrium as a consequence of product-market competition (Hermalin 1994). More generally, the discipline of product-market competition can be a substitute for incentive compensation, thus serving as another source of heterogeneity.³⁵ These theoretical predictions of heterogeneity in incentive compensation are given empirically validity by Kole (1997), who examined executive compensation contracts and documents considerable variation across them.

What is the implication of this variety for empirical work? Consider a possible regression specification:

$$\text{Comp}_n = \beta_0 + \beta_1 \times \text{Perf}_{1n} + \cdots + \beta_J \times \text{Perf}_{Jn} + \varepsilon_n, \quad (5)$$

where Comp_n is the compensation of the n th executive (typically firm n 's CEO) and Perf_{jn} is the j th performance metric (e.g., ROA) for the n th executive's firm.³⁶ What is the interpretation of (5)? Presumably, the coefficients (the β s) are the terms of the compensation contract.³⁷ But which firm's? If, as theory and evidence indicate, different firms will utilize different contracts, then there is a fundamental misspecification in (5), because (5) rests on the erroneous assumption that all firms are using the same compensation contract.

The consequences of this misspecification are similar to the problem identified in Figure 3. If firms A and B tend to base compensation on Perf_1 , while C and D tend to base it on Perf_2 , then the situation will resemble that shown in Figure 4. The true sensitivity of pay to performance for those firms that base compensation on Perf_1 is the slope of the "true" line.³⁸ The econometrician will, however, measure it as the slope of the estimated line. Consequently, the estimates of all coefficients are biased downward insofar as they understate the true sensitivity of pay to performance measures for those firms that base compensation on those performance measures.

35. The idea that market competition serves to discipline managers is sometimes attributed to Hicks (1935) as the "quiet-life" hypothesis. Formalizing it has not proved easy (see Allen and Gale 2000 for a discussion of the intellectual history of the quiet-life hypothesis). Part of the problem, as noted by Hermalin (1992), is that product-market competition introduces a number of contradictory effects. Important articles in this area include Hart (1983), Scharfstein (1988), Schmidt (1997), and Allen and Gale (2000). Empirical studies include Bertrand and Mullainathan (2003) and Giroud and Mueller (2008). The latter, in particular, finds evidence that product-market competition mitigates managerial slack. A related literature (see, e.g., Aghion et al. 2005 and cites therein) considers the complementary question of how competition affects incentives to innovate and become more productive.

36. An actual regression of this sort could also have numerous nonperformance controls (e.g., for industry or firm size). They have been omitted from (5) to avoid unnecessary clutter. In addition, the dependent variable is often the log of compensation; taking logs would not change the point being made here. Finally, what compensation is and how it is best measured is a tricky empirical issue (see, e.g., Jensen and Murphy 1990; Hall and Liebman 1998; Hermalin and Wallace 2001). These details are, however, not relevant for the point being made here.

37. Except under strong conditions (see Holmström and Milgrom 1987), a linear compensation scheme is not guaranteed to be the optimal scheme. Indeed, it is straightforward to construct examples in which linear compensation would be suboptimal. Given that real-life compensation is not linear (bonuses, e.g., are rarely—if ever—negative and stock options pay off nonlinearly), the use of a linear specification is, in itself, questionable.

38. True is in quotes because there are multiple true relations—in this case one for firms A and B and another for firms C and D.

Figure 4. Downward bias in measures of sensitivity of pay to performance.

Hermalin and Wallace (2001) attempt to deal with this issue by allowing the coefficients in (5) to vary across firms (such an analysis requires, obviously, panel data). Consistent with the concerns raised above and in Figure 4, they show, using a two-step estimator of a hierarchical linear model based on Wong and Mason (1991), that the estimated coefficients are greater under such a specification than using ordinary least squares (OLS).³⁹ In other words, as predicted, failure to treat the coefficients—that is, the parameters of the compensation contract—as varying across firms leads to a downward bias in their estimation. In addition, consistent with the idea that the different dimensions of governance could be substitutes and that firms vary with respect to the performance measures to which they make compensation sensitive, Hermalin and Wallace find a negative correlation between the coefficients on the two performance measures they investigate. Thus, firms that make CEO pay highly sensitive to one measure tend, all else being equal, not to make it particularly sensitive to the other and vice versa.

Even if the different dimensions of governance are complements—so a high-type firm will tend to have more governance in all dimensions than a low-type firm—(5) is still misspecified. To see this, suppose there is only one performance measure r , which is distributed normally with mean $a\tau$ and variance σ^2 , where $a \in \mathbb{R}_+$ is the CEO's action and τ again denotes the firm's type. Suppose the CEO's utility is $-\exp(\frac{1}{2}a^2 - y)$, where y is her income. Limit attention to affine incentive contracts: $y = \beta_0 + \beta_1 r$. Hence, the CEO's equilibrium expected utility is a monotonic transformation of⁴⁰

$$\beta_0 + \frac{1}{2}\beta_1^2(\tau^2 - \sigma^2). \quad (6)$$

39. Because they estimate a distribution of coefficients, a more precise summary of their results is that the distribution estimated using their specification lies to the right (has a greater mean) than under OLS.

40. The CEO's expected utility is readily seen to be a monotonic transformation of

$$\beta_0 + \beta_1 a \tau - \frac{1}{2}\beta_1^2 \sigma^2 - \frac{1}{2}a^2.$$

Hence, the CEO maximizes her expected utility by choosing $a = \beta_1 \tau$.

Suppose, perhaps unrealistically, that investors have all the bargaining power and are thus able to hold the CEO to her reservation utility. If $\underline{u}$ is her (suitably transformed) reservation utility, then, from (6), it must be that $\beta_0 = \underline{u} - \beta_1^2(\tau^2 - \sigma^2)/2$. Equilibrium expected compensation and firm expected profit are thus, respectively,

$$\underline{u} + \frac{1}{2}\beta_1^2(\tau^2 + \sigma^2) \quad \text{and} \quad \beta_1\tau^2 - \frac{1}{2}\beta_1^2(\tau^2 + \sigma^2) - \underline{u}.$$

Investors will set β_1 to maximize the latter expression; hence, $\beta_1 = \tau^2(\tau^2 + \sigma^2)^{-1}$. Observe β_1 is increasing in τ ; that is, consistent with the discussion above, higher type firms employ stronger governance than do lower type firms. Moreover, as claimed, different firms are using different contracts—the implicit assumption in (5) of a common compensation contract is invalid.

The adverse consequences of this misspecification in (5) can be illustrated by the following simulation. Set $\underline{u} = 0$ and $\sigma^2 = 1$. Construct a “sample” of 10,001 firms, where $\tau_1 = 1$ and $\tau_n = \tau_{n-1} + 1/10$, $000, 1 < n \leq 10,001$. For each firm randomly generate r as a normal random variable with mean $a_n\tau_n$, or substituting, mean $\tau_n^4(\tau_n^2 + \sigma^2)^{-1}$. Calculate the corresponding compensation for each firm, and then estimate (5) using OLS from these data.⁴¹ Multiple runs of this simulation all came back with estimates of β_1 between .575 and .580. The true β_1 s range from .5 to .8, with 82% of them being greater than .58; that is, the estimated sensitivity of pay to performance from (5) dramatically understates the actual sensitivity in the sample.⁴²

This insight is more than just nit-picking. The question one is investigating when estimating the sensitivity of pay to performance is not whether there is a positive relation—it is virtually inconceivable that they are negatively correlated in reality—but rather, how sensitive? Do executives operate under high-powered incentives or not? Jensen and Murphy (1990), who estimate an equation similar to (5), argue that CEOs operate under fairly low-powered incentives; they estimate that CEO wealth changes by \$3.25 per \$1,000 increase in shareholder wealth. They cite earlier studies that found a pay-to-performance elasticity of approximately 0.1, a number consistent with their own estimates. They argue that such estimates of sensitivity are “inconsistent with the implications of formal agency models of optimal contracting” (Jensen and Murphy 1990: 227). They go on to suggest that outside political forces “implicitly regulate executive compensation by constraining the type of contracts that can be written between management and shareholders.”⁴³ Haubrich (1994) disputes this conclusion. He conducts numerical simulations using parameterized versions of the Grossman and Hart (1983) model, calibrated using real-life data, to show that the Jensen and Murphy estimates need not be at odds with optimal contracting.⁴⁴ Hall and Liebman (1998) also estimate an equation similar to (5) and find a greater sensitivity of pay to performance than did Jensen and Murphy. They ascribe the difference in findings between the two studies to their focus on a later period of time, during which CEOs held more stock and stock options than before. Bebchuk and Fried (2003, 2004) also

41. The Mathematica program used for this is available from the author upon request.

42. The true average of the β_1 s is .678.

43. Bebchuk and Fried (2004) refer to these as “outrage” costs; although, in contrast to Jensen and Murphy, they believe these are not sufficiently deterring high levels of compensation.

44. See also Haubrich and Popova (1998) for another calibration exercise that reaches a similar conclusion.

argue that the pay-to-performance sensitivity is too low, but do so from the perspective that managers have too much power and are being unduly rewarded, almost independently of their performance. Hall and Murphy (2003) take issue with that view, but they, too, suggest that firms may fail to be setting the sensitivity of pay to performance optimally (they suggest that the costs of stock options are misperceived as being “free”—see, in particular, Hall and Murphy 2003: 66–69).⁴⁵ What the discussion here suggests, however, is that the debate over executive compensation is being conducted under a possibly misleading understanding of what the data actually say. If there are systematic biases of the sort identified above, then the sensitivity of pay to performance could be higher than heretofore estimated (at least for those corporations that rely on that means of governance).⁴⁶

This section has sought to make the following points. The inherent heterogeneity in governance solutions—both in structure and intensity—is a first-order problem for the empirical study of governance (as well as a source of puzzles for theoreticians). Cross-sectional regressions, in particular, must be viewed with great caution, as they are subject to misinterpretation.

6. Dispersed Shareholders, Managerial Power, and Governance

Many of the complaints about governance are that managers have too much power vis-à-vis the shareholders (see, e.g., Lorsch and MacIver 1989; Bebchuk and Fried 2004). Since at least Berle and Means (1932), this disparity in power has been attributed to the dispersion of ownership. In particular, any one shareholder holds too few shares to have any power him or herself; that is, alone, he or she does not possess the votes to control the board of directors and, through it, management. A lone shareholder could, in theory, seek to build a coalition of shareholders with sufficient power to control the board of directors, but—traditionally at least—such action is costly. Because our lone shareholder bears the cost, but shares in the benefit, the usual theory of positive externalities applies: any one shareholder will undersupply efforts to rein in management. Not surprisingly, attempts to gain control of the board of directors by existing shareholders are relatively rare events.⁴⁷

As Grossman and Hart (1980) observed, a similar problem confronts an outside actor who attempts to take over a corporation. If the motivation for such a takeover is the outside actor's belief that it can generate greater returns from the assets of the corporation, then it will behoove the outside actor to launch a takeover bid provided it will get a sufficient share of the increase in returns it generates. The problem is that an existing shareholder will reason as follows. “Because I

45. For more complete surveys of the debate on executive pay, especially whether it is appropriately sensitive to performance, see Devers et al. (2007) and Edmans and Gabaix (2009).

46. For large corporations (e.g., Fortune 500 companies), reliance on incentive compensation (e.g., use of bonuses or stock options) has tended to be the norm. For smaller corporations, however, this has been—historically at least—less universally true. See, for example, Hermalin and Wallace (2001) for data on the savings and loan industry. See also Hall and Murphy (2003) for a discussion on the growing use of stock-option compensation during the 1980s and 1990s.

47. Over a 16-year period, Mulherin and Poulsen (1998) find there were only 270 proxy contests (attempts to change the board of directors) at NYSE and Nasdaq-listed firms (an average of 16.875 contests per year). Of these, roughly half led to changes in management. This rate of “success” clearly overstates the *ex ante* probability of success, because presumably such contests are not undertaken unless there is a reasonable chance of success.

own such a small proportion of shares, the odds that my tendering my shares will be pivotal to the success of the takeover bid are so small as to be negligible. Hence, if I retain my shares, I will enjoy the benefits of the improved management. I, therefore, should not sell unless the bid price equals the expected present value of the returns I will enjoy under this improved management.” Given this reasoning, existing shareholders will sell only if given all the gains created by the outside actor. This, however, eliminates the gains from launching a takeover bid in the first place. Of course, takeovers do occur, so there must be ways around this free-riding problem. Grossman and Hart (1980) suggest some means of reducing the free-riding problem by limiting the returns to those shareholders who hold out (the *ex post* minority).⁴⁸

Such free-riding problems are less pronounced if there is a shareholder whose holdings are relatively large. The governance literature has thus devoted considerable attention to large shareholders (blockholders).⁴⁹ The classic article in this regard is Shleifer and Vishny (1986), which considers how the presence of a large blockholder can serve to overcome the free-riding problems identified above. The presence of a large blockholder is not, however, unambiguously good for governance. A large blockholder can use its power for evil as well as good. In a reverse of the free-riding problem, if the blockholder can use its power to engage in self-dealing with the corporation (e.g., induce the corporation to buy inputs at inflated prices from a supplier it fully owns), then the blockholder gets all the benefit but incurs only a portion of the cost. This problem is potentially more severe when there is a pyramid structure of ownership, which permits a shareholder to control the votes but have a more limited financial exposure.⁵⁰ Such ownership structures are more common in Europe and Asia than in the United States. See Becht et al. (2003: 24–29) for more on blockholders.

A remark is in order at this juncture. Although dispersed ownership would seem to limit shareholders’ ability to control management effectively, it is nevertheless an equilibrium phenomenon. In other words, as Demsetz and Lehn (1985) note, ownership structure is endogenous. Consequently, if we observe dispersed ownership, then we must at least entertain the idea that the costs of dispersion are not necessarily that great (or that the net benefits of concentration are not that great). Otherwise, it is hard to see how the system could have persisted—\$100 bills do not linger long on the sidewalk. This is not—I hasten to add—to claim that dispersed ownership is not a binding constraint with respect to achieving the ideal in governance, but rather that its cost cannot be excessive.

This last point can be readily illustrated. Let return r be distributed normally with mean $\mu + g$ and variance σ^2 . Suppose, initially, the firm has a large shareholder. She oversees management. Suppose she is undiversified and, so, concerned about risk. In particular, assume her utility is $-\exp(C(g) - \alpha r)$, where $C(g)$ is the cost she incurs to monitor—provide level of governance

48. See Hermalin and Schwartz (1996) for a discussion of the relevant law concerning freeze-outs of minority shareholders and some of the economic implications of the law in this regard.

49. A related literature looks at the roles of main banks in German and Japanese governance. See, for example, Hoshi et al. (1990), Hellwig (1991), and Kaplan (1994a,b). Hellwig (2000) contains a partial survey of this literature.

50. As an example, suppose an individual owns 51% of company A, which in turn owns 51% of company B, which in turn owns 51% of company C. Given that the individual controls A, which controls B, which controls C, the individual controls C. But he or she has a claim on just $.51^3 \approx 13\%$ of company C’s returns.

g —and $\alpha \in (0, 1]$ is her share of the company. A monotone transformation of her expected utility is

$$\alpha(\mu + g) - \frac{1}{2}\alpha^2\sigma^2 - C(g). \quad (7)$$

Suppose that $C : \mathbb{R} \rightarrow \mathbb{R}$ is strictly convex. Application of Lemma 1 reveals that the g that maximizes her expected utility cannot increase as α decreases (and is falling in α when it is positive).

Imagine, initially, that this shareholder owns 100% of the company (she is its founder, perhaps). Assume she can sell shares to diversified and atomistic shareholders, who can therefore be considered to be risk neutral. They will pay the expected return $\mu + g$ times the portion of the firm they purchase; hence, the large shareholder gets $(1 - \alpha)(\mu + g)$ with certainty. Her expected utility is, then

$$\mu + g - \frac{1}{2}\alpha^2\sigma^2 - C(g). \quad (8)$$

If the large shareholder could commit to a level of governance, then clearly she does best to choose the g that maximizes (8). That could be time inconsistent, however: when she actually chooses g , her relevant utility is given by (7) and her incentive would be to maximize it. Let us suppose that is what will happen. Let $g(\alpha)$ maximize (7). New investors anticipate this and take it into account when bidding for shares; hence, they pay $(1 - \alpha)(\mu + g(\alpha))$ for the portion of the firm they buy. The proportion of the corporation that the large shareholder retains maximizes

$$\mu + g(\alpha) - \frac{1}{2}\alpha^2\sigma^2 - C(g(\alpha)).$$

Utilizing the Envelope Theorem, the first-order condition for maximizing that expression with respect to α is equivalent to

$$(1 - \alpha)g'(\alpha) - \alpha\sigma^2 \leq 0, \quad (9)$$

with equality holding only if the optimal α is positive. Observe that $\alpha = 1$ cannot be a solution to (9). The large shareholder will sell some portion of the company even though that guarantees a worsening of governance. The intuition is clear. Starting from $\alpha = 1$, a small reduction in α has a second-order effect on the level of governance (and, thus, share value), but a first-order effect on the risk she must bear. Not surprisingly, therefore, she will sell some of her shares.

Observe that the large shareholder would be strictly better off if she could commit to a governance level before selling her shares (i.e., commit to the g that maximizes (8)). Let g^* be the level of governance that maximizes (8). If such commitment were possible, then the large shareholder would sell 100% of her stake. If we assume that the large shareholder's commitment to g^* is part of a contract with the purchasers, then it is readily shown to be renegotiation proof. If the large shareholder sought to reduce governance by Δ , then she could induce the purchasers to agree only if they receive Δ in compensation. Given that g^* maximizes (8), $\Delta = 0$ must maximize $-\Delta - C(g^* - \Delta)$.

Here, as shown, the large shareholder's commitment to a governance level is renegotiation proof. This result is unlikely to be general or robust to the introduction of more real-world issues. First, as has been shown in a variety of important settings, many ideal contracts are not renegotiation proof (a particularly pertinent example with respect to governance would be Fudenberg and Tirole 1990). Second, new information could arise that renders a previously optimal contract suboptimal. Admittedly, in theory, the original contract could be designed so as to allow the incorporation of any new information. In reality, however, bounded rationality, legal constraints, and difficulties in verifying all relevant new information mean that no contract could incorporate all new information, which means renegotiation could be Pareto improving. If parties can benefit from renegotiating, then it seems reasonable to suppose that they will.⁵¹

One reason commitment is difficult is that people cannot be bound to a firm. For example, the large shareholder above could quit her job as the supplier of governance. Given this, the parties would again be limited to time-consistent governance levels. Even if the large shareholder could not quit without penalty under her employment contract, as a matter of law such penalties are limited (both by the ability of the large shareholder to seek bankruptcy protection and by the law's abhorrence of penalty clauses—see, e.g., Hermalin et al. 2007: 99–126). The ability of key executives to quit gives them a lever with which to force the firm to renegotiate with them. In theory, a firm might seek to develop a reputation for never renegotiating, but as a practical matter achieving such a reputation is daunting and, thus, unlikely.⁵²

Inability to commit or to avoid renegotiation can potentially explain many oddities of governance. For instance, suppose that investors put in place what they believe to be the optimal governance system. Over time, the firm's CEO proves himself to be of high ability. As such, the CEO gains bargaining power—he has proved himself a rare commodity, which, because he cannot be bound to the firm, provides him market power. One thing he will want is more money. Another potential goal is laxer governance (perhaps, e.g., for career concern issues as discussed earlier). Paying the CEO more is a first-order loss for the investors. Relaxing the governance system, given that it was at an optimum, is a second-order loss. Hence, investors will initially be more yielding to the CEO's demand for laxer governance than his demand for more pay. Hermalin and Weisbach (1998) use this insight to explain why a long-serving CEO can gain influence over the board of directors: At any point in time, the incumbent board believes it is engaging in the optimal level of monitoring. As such, giving in to the CEO's demand to add a director friendly to him to the board, which will lower monitoring somewhat, is a second-order loss for

51. This principle is actually not universally accepted in the literature; some authors have argued that, in some circumstances, there can be off-the-equilibrium-path outcomes that the parties would like to renegotiate but cannot (i.e., on some off-the-equilibrium paths the parties leave money on the table). See Hermalin et al. (2007: 84–86) for a discussion and survey of the relevant literature.

52. One factor that makes developing such a reputation daunting is that, although the firm is infinitely lived, the directors—the people actually doing the negotiating—are not. Again, theory permits short-lived individuals to carry an infinitely lived firm's reputation—see, for example, the relevant sections of Hermalin ("Leadership and Corporate Culture," this volume)—but it by no means guarantees they can do so. Furthermore, it is possible that directors would not wish to promote a norm of no renegotiation: many of them are themselves CEOs of other firms; others of them make a nontrivial income serving as directors and could therefore wish to avoid developing a reputation of being too hard-nosed (given that some set of CEOs play a role in their obtaining their board seats). See Adams et al. (2010) for a discussion of the incentives directors have to avoid being seen as "boat rockers."

the incumbent board and, thus, preferable to giving in to the CEO's demand for more pay. In other words, the CEO's utility can be increased either through more money or less governance, and on the initial margin, the latter costs the investors less than the former.

7. More Thoughts on Shareholder Control

The famous German banker Carl Fürstenberg (1850–1933) once remarked: “Shareholders are stupid and impertinent—stupid because they give their money to somebody else without any effective control over what this person is doing with it and impertinent because they ask for a dividend as a reward for their stupidity” (quoted in Hellwig 2000: 109). Although exaggerated, as witticisms often are, the remark nonetheless illuminates a basic truth: The legitimacy of shareholder complaints about their lack of control is limited—no one compelled them to purchase equity, and they are, in expectation at least, compensated for the risks they bear. Consequently, one should be cautious about extolling the virtues of increasing shareholder control, especially if imposed via regulatory fiat.

In particular, most of the governance relations we observe emerged as the consequence of (at least implicit) bargaining between investors and controlling parties. The general presumption in economics is that private parties will arrive at a better contract than one that can be imposed by the state. There are, to be sure, exceptions to this presumption (for a discussion, see, e.g., Hermalin et al. 2007: 18–56). But even if these exceptions apply, their existence does not necessarily entail intervention on behalf of the shareholders.

Another reason to be cautious about interventions that strengthen the shareholders' control is that shareholders are not the only investors in the firm. There are other providers of financial capital, such as the debtholders. Another class of investors are the workers who invest human capital (as noted above and in Tirole 2001; Roberts and Van den Steen 2003).

With respect to debtholders, there is the well-known asset substitution problem (Harris and Raviv 1991): given limited liability, shareholders have an incentive to want the firm to take on risk, even at the expense of expected return, as the firm nears bankruptcy. Hermalin and Wallace (1994) provide illustrative empirical evidence on this matter. In the 1980s, stock savings and loans (thrifts) held far riskier portfolios than did mutual savings and loans. Consequently, the probability of a stock savings and loan going bankrupt was 4.5 times that of a mutual, even though evidence shows that stock savings and loans were more efficiently operated than mutuals *ceteris paribus*.

Similarly, at any point in time, the interests of investors of financial capital and those of investors of human capital need not coincide. For instance, changed circumstances can make physical capital more valuable in alternative uses than in its current uses, but such a reallocation of physical capital could severely reduce the return on investment to human capital. If the financial investors have sufficient control of the enterprise, they could decide to reallocate the physical capital at the expense of the human capital investors (the workers). Indeed, in some circumstances, they could use this power to expropriate some of the return to human capital (e.g., threaten reallocation to reduce wages). Shleifer and Summers (1988) raise this issue in terms of assessing the social desirability of takeovers. Roberts and Van den Steen (2003) present some formal models that explore these issues. In short, when the concerns of other investors are taken into account, it is not obvious that less-than-full shareholder control is a bad thing.

With respect to the concern that shareholders have too little control, I would argue the following:

1. The degree of shareholder control could reflect a rational trade-off between the benefits of control and the wish to hold a diversified portfolio. (See previous section.)
2. The degree of shareholder control also reflects initial and ongoing negotiations between shareholders and management. (See Section 4.) In particular, shareholders may trade off less control in exchange for less managerial remuneration. (Again, see previous section.)
3. The degree to which shareholders lack control may be overstated because of issues with the empirical tests used to gauge the strength of governance. (See Section 5.)
4. Because there are other investors, giving shareholders (or a subset of shareholders) too much control can adversely affect these other investors (including minority shareholders) and thus their willingness to invest.

8. Where Does the Field Go Next?

To conclude this chapter, let me briefly outline what I see as promising directions for future research in the area of corporate governance.

8.1. New Empirical Approaches

Although of value, much of the existing empirical literature in corporate governance is plagued with problems. Identification is an especially difficult problem, given that almost all variables of interest are endogenous. New identification strategies would be of great value. For example, the logic of regression discontinuity design (for a survey, see Lee and Lemieux 2010) could be used: firms that just satisfy certain regulatory restrictions are likely the firms for which these restrictions are binding and, hence, arguably value reducing. Their behavior and performance should, *ceteris paribus*, vary from those that satisfy the restrictions “with room to spare.”⁵³ In the same vein, imposition of restrictions can serve as a “natural” experiment. This approach will be especially valuable when some firms are “assigned” to the treatment group (i.e., they must adjust their governance structures to come into compliance) and others are assigned to the control group (i.e., they do not need to adjust their structures to be in compliance).

In addition, interpreting regression results is complicated by the heterogeneity in governance structures. As Demsetz and Lehn (1985), among others, have noted, causal interpretations of

53. Cuñat et al. (in press) is noteworthy in this regard as a paper that utilizes the regression discontinuity approach. They use close votes on proxy ballots concerning corporate governance provisions as a means of identifying the market’s valuation of unanticipated good news about governance. Although provocative, their results are somewhat difficult to interpret, because the ballot measures in question are not binding. Hence, it is difficult to know what information a close vote reveals to the market. One possible interpretation, given by the authors, is that such a firm will have better governance policies than previously expected. Another is that the market learns the shareholders are “tougher” (paying attention to management and more willing to challenge it) than previously thought. Because management realizes it faces tougher shareholders, it is less inclined to act at odds with shareholder wishes for fear of retribution (e.g., shareholders are judged more likely to vote against management in a proxy contest or in a hostile takeover).

regressions between governance structures and firm performance are especially problematic in this regard (even assuming that the joint endogeneity issue has been resolved). As I have sketched out in this chapter, economic theory offers ways to think about such regressions, but more work is needed both with regard to developing the theory and to its use in the design of empirical tests. Heterogeneity is also an issue insofar as it makes the results of cross-sectional regressions suspect; there is strong reason to believe many such regressions will have coefficients that are biased downward. Various hierarchical models and other variations on random-coefficients models should be employed. Such models dictate the use of panel datasets.

8.2. Theory

Many aspects of governance represent applications of agency and other contracting theory. There are dimensions to governance, however, that fall outside the general frameworks or that otherwise exhibit novel features. One direction is to expand the canon beyond the typical single principal–single agent perspective (e.g., shareholders and CEO). Governance involves multiple principals (e.g., large and small shareholders, and equity and debtholders), hierarchical structures (e.g., shareholders–board of directors–management), and teams of agents, among other features. Better modeling of governance with multiple classes of investors, especially taking human capital investment seriously, is another priority. Theory should also explore the dynamic aspects of governance: How do governance institutions evolve over time, optimally and in practice? To what extent is governance a nexus of contracts aimed at controlling the management of the firm in an ever-changing environment? To what extent is governance a substitute for formal contracting, reflecting the inherent impossibility of complete contracting over long horizons with unforeseen contingencies? Finally, what do less neo-classical concepts, such as leadership, corporate culture, and various cognitive biases, have to say about the structure of corporate governance?

8.3. Perspective

A common view in governance research is that the aim of governance is to improve shareholder control. For a number of reasons, it is not clear that should necessarily be the aim of governance. A more appropriate view could be that governance is about balancing the (possibly disparate) needs of investors to have some measure of protection against mismanagement, misallocation, and misappropriation against the various costs of providing these protections.

Given the importance of the topic, governance research continues to be valued. With a large number of open questions, there are plenty of *terrae incognitae* left to be explored.

Incentives in Hierarchies

Dilip Mookherjee

1. Introduction

The twentieth century witnessed the emergence of large organizations in the private, public, and nonprofit sectors. Alfred Chandler's (1962, 1977) classic studies *Strategy and Structure* and *The Visible Hand* document the historical transformation of American industrial enterprises from small or medium-sized owner-managed firms in the early nineteenth century into large business conglomerates controlled by a hierarchy of professional managers by the middle of the twentieth century. Likewise, government agencies managed by professional bureaucracies have grown in size and scope throughout the course of the twentieth century, accompanying the growth of the role of governments in taxation, regulation, and delivery of public services.

The internal organization of private firms and government agencies is therefore a topic of considerable interest for both academics and policy practitioners interested in such issues as determinants of productivity, income distribution, human resource development, and efficiency of government. It is now commonly accepted that the size and internal structure of firms is an important determinant of their productivity and profitability. As various management best sellers indicate, firms seem to vary considerably in how well managed they are. Organizations that are too large are widely believed to be overly bureaucratic, unresponsive, and their top management "out of touch" with ground reality—and this is believed to be the key problem with socialist economies with large state-owned firms or large government bureaucracies, compared with more decentralized market economies. Yet conventional economic theory has difficulty explaining why this is so; or why some organizations are not as well managed as others; or the exact manner in which size, structure, and operating rules of organizations determine their effectiveness and productivity. Relevant attributes of organizational structure include the shape (e.g., the number of vertical layers, spans of control); allocation of authority and responsibility across managers; grouping of functions and managers into different departments; processes by which information is distributed, processed,

I thank Alberto Motta; Masatoshi Tsumagari; and the volume editors, Robert Gibbons and John Roberts, for useful comments.

and communicated across managers; the way that managers are evaluated and compensated; and how all this eventually affects the way decisions are made and coordinated across the organization.

The internal organization of large firms is also a topic of considerable interest for those interested in inequality and social mobility, given the large fraction of the workforce in modern economies employed as white-collar occupations involving managerial, secretarial, or supervisory jobs. Theories of income distribution need to grapple with the question of what roles managers play in organizations, how they are evaluated and compensated, and how these roles vary across different layers of management as well as between white-collar and blue-collar workers.

Managerial hierarchies pose a significant challenge for conventional economic theory, raising such issues as the separation of ownership from management and the functional role of managers in productive enterprises. What prevents owners from managing the firms they own? Alfred Marshall (1920: Book IV, Ch. XII) listed organization as a fourth critical factor of production besides land, labor, and capital, and subsequently included management as a key ingredient of organization. Yet more than a century later, models of management are still not part of the central corpus of the neoclassical theory of the firm. In the context of industrial or service enterprises that account for the bulk of all economic activity in developed countries, fixed factors such as land do not play an important role, creating challenges for explaining limits to the size of firms. Although many believe that time and attention of top managers is one of the most important fixed factors that account for limits to the size of firms, modeling this trait has posed a significant challenge for economic theory. Part of the reason is the difficulty of modeling cognitive capacities of managers to process information, make decisions, and get things done—that belong to the realm of bounded rationality that Herbert Simon (1955) and Oliver Williamson (1981) have emphasized are key to understanding organizations and the role that managers play in them.

Nevertheless, the nineteenth century view of a firm as an entity whose sole objective is to maximize profits has now evolved to a nexus of contracts among a large number of important stakeholders and functionaries (see, e.g., Milgrom and Roberts 1992). The firm is viewed as an organization or collective of different agents with dispersed information, responsibilities, and noncongruent interests. Accordingly, problems of asymmetric information and incentives play an important role in the modern theory of the firm. Yet contemporary mainstream theory of information economics as represented by the principal-agent paradigm is still struggling to explain why authority and responsibility are distributed across different managers in an organization, instead of being centralized. The Revelation Principle, which plays a central role in standard principal-agent theory (e.g., Myerson 1982), states that any allocation of authority in an organization can be replicated by a degenerate centralized organization in which all agents communicate their private information to the owner or a central headquarter office (“principal”). The principal then processes this information and makes all relevant decisions, subsequently sending instructions to all agents concerning what they should do. In this kind of organization the only role of agents is to communicate information and receive instructions; the mechanism needs to be designed to encourage honest and obedient behavior from all of them. In this setting there is no role for a managerial hierarchy: all authority is vested in the principal.

To create a theory of managerial organizations, it is necessary to go back to the foundational question: What do managers do? How or why do they do these tasks better than the principal can? To quote Chandler:

Just what, then, are the functions of the executives responsible for the functions of the enterprise? They coordinate, appraise and plan. They may, at the same time, do the actual buying, selling, advertising, accounting, manufacturing, engineering or research, but in the modern enterprise the execution or carrying out of these functions is usually left to such employees as salesmen, buyers, production supervisors and foremen, technicians and designers. In many cases, the executive does not even personally supervise the working force but rather administers the duties of other executives. In planning and coordinating the work of subordinate managers or supervisors, he allocates tasks and makes available the necessary equipment, materials, and other physical resources necessary to carry out the various jobs. In appraising their activities, he must decide whether the employees or subordinate managers are handling their tasks satisfactorily. If not, he can take action by changing or bringing in new physical equipment and supplies, by transferring or shifting the personnel, or by expanding or cutting down available funds. Thus, the term, *administration*, as used here, includes executive action and orders as well as the decisions taken in coordinating, appraising, and planning the work of the enterprise and in allocating its resources. [Chandler 1962: 8]

Therefore, managers perform at least three important functions: they (1) process information helpful in decisionmaking by the firm regarding production, marketing, technology, employment, and suppliers; (2) supervise (i.e., generate and supply information used to evaluate and compensate employees and suppliers); and (3) make decisions concerning production, marketing, and contracting with employees and suppliers on behalf of the owners.

The first two functions pertain to the role of managers as processors or generators of information useful in decisionmaking by others. Only the last function includes the role of managers as decisionmakers. This pertains to the notion of hierarchy as a inverted-tree-like asymmetric pattern of distribution of authority within an organization. As emphasized in the writings of Coase (1937) and Simon (1951), a firm conceptualized as a hierarchical relation between an owner and employee is distinct from a more symmetric market relationship between the owner and an outside contractor. In this vein, Van den Steen (2010) defines hierarchical or interpersonal authority as a situation where the owner or boss tells the employee what actions to take, which the latter is expected (or incentivized) to obey. The employee may be inclined to select other actions on the basis of her own information or her personal motivation; the terms of employment include monitoring of actions or their consequences, combined with suitable rewards and penalties, to induce the employee to obey the owner's instructions. In contrast, an external contractor retains more control over her own actions.

It is evident that this notion of hierarchical authority is closely related to that of centralization of decisionmaking: the owner decides what the employee should do and incentivizes the latter to obey. And a market relationship with an external contractor involves greater delegation of decisionmaking to the latter. However, one cannot identify firms as distinct from market relationships solely in terms of the distribution of decisionmaking authority. Intrafirm relationships can allow delegation of some decisionmaking authority to employees, just as mar-

ket relationships may involve some instructions sent by clients to suppliers. For this reason, most modern theories of the boundaries between firms and markets emphasize ownership of assets as the defining characteristic. If the employee works with some complementary assets, Van den Steen (2010), for instance, defines a firm or hierarchy as a situation where assets are owned by the employer, and the employer exercises hierarchical authority over the employee. In contrast, in a market relationship between the firm owner and an external contractor, the productive assets are owned by the latter, and the former does not exercise authority over the contractor in the same way as she does over her employees. Van den Steen's theory provides reasons for synergistic connections between asset ownership and decisionmaking authority patterns, so that they tend to be distributed in a similar way (e.g., explaining why asset owners tend to retain more decisionmaking authority).

It is important to clarify at the outset that the literature surveyed in this chapter does not address the question of boundaries between firms and markets or any of the issues relating to asset ownership. Instead it is concerned solely with the question of distribution of decisionmaking authority among sets of agents who work together for productive reasons and enter into contracts with one another that define and shape their interactions. It applies equally to intrafirm organization and to contractual relationships among different firms or suppliers. Most of our interest is in models of organizations with at least three players: in the context of a firm, an employer, owner, or principal (P); a manager-cum-employee (M); and an employee or productive agent (A), who works alone or in collaboration with M to generate a productive benefit for P. In the context of supplier contracting networks, P could be the customer, M could be a prime contractor, and A a subcontractor. In models focusing on the supervisory role of managers, M supervises the actions of A and sends reports to P, which the latter uses in evaluating and compensating A. These models are considered in Section 2. Subsequent sections address the allocation of decisionmaking authority between P and M. A completely centralized organization is one where P retains all authority. The role of M and A is to send reports to P and await instructions from the latter. Alternatively, P could delegate authority to M over decisions concerning production and contracting with A, and evaluate and compensate M on the basis of some measure of performance of the firm or division in question. Later sections address hierarchical allocations of authority in more complex organizations involving more productive agents, multiple products, horizontal layers (i.e., divisions or branches), and vertical layers. The aim is to (1) describe the performance of any given hierarchical pattern of allocating authority under suitable assumptions concerning monitoring and incentive mechanisms available, (2) compare the performance across different patterns of delegation and organizational patterns for a given scale of the organization, and (3) ultimately address the question of organizational diseconomies of scale.

To set this in perspective, it is useful to delineate many issues not addressed in it, many of which are addressed by other chapters in this volume. Because theories of costly information processing are still in a state of relative infancy and have yet to be combined with incentive problems, the theories described here will abstract from them. Garicano and van Zandt (this volume) provides an overview of models which focus on the role of managers as processors of information *per se*. This issue is also partially addressed by Bolton and Dewatripont (this volume).

My main focus is on models of hierarchies in which incentive considerations play an important role. Accordingly, many interesting models of hierarchies based on team theory (Radner

and Marschak 1972), which abstracts from incentive considerations, are not included. In addition, models based on (exogenously) incomplete contracts will not be covered in detail, as they are included in Bolton and Dewatripont (this volume); they also overlap with the discussion by Segal and Whinston (this volume) of property rights. Also ignored are models of interaction between formal and informal contracts, as in the work of Baker et al. (1999).

Nevertheless, some form of contractual incompleteness is essential for delegation to have some benefits. Hence, Section 4 describes contracting models where strategic renegotiation, complexity, or communication costs are explicitly incorporated to explain why contracts may be incomplete and then discuss their implications for the performance of different kinds of hierarchies. Many of these branches of the literature have posed challenges for conventional economic theory and are nowhere near being settled. Despite these problems, I have sought to include them for the sake of completeness, for those interested in pursuing these avenues in future research and the possibility that they may generate useful applications in the future.

Section 2 describes the literature on supervision hierarchies, following the work of Calvo and Wellisz (1978), in which managers are modeled as supervisors. The rationale for supervision is that it helps limit the asymmetry of information between employees and owners, thus limiting the scope for opportunistic behavior by the former. Owing to limitations of time or expertise, owners may seek to supplement their own supervisory activities with information supplied by third-party supervisors. Yet these hired supervisors also need to be motivated to apply effort in supervision and thus need to be supervised themselves. This creates the rationale for a hierarchy of supervisors. Much of this literature has sought to explore implications for limits to the size of firms, as firms with a larger scale of operations employ more workers and thus need a larger hierarchy of supervisors, causing organizational diseconomies of scale, owing to resultant losses of control across successive vertical layers of managers. This intuitive idea, expressed originally by Williamson (1967), however, has turned out to be quite difficult to model. We also describe some recent literature on supervision hierarchies following Tirole (1986), which focuses on problems of collusion between supervisors and supervisees, ways of combating these problems, and their implications for performance.

Section 3 turns to models of delegation of decisionmaking authority to managers. The focus in this section is on the attendant cost or “control loss” incurred by the principal, owing to incentive problems (i.e., noncongruence of goals and information between owners and managers). The benefits of delegation are not studied in this approach, as these are presumed to arise from unmodeled costs of centralizing all information processing and decisionmaking responsibilities with the principal. The advantage of this approach is that it utilizes tools of mechanism design theory, which rely on the assumption of complete contracts, in an environment where the Revelation Principle applies: the principal is assumed to be able to commit to a comprehensive contract; there are no costs of communication or contractual complexity; and agents behave noncooperatively. These models help show the precise circumstances under which delegation arrangements can be structured in a way to avoid any loss of control, so that they can implement optimal allocations. Briefly, this requires three sets of conditions: risk neutrality of managers, ability of the principal to monitor measures of performance pertaining to the allocation of effort or payments between managers and their subordinates, and ability to prevent collusion (in the form of unobserved side payments or communication). Violation of any of

these conditions—financial constraints faced by managers, lack of suitable accounting systems, or collusion—constitute potential sources of control loss. The implications of collusion are subsequently considered in this section. This branch of the literature is less settled, owing to the inherent complexity of the issue and different ways it has been formulated by numerous authors.

Section 4 subsequently addresses the question of the benefits of delegation in conjunction with its costs. This necessitates a framework in which the Revelation Principle no longer applies and contracts are incomplete. I describe models based, respectively, on limited commitment ability of the principal and on costs of communication or contractual complexity. Either of these frameworks is shown to generate a theory of delegation, trading off its costs and benefits. When the underlying problem is the possibility of strategic renegotiation, delegating control is beneficial from an incentive standpoint, but it raises problems of coordinating the agent's actions with information that subsequently becomes available to the principal. In contexts involving complexity or communication costs, delegation permits actions to be responsive to information available to agents that they cannot communicate to the principal or to third-party contract enforcers. This has to be traded off against the costs of control loss considered in Section 3. The value of delegation thus depends on the determinants of control loss, such as managerial financial constraints, problems of monitoring, or collusion. The theory also suggests the value of intermediate organizational structures, where some decisions, such as contracting and evaluation, are centralized, while authority over production decisions is delegated to employees.

The abovementioned sections deal with the simplest possible model of a hierarchy involving three vertical layers, consisting of a single principal at the top, a single manager in the middle, and one or two productive agents at the bottom. Models of larger and more complex hierarchies are considered in Section 5; these models build on the simpler ones in earlier sections. They focus on problems of horizontal coordination across departments, scale diseconomies, and grouping of activities into departments (e.g., U-form versus M-form hierarchies).

Finally, Section 6 concludes with an assessment of the achievements and shortcomings of the literature and possible research directions for the future.

2. Organizational Scale Diseconomies and Supervision Hierarchies

Williamson (1967) initiated the modern literature on the limits to size of hierarchical firms arising from the control losses associated with internal management problems. His theory is based on a behavioral theory of how losses of information and control arise across vertical layers of management. The other ingredient in the theory is the limit to the span of control of any given manager; that is, the number of subordinates that any manager can oversee owing to problems of limited time and attention. Given the limits of span of control, it is not possible for the firm to grow without adding vertical layers of management. But then the vertical control losses cascade across the various layers, implying rising inefficiency as the firm grows.

The source of these control losses are not explained by Williamson's model. He provides as motivation errors in serial reproduction demonstrated in social psychology experiments, wherein losses in information can occur when it passes through a succession of individuals, despite each individual in the chain being satisfied they have passed on all important features of their own information with little or no change. Hence, top managers in organizations tend to be progressively out of touch with events at the ground level, as the number of vertical layers

increase. Other sources of control loss are asymmetric information and opportunistic behavior by subordinates, which were not, however, part of the formal model. We start by describing Williamson's formulation, followed by the effort of Calvo and Wellisz (1978) to provide a microfoundation for vertical control losses owing to incentive problems.

2.1. The Williamson-Calvo-Wellisz Model

The simplest version of Williamson's model has an exogenously given span of control s at each layer. At the top level ($i = 1$) of the firm there is one owner or principal, supervising s managers at level $i = 2$, each of whom are supervising s level-3 managers in turn, and so on. At the very bottom layer n , there are thus s^{n-1} employees, the production workers of the firm. All layers $i = 1, \dots, n - 1$ consist of managers or supervisors, layer i consisting of s^{i-1} managers. The production function yields the firm's output as a Cobb-Douglas function of the number of production workers s^{n-1} and a level of total factor productivity that reflects a proportional loss of output owing to control loss at each management layer: $y = (\bar{a}s)^{n-1}$, where $\bar{a} \in (0, 1)$ is the vertical control loss parameter reflecting communication and incentive problems.

Williamson also assumes an exogenous rate of wage progression across layers of the hierarchy; $\beta > 1$ is the ratio of wages at one level to the level below. Hence, if w_0 denotes the wage of production workers, level $n - 1$ managers earn βw_0 , and level i managers earn $w_0 \beta^{n-i}$.

If the firm faces product price P on the output market (net of raw material costs per unit of output) and wage rate w_0 for production workers on the labor market, it selects a size (or number of layers n) to maximize $P(\bar{a}s)^{n-1} - w_0 \sum_{i=1}^n s^{i-1} \beta^{n-i}$. This expression yields an equation for the number of layers as a function of span of control, the vertical control loss parameter $\bar{a}$, the wage rate for production workers, and the rate of wage growth across layers:

$$n^* = 1 + \frac{1}{\log \bar{a}} \left[\log \frac{w_0}{P} + \log \frac{s}{s - \beta} + \log \left(\frac{\log s}{\log \bar{a}s} \right) \right]. \quad (1)$$

Firm size is finite if $\bar{a} < 1$ and tends to ∞ as control losses disappear ($\bar{a} \rightarrow 1$). It is also increasing in s , the span of control.

An extended version of this model makes the span of control s endogenous by postulating that the vertical control loss at any layer is increasing in s . This captures the intuitive idea that limits on time and attention of any supervisor cause loss of control per subordinate when the supervisor has to supervise more people. Hence, $\bar{a}$ is decreasing in s . With the specific functional form $\bar{a}(s) = \exp[-ks^2]$, Williamson (1967) shows that larger firms have higher n and lower s , but this result seems to depend on the specific functional form chosen.

Williamson's model has the virtue of delivering predictions concerning size and structure of firms based on technology and product and labor market characteristics that can be empirically tested. However, the key ingredients of the theory—vertical control loss $\bar{a}$ and the rate of wage progression β in the hierarchy—are taken as given. Much of the literature described in this chapter can be viewed as an attempt to endogenize these factors on the basis of incentive considerations and thereby provide a microfoundation for the Williamson model. As we shall see, this goal has yet to be fully achieved.

Calvo and Wellisz (1978) were among the first to attempt endogenization, using a model of supervision and wage incentives. In this model, all workers and supervisors are identical: they have a utility function $u(c) - v(a)$, where u is a smooth, strictly increasing, concave function of consumption or earnings c ; v is a smooth, strictly increasing, convex function representing disutility of effort $a \in [0, 1]$, which is the fraction of the week worked; and $u(0) = v(0) = 0$. A production worker applying effort a generates revenue Pa for the employer, where P is a given parameter depending on output price, raw material costs, and technology.

The supervision process is as follows. Supervisors allocate their time equally between monitoring all their subordinates. If the number of supervisors at level i is denoted by M_i , and if they work a_i fraction of the week, the amount of time devoted to supervision per level- $(i + 1)$ employee is $\frac{a_i M_i}{M_{i+1}}$. With probability $p_{i+1} \equiv g(\frac{a_i M_i}{M_{i+1}})$, the true value of a_{i+1} , the time worked by any level- $(i + 1)$ employee will become known, where g is a strictly increasing function satisfying $g(0) = 0$ and $g(\infty) \in (0, 1]$. Here it is assumed that supervisors report their findings honestly to the employer.

Let w_{i+1} denote the wage paid for full-time work to a level- $(i + 1)$ employee. This will be determined endogenously, as explained below. If the employer learns from supervisor reports that an employee at level $i + 1$ worked a_{i+1} , this employee is paid $a_{i+1}w_{i+1}$. If no information is available, the employee is presumed to have worked full time and is paid a wage of w_{i+1} . Hence, workers detected shirking are punished by having wages withheld for the fraction of time they are reliably known to have shirked.

Consider a worker who is monitored with probability p and paid a full-time wage of w . This worker will choose to work a^* fraction of the time, which maximizes $pu(wa) + (1 - p)u(w) - v(a)$. Clearly, this expression is increasing in p and is also a function of w : let it be denoted by $a^*(p; w)$. The worker will agree to work for the firm if $V(p, w) \equiv pu(wa^*(p, w)) + (1 - p)u(w) - v(a^*(p, w)) \geq \underline{u}$, a given positive level of utility that forms the worker's outside option. Clearly $V(p, w)$ is increasing in w and decreasing in p .

Consider first a firm where the owner herself supervises all production workers, in what we may call a "one-layer hierarchy." Assume that the owner has a fixed amount of time, normalized to unity, available to supervise the workers. The optimal size of such a firm is defined by the solution to the following problem: choose n , the number of production workers, and a wage w , to maximize $nPa^*(p, w) - [pwa^*(p, w) + (1 - p)w]n$, subject to $p = g(\frac{1}{n})$ and the participation constraint for workers. It is easy to verify that there is an interior optimum for both n and w for this problem. In particular, as n rises, the monitoring probability p falls, inducing workers to shirk. As n tends to ∞ , p tends to 0, and workers then tend to apply zero effort, in which case firm profits tend to $-\infty$ (because the firm needs to pay a positive wage to attract workers). Hence, firm size is bounded if it is owner managed (i.e., a one-layer hierarchy). Denote by π_1^* the maximized level of profit achieved by the owner in this case.

One way for the firm to expand is to hire third-party supervisors. In a two-layer hierarchy, the owner employs a number of supervisors and asks them to monitor production workers. The owner herself monitors the supervisors, which ensures that the supervisors exert effort in monitoring production workers, which in turns motivates the latter to apply effort in production. The incentive problem for choice of effort by supervisors (as well as the participation constraint) is exactly analogous to that of production workers. In a two-layer hierarchy the owner selects the number of supervisors and the number of production workers supervised by each supervisor, as

well as the wages at each layer. Hiring level-1 supervisors relieves the owner with regard to supervisory responsibility, thus enabling the firm to employ more production workers and ensure that their efforts do not get diluted owing to the shrinking probability of being monitored when the owner alone has to conduct all supervision. This model formalizes the notion of vertical control loss and how it increases in the span of control. The Calvo-Wellisz model thus allows a simple and elegant model of these critical variables that were assumed exogenous in the Williamson model. Moreover, the wage structure in the hierarchy is also endogenously determined.

The salient question is whether these control losses arising for incentive reasons limit the size of the firm. Let π_n^* denote the level of maximum profit earned by the owner in an n -layer hierarchy. The interesting result in the Calvo-Wellisz (1978) paper is that this model does not provide a limit to the size of the firm. The key proposition is the following. *Suppose $\pi_1^* > P$, that is, it is more profitable for the owner to hire production workers and form a one-layer hierarchy rather than do all the production work herself. Then $\pi_n^* \rightarrow \infty$ as $n \rightarrow \infty$.*

Here is an outline of the argument. It suffices to show there is a way of expanding the number of production workers indefinitely by raising n , which leads to unbounded profits. This method involves replicating the optimal incentive arrangement for production workers for every layer of supervisor in an n -layer hierarchy. Specifically, letting a^* , w^* , n^* denote the optimal values of a , n , w , respectively, in a one-layer hierarchy, select a constant span of control $s^* = n^*$ at each level of the hierarchy, and pay the same wages at all levels. Hence, the number of supervisors at a pair of successive levels $i - 1$ and i is selected so that $\frac{a^* M_{i-1}}{M_i} = \frac{1}{n^*}$. Provided supervisors at level $i - 1$ are working a^* each, each level- i supervisor is monitored with the same probability $p^* \equiv \frac{1}{n^*}$ as are production workers in a one-layer hierarchy. Hence, it is optimal for each such supervisor to agree to work for this firm, and work a^* fraction of the time. Letting W^* denote the expected wage cost per employee $p^* w^* a^* + (1 - p^*) w^*$, expanding the firm from $n - 1$ to n layers results in an increase in profit by

$$\begin{aligned} Pa^*(M_n - M_{n-1}) - M_n W^* &= M_n [Pa^*(1 - \frac{M_{n-1}}{M_n}) - W^*] = M_n [Pa^* - P \frac{1}{n^*} - W^*] \\ &= \frac{M_n}{n^*} [(Pa^* - W^*)n^* - P] = \frac{M_n}{n^*} [\pi_1^* - P], \end{aligned}$$

which grows without limit as $M_n \rightarrow \infty$. Essentially, the mechanism in place in a one-layer hierarchy can be replicated independently for each supervisor at each layer. Hence, the model shows that incentive problems do not necessarily constitute a source of control loss that limits the size of firms. Formalizing the simple Williamsonian intuition will require some additional ingredients.

Of course the preceding model is somewhat special in a number of respects, such as the symmetry between workers and supervisors and their respective incentive problems. It turns out, however, that the basic result is robust to many variations that make the model more realistic (Datta 1996; Tsumagari 1999). Both these papers consider contexts in which supervisory effort cannot be directly monitored. Datta studies a context in which supervisors are evaluated indirectly by monitoring the output of production workers directly or indirectly under their supervision. Here the Calvo and Wellisz (1978) replication arguments continue to apply under plausible assumptions: supervisors are evaluated on the basis of the performance of their

respective divisions and internalize the effect of their own shirking on their subordinates' efforts. Tsumagari considers a context in which supervisors have overlapping jurisdictions, with cross-checking of reports of different supervisors. In this context the firm can expand horizontally rather than vertically, with each supervisor being cross-checked against reports of adjacent supervisors; again, firm size is unbounded under reasonable conditions.

Another variation was suggested by Calvo and Wellisz (1978) themselves, in which supervisees know in advance exactly when they are being monitored, so the fraction of time they work equals the fraction of time they are monitored. This implies that to get n production workers to work any fixed positive a fraction of the week, it is necessary to have them supervised by the same number of supervisors working a fraction of the week, and the same is true in turn for the supervisors themselves, so ultimately the owner will have to personally spend at least na fraction of the week. Given the limit on the total time available to the owner, it is impossible to let n grow indefinitely while a is bounded away from zero. In that case firm size is limited. However, this constraint no longer holds once there is some scope for random audits, wherein workers do not know in advance when or whether they will be monitored. In that case one supervisor working a fraction of the week can supervise and ensure that $n > 1$ subordinates will also work a fraction of the week. The logic of the model described above then kicks in to ensure that the firm can grow indefinitely.

Qian (1994) returns to this question with a formulation that combines aspects of the Calvo-Wellisz model with Williamson's (1967) model. The critical departure from the Calvo-Wellisz model is the production function. Because the number of production workers in the n -layer Calvo-Wellisz hierarchy equals M_n , the gross revenue of the firm in the Calvo-Wellisz model equals $PM_n a_n$ if the layer- i employees apply effort a_i . Qian assumes instead a gross revenue that equals $PM_n a_n a_{n-1} \dots a_1$. In other words, there is an additional source of revenue loss $a_{n-1} \dots a_1$ arising from the existence of supervisors at intermediate levels of the hierarchy. Qian uses a variant of the incentive model of Calvo and Wellisz, whereby any shirking of the employee below the mandated effort level a^* is punished with a zero wage. Consequently, an employee monitored with probability p needs to be paid an efficiency wage of $\underline{w} \equiv \frac{v(a^*)}{p} = sv(a^*)$ to induce an effort of a^* , where $s \equiv \frac{1}{p}$ denotes the span of control of the employees' supervisor. The costs of increasing the span of control are thus represented by a corresponding linear increase in the efficiency wage for a given level of effort.

Using this formulation, Qian (1994) studies the problem of determining the optimal hierarchy (i.e., number of layers, span of control at every layer, and efforts and corresponding wages at each layer). If feasible effort a for any employee is zero or one, then clearly every employee must be induced to work ($a = 1$), and the formulation coincides with Calvo and Wellisz (1978). In this case, there is no limit to firm size. The other case that Qian investigates is where a can be any number in the unit interval, and $v(a) \rightarrow \infty$ as $a \rightarrow 1$. In that case it is impossible to get anyone to work full time, and every agent must put in an interior $a \in (0, 1)$ in any optimal arrangement, with a bounded away from 1. Given the specification of the production function, however, this case implies that the supplementary control losses $a_{n-1} \dots a_1$ arising from the existence of intermediate supervisors must cascade, implying that the firm's revenue eventually converges to zero as the number of layers grows without bound. A limit to the size of the firm obtains. But it is due entirely to vertical control losses, which remain unexplained. It is not clear why the effort of the supervisors has any effect over and above the way they influence the effort of

those they supervise. Perhaps managers do other things apart from supervise workers, but these are not included or explained. Hence the Calvo and Wellisz puzzle of limits to firm size is not really resolved in this model. This shortcoming motivates the consideration of the possibility of collusion between supervisors and workers, a factor ignored by the preceding models.

2.2. Collusion and Supervision

The literature on collusion and supervision was pioneered by Tirole (1986). His model has a principal P and an agent A who produces revenue $\theta + a$ for P , where $\theta \in \{\theta_L, \theta_H\}$ is a productivity realization that is observed by A before choosing a level of effort a . Productivity can be either low (θ_L) or high (θ_H), where $\theta_H > \theta_L > 0$. P 's net payoff is the expected value of $\theta + a - w$, where w is the wage paid to A . A 's payoff is $u(w - v(a))$, where v is an increasing convex function of $a \geq 0$, and u is a strictly increasing concave function. A has a reservation utility normalized to 0.

P can hire a supervisor S , who may observe the realization of θ , though he cannot observe the agent's effort a . The information that S can observe in the process of supervision is represented by a signal σ with three possible realizations: θ_L , θ_H , and ϕ . If $\sigma = \theta_i$, $i = L, H$, the true state is exactly θ_i : in this case S learns the true state with certainty. However, the signal may also equal ϕ in either state: in this case S does not learn the true state. Tirole assumes that the signal represents hard information: S can submit definite evidence to P concerning the realization of the signal when it reveals the true state. S cannot fabricate evidence when there is none (i.e., he cannot produce any evidence when $\sigma = \phi$). The only option for behaving strategically is to suppress evidence: S can claim $\sigma = \phi$ when he did receive evidence of the true state. Unlike the Calvo-Wellisz model, supervisory effort per se generates no disutility for S . The latter's utility is $V(c)$, where c denotes the financial return of S , and V is a strictly increasing concave function. S also has a given outside option level of utility.

P lacks the capacity or time to supervise the agent herself. In this situation, she would design an incentive contract for A , which, as per the standard model of incentives with adverse selection, motivates the first-best effort a^* satisfying $v'(a^*) = 1$ when A observes $\theta = \theta_H$, and a lower level of effort $\underline{a}$ when A observes $\theta = \theta_L$. In the former state A earns an incentive rent (i.e., obtains a wage high enough to end up with a payoff above his outside option). In the latter state A earns zero rent (i.e., a net payoff equal to the outside option). In this equilibrium, A is indifferent in the high-productivity state between producing the revenue of $(\theta_H + a^*)$ and $(\theta_H + \underline{a})$. The rent earned by A in the high-productivity state is the price or bonus paid by P to induce A to apply high effort in this state, rather than slacking off on effort (reducing a from a^* to $\underline{a} - (\theta_H - \theta_L)$ and pretending that the state is θ_L instead of θ_H).

When S is hired and does not collude with A , he reports the realization of the signal truthfully to P . This reduces the informational asymmetry between P and A , enabling P to avoid paying the incentive rent to A when there is firm evidence that the true state is θ_H . This is the benefit P obtains from hiring S , which has to be traded off against the cost of hiring S . If S 's outside option is low enough (e.g., if it is zero), the cost of hiring S is low enough that it is profitable for P to hire S . Here S earns a fixed salary of c , just equal to the level necessary to induce him to accept the job.

But now A has an incentive to bribe S to suppress evidence of the high-productivity state, and so qualify for the incentive rent. S does not mind accepting the bribe, as the salary c is fixed, while

A gains the incentive rent as a result of the suppression of evidence. Tirole (1986) assumes that there are no frictions in collusion—it can be modeled as an enforceable side-contract between S and A, which cannot be observed by P. Moreover, A knows exactly what evidence is available to S, so in the case where S receives evidence, there is no asymmetric information between S and A. Effectively, then, S and A will then jointly behave as if they were a single player, earning a pecuniary equivalent payoff of $c + w - v(a)$ equal to the sum of their respective payoffs. The second-best payoff achieved by P is thus no longer achievable in the presence of collusion.

Tirole goes on to solve for the third-best contract, which maximizes P's expected payoff, subject to both individual and joint collusive incentives of S and A. An argument analogous to the Revelation Principle shows that P can confine attention to contracts that are collusion proof (i.e., in which S and A have no incentive to enter into a collusive agreement), and S reports his evidence truthfully to P. This is achieved partly by P offering S a selective reward for disclosing evidence of high productivity, as well as reducing the power of A's incentives and rents, both of which reduce the stakes for collusion. A has less to gain by bribing S to suppress evidence of high productivity, and S is less willing to suppress this evidence. The net consequence is that S will be forced to bear the risk associated with the availability of evidence, for which P will have to pay S a risk premium if S is risk averse. And A will be provided with less effort incentive. On both counts P's profitability will decline, compared with the second-best outcome. The extent to which this decline occurs depends on how risk averse S is. If S is risk neutral, P does not lose at all: P can effectively sell the firm to S and thereby overcome the problem of collusion entirely—there is no loss of either profitability or productivity. At the other extreme, if S is infinitely risk averse, no risk can be imposed on S at all, which implies no incentive rents can be paid to A; the firm ends up with low productivity and profitability. Nevertheless, even in this case it pays P to hire S if the latter has a zero outside option, owing to the advocacy role he plays on behalf of A (by providing evidence of state θ_L when it occurs, which is in the joint interest of S and A). In general, when S is somewhat but not infinitely risk averse, the three-layer hierarchy is more profitable than the two-layer one in which S is not hired, though the agent may become less productive owing to the reduction in the power of incentives.

Tirole's model provides an useful illustration of the problem of collusion and its consequences. Worker incentives are lower in the three-layer hierarchy compared with the two-layer one. The costs of collusion are the rents P has to pay the supervisor to deter collusion and the lower effort of the worker. The severity of these costs depends on the risk aversion of the supervisor. Despite these collusion costs, they are outweighed by the benefits of hiring a supervisor. We shall see in subsequent sections that similar results arise in the literature on delegation. Interesting applications of this theory to auditing and regulation have been developed. For instance, Kofman and Lawaree (1993) extend Tirole's model to include external and internal auditors and explain the role of the former in cross-checking reports made by internal auditors who may be colluding with workers. Laffont and Tirole (1993) develop a comprehensive theory of regulation of natural monopolies based on the role of regulators who monitor firms' technology and cost-cutting efforts and can be potentially bribed to not disclose their findings publicly.

Comparatively less attention has been devoted to the question of whether collusion can serve as a source of control loss that limits the size of firms. Datta (1996) sketches an example where collusion limits firm size. Supervisors are evaluated by audits of production workers in their divisions. Firms must grow by adding vertical layers owing to endogenous limits on the span of control, and collusion is deterred by inconsistency of audit reports at successive vertical layers.

The larger the firm gets, the lower the likelihood of such inconsistencies becomes. In contrast, collusion does not limit the size of the firm in the Tsumagari (1999) model based on overlapping jurisdictions of different supervisors. In his model, the firm grows horizontally; hence, there is no problem of cascading control losses.

In summary, models of supervision hierarchies have illustrated some of the difficulties in explaining limits to firm size. Collusion is probably important in understanding why larger organizations tend to be less productive and why middle managers earn large rents. But we still do not have tractable models of determinate firm size and structure based on collusion and supervision.

3. Delegation and Loss of Control with Complete Contracts

The previous section focused on the supervisory role of managers, pertaining to the generation of information concerning the activities of subordinates that helps evaluate and motivate the latter. Supervision *per se* does not include any responsibility for actual decisions. Conceptually there is little difference between supervisors and external consultants, whom the principal may rely on to generate information relevant to the decisions she makes. The models do not explain why authority over decisions may be delegated. In the supervision models, the principal still contracts with all workers and suppliers personally and makes all relevant production, technology, marketing, and sourcing decisions.

In this and succeeding sections I focus on the question of delegation of key operating decisions to managers. As the quote from Chandler (1962) in Section 1 indicates, although managers may play some role in the production process themselves, they rarely do so at higher levels of the hierarchy. Their functions include contracting and supervision of subordinates, allocating resources, and coordinating the activities of departments under their control, apart from long-term planning. The principal or owners rarely become personally involved in the internal administration of the enterprise.

From an analytical perspective, we therefore need to understand the implications of delegation of contracting with subordinates to managers, where the term “contracting” includes production and sourcing decisions, coordination of production and allocation of resources, recruitment, and supervision and evaluation of employees and suppliers. In this section I do not pose the question of why the principal does not carry out these tasks herself (i.e., what the value of delegation of contracting is). Instead, I simply assume that decisions will be delegated and study how the principal ought to evaluate and compensate a self-interested manager. This is precisely the problem of potential loss of control. The questions posed by these models are: What are the determinants of this loss of control? What are the strategies for ameliorating it?

In Section 3.1, I assume the conditions underlying the Revelation Principle are valid: there are no costs of communication, complexity, or information processing; the principal can commit to a comprehensive contract; and agents do not collude. Under these circumstances the Revelation Principle (e.g., Myerson 1982) tells us that centralized decisionmaking—where the principal contracts and communicates with all agents personally and makes all relevant decisions based on reports of private information of the agents—can always perform at least as well as any method of decentralizing these responsibilities. Hence, delegation can never outperform centralization. The question addressed instead is: can delegation of key

responsibilities to self-interested managers achieve the same level of profit for the principal as any centralized mechanism? If so, delegation is costless and is a way of implementing the optimal mechanism.

We shall subsequently explore the consequences of dropping different assumptions underlying the Revelation Principle. The latter part of this section explores the effects of collusion among agents, preserving all the other assumptions. Section 4 examines the consequences of inability of the principal to commit to a mechanism or of costs of communication and complexity. Because subsequent sections build on this one, it makes sense to explain the results in some detail.

3.1. The Basic Model

The standard model in this section is a simple adverse selection contracting problem. Analogous questions in a moral hazard setting have been studied by Baliga and Sjöström (1998) and Macho-Stadler and Perez-Castrillo (1998). There is one Principal P, one or two agents A (or A_i , $i = 1, 2$), and a third-party manager M. Extension of these models to incorporate more agents, managers, or layers will be covered in Section 5. The agents carry out productive tasks that generate a revenue or gross benefit B for P. In the single-agent case, A delivers a good or service $a \geq 0$ that generates a benefit $B(a)$. In the two-agent case A_i delivers $a_i \geq 0$, and the benefit is $B(a_1, a_2)$. The two goods delivered could be perfect substitutes, in which case B depends only on $a_1 + a_2$; in this case the mechanism design problem reduces to a procurement auction with variable quantities. Or the two goods could be perfect complements: $B = \min\{a_1, a_2\}$. More generally, a_1 and a_2 could be neither perfect substitutes nor perfect complements, as represented by a production function with a constant elasticity of substitution.

Agents are privately informed regarding their cost of production before they need to commit to deciding whether to participate in the mechanisms concerned. In other words, contracting occurs at the interim stage, where each agent knows his own cost but not the cost realizations of others. Most authors assume that each agent's unit cost does not vary with the level of production, and this unit cost is uncertain. Some authors assume that these costs can take one of two possible values. Others assume they are distributed on an interval of the real line, with a standard monotone hazard rate assumption on the distribution, which ensures that global incentive constraints can be ignored. Specifically, if θ_i is the unit cost incurred by A_i , it is distributed according to a cumulative distribution function F_i and density f_i on an interval $[\underline{\theta}_i, \bar{\theta}_i]$, where $\theta_i + \frac{F_i(\theta_i)}{f_i(\theta_i)}$ is nondecreasing in θ_i , an assumption satisfied by the uniform, exponential, and many other well-known distributions. Throughout it is assumed that θ_1, θ_2 are independently distributed. Moreover, most formulations assume risk neutrality and zero outside option utilities for agents. Hence, P's payoff is $B(a_1, a_2) - t_1 - t_2 - t_M$, where t_1, t_2 , and t_M denote transfers made by P to A_1, A_2 , and M, respectively. The payoff of A_i is $T_i - \theta_i a_i$ and of M is T_M , where T_i and T_M denote net transfers received by A_i and M, respectively. In the centralized mechanism without any collusion, $T_i = t_i$ and $T_M = t_M$, but this is not the case in decentralized mechanisms or in the presence of collusion, owing to side-transfers between the agents.

Many authors have studied what we shall call the "restricted version" of the standard problem, in which each agent's cost takes one of two possible values, and the inputs produced by the

two agents are perfect complements. Other authors have studied the continuous version of this problem, in which costs are distributed according to a density on an interval on the real line, and no restriction is imposed on the benefit function.

Decisionmaking responsibility can be delegated either to one of the productive agents or to the third-party manager M . The latter may also act as a supervisor of the productive agents, receiving a private signal of their cost realizations. Agents and the manager all act in a self-interested fashion.

In this section I assume that it is possible for anyone with contracting authority to commit to a comprehensive contract, which includes details of communication protocols (i.e., the message sets, who communicates with whom and when, etc.), production assignments, and transfers. Owing to the Revelation Principle, it will suffice to focus on revelation mechanisms in the centralized regime, where agents report their private information and receive instructions concerning production assignments. The outputs a_i they deliver are assumed to be costlessly monitored; transfers can be conditioned on these outputs, and/or reports communicated. In the decentralized regime, assumptions concerning sequencing, communication, and observability will be made explicit in due course.

3.2. Single Agent, No Collusion

Here A produces a at cost θa , P 's net payoff is $B(a) - t$, and A 's is $t - \theta a$. In this setting the following mechanisms can be compared: (1) centralization, denoted by $(P^* - A)$, where “ $*$ ” depicts the decisionmaker and a “ $-$ ” indicates a line of hierarchical control; (2) agent-based decentralization, denoted by $(P - A^*)$; and (3) manager-based decentralization, denoted by $(P - M^* - A)$. In $(P^* - A)$, P retains all decision rights. In $(P - A^*)$, P contracts with A but delegates production decisions to A . In $(P - M^* - A)$, P delegates contracting and production decisions to M and contracts with M alone. M contracts in turn with A . M is evaluated and compensated by P based on the revenue generated. Other mechanisms are also possible, such as $(P^* - (M, A))$, where M 's role is purely supervisory or consultative and thus is on the same hierarchical level as A , depicted by the parentheses around the set of agents M and A at that level. Here P contracts with both M and A , and M 's responsibility is limited to submitting a report to P concerning the signal concerning A 's cost. P uses this information to evaluate and compensate A .

It is obvious that centralization $(P^* - A)$ and agent-based decentralization $(P - A^*)$ achieve equivalent outcomes, in what is often referred to as the “Taxation Principle.” Under the former, P designs an incentive-compatible revelation mechanism $a(\theta)$, $t(\theta)$, in which A is always motivated to report truthfully. Equivalent outcomes are achieved in agent-based decentralization by P instead offering A a nonlinear incentive mechanism $t(a)$ equal to $t(\theta)$ if $a = a(\theta)$ for some θ and 0 otherwise. The incentive compatibility of the original revelation mechanism implies that this nonlinear function is well defined and motivates A to select the same production in every state as did P in the centralized regime. The converse is equally straightforward, amounting to the proof of the Revelation Principle. Generalizations of this result to contexts with production or monitoring uncertainty (i.e., where P 's revenue or measured performance is not a but is some function $R(a, \epsilon)$, where ϵ is a random variable unobserved by A at the time of selecting a) have been provided by Melumad and Reichelstein (1989).

Matters are somewhat more interesting when P has the opportunity of using the services of M to supervise the agent. If M and A do not collude, P can obtain M 's information costlessly in the centralized mechanism $P^* - (M, A)$, because M does not have any incentive to hide his information. Here the outcome is the same as if P contracted with A with the same information as M . This is no longer the case in the decentralized variant ($P - M^* - A$), because M can act strategically with respect to his information. This result is easy to see if M is perfectly informed about the cost realization θ : in that case M can procure any quantity a from A at cost θa , and the problem is equivalent to P contracting with A in the absence of M . The same result is also evident when M 's information about θ is identical to P 's. Hence, delegation to M is typically costly in this setting.

3.3. Two Agents, No Collusion

We now come to a model involving two productive agents and a single principal, considered by various authors in diverse settings of regulation and internal organization (Baron and Besanko 1992; Gilbert and Riordan 1995; Melumad et al. 1992, 1995; Laffont and Martimort 1998; Severinov 2008). This model is extended in subsequent sections on collusion and incomplete contracts, so it makes sense to present the results in some detail.

The chief question concerns implications of delegating contracting and production decisions to one of the two agents. In the regulation context, the regulated entity may be a downstream service provider who procures a essential input from an upstream firm. The question is whether the regulator should regulate both firms directly as well as all aspects of production and transfers between them or whether only the downstream firm ought to be regulated and is free to procure its inputs from the upstream provider. In a team-production setting within a firm, the employer could retain all authority and treat the different team members symmetrically. Alternatively, she could appoint one of them as the manager and delegate decisions concerning contracting with other agents to the manager. An additional alternative is to hire a manager M^* who plays no productive role but supervises the producing agents.

In this setting, the alternatives are (1) centralization ($P^* - (A_1, A_2)$); (2) agent-based delegation ($P - A_1^* - A_2$), where P delegates to A_1 the responsibility of communicating and contracting with A_2 ; and (3) manager-based delegation ($P - M^* - (A_1, A_2)$), where P delegates to M the responsibility of contracting with A_1, A_2 . Variants of these include ($P - (A_1^*, A_2^*)$), where P contracts with the two agents but delegates to them the right to make their own production decisions. Another is ($P^* - (M, A_1, A_2)$), where P retains all decision rights, and the sole responsibility of M is to communicate reports to P .

Consider the comparison between the centralized ($P^* - (A_1, A_2)$) and decentralized ($P - A_1^* - A_2$) variants. There are many variants of the decentralized version, differing with respect to the precise sequencing of contracting, and the information available to P concerning the performance of the manager-cum-worker A_1 .

A key result here is that *delegation to A_1 is optimal (i.e., can achieve the same expected profit as centralized contracting), if (1) the sequence of contracting is "top-down" in the sense that P contracts with A_1 ¹ before A_1 communicates or contracts with A_2 ; (2) P monitors both the gross revenue B*

1. This contract includes both a commitment from A_1 to participate in the mechanism, and submission of a report concerning his own state.

and either the payment t_2 made by A_1 to A_2 or the input a_1 delivered by A_1 alone; and (3) A_1 is risk neutral and is not subject to any limited liability constraint.²

The argument is constructive: P can offer A_1 a contract that makes the latter a residual claimant on profits earned by the former, adjusted by a subsidy for payments made to A_2 or on the extent of input supplied by the latter. The subsidy corrects for the tendency of A_1 to procure too little from the other agent, owing to her tendency to maximize her own information rents. This problem is key with delegation, closely related to the phenomenon of “double marginalization of rents” (DMR) in the industrial organization literature on vertical contracting relationships (see, e.g., Tirole 1988). Contracting with adverse selection gives rise to monopsony distortions: owing to the trade-off between productive efficiency and incentive rents, too little tends to be procured by those in middle tiers.

Nevertheless, these papers show that the problem can be overcome under the specified assumptions of risk neutrality, appropriate sequencing of contracts to prevent collusion, and monitoring of contributions of the manager vis-à-vis the rest of the team. When the latter takes the form of monitoring of payments, the incentive system for the manager resembles that of decentralized profit or cost centers within firms (Melumad et al. 1992). Observability of aggregate cost of the division suffices to overcome the DMR problem. It is not necessary for P to observe further details of the side-contracts designed by A_1 or the communication of the latter with his subordinates.

Nevertheless, some monitoring of side-contracts (or A_1 's output a_1) is essential, as long as there is some substitutability between a_1 and a_2 . Only in the case of perfect complementarity (a Leontief production function) can the DMR problem be avoided if P does not monitor any aspect of the transactions between A_1 and his subordinates. And even in that case, there would be a tendency for A_1 to generate too much aggregate revenue. This tendency provides a possible explanation for the empire-building tendencies of managers, which shareholders seek to limit in various ways (e.g., using a compensation formula where fractional bonus coefficients are used to reduce the manager's inclination to overexpand operations). The conflict of interest between owner and manager arises owing to the informational rents earned by the manager, which the manager sees as a benefit, but the shareholders see as a cost. Baron and Besanko (1992), who study the case of perfect complementarity, avoid this problem by centralizing the production decision while delegating A_1 only the responsibility for contracting and communicating with A_2 . The DMR problem is then avoided by reducing the extent of responsibility delegated.

The other assumptions (1) and (3) also play an essential role in ensuring the optimality of delegation. Delegation enlarges the extent of asymmetric information between P and A_1 , as the latter is now privately informed both about his own cost θ_1 and those of his subordinates θ_2 . This knowledge would expand the informational rents that A_1 would earn vis-à-vis P, on top of the rents that A_2 earns. This scenario is another version of the DMR problem. It is avoided with assumption (1) of top-down contracting, because A_1 contracts with P before he learns the realization of θ_2 . These additional rents can then be “taxed” away at the time of contracting. For this it is necessary that A_1 end up with a negative payoff in some states of the world (e.g., when both θ_1 and θ_2 end up too high). This situation would not be possible

2. Severinov (2008) shows that additional conditions on the degree of complementarity between the inputs supplied by the two agents are needed if cost types have a discrete rather than a continuous distribution.

if there were a limited liability constraint requiring A_1 's payoff be nonnegative in all states of the world. This observation is the central point made by McAfee and McMillan (1995), which underlies their model of organizational diseconomies of scale. Such a context is similar to one where A_1 communicates with A_2 before contracting with P , so the former knows the state of the world before committing to participate in the contract offered by P . In that world, A_1 will earn additional informational rents owing to the privacy of his information concerning the realization of θ_2 . There is then a cascading of information rents across successive vertical layers of the hierarchy.

Similarly, if A_1 were risk averse, she would incur risk associated with the realization of her subordinates' costs in the delegation arrangement, for which P would have to compensate A_1 with an additional risk premium. This is the main idea underlying the Faure-Grimaud and Martimort (2001) and Faure-Grimaud et al. (2000) model of the cost of delegation. The point is qualitatively similar to that made by Tirole (1986) in a different setting, as well as by McAfee and McMillan (1995). It is particularly relevant to the case of managers in firms who are likely to be risk averse and subject to limited liability concerns. The optimality result seems applicable, if at all, to the case of supply chains in defense procurement or healthcare contracting, in which P is the government and the agents correspond to large corporations with deep pockets and ample access to capital markets.

3.4. Delegation to Information Intermediaries

Consider next the costs of delegating management of a firm with two (or more) productive workers to a third-party supervisor or intermediary M who does not carry out any productive tasks. As Chandler (1962) noted, most top executives in large organizations are not involved in any productive activity themselves. The value of hiring such professional managers presumably lies in their ability to supervise and coordinate the activities of productive agents. So suppose that M receives signals about the realization of costs of different agents. Presumably, M is better informed than P ; otherwise, it would not pay for P to hire the former.

An interesting problem here is comparing the costs and benefits of P managing the firm herself (the $(P^* - (A_1, A_2))$ organization) with those of delegating management to M (the $(P - M^* - (A_1, A_2))$ organization).³ The advantage of delegation is that it takes advantage of M 's expertise and supervision. The disadvantage is that M will behave strategically with respect to this information vis-à-vis P and extract corresponding informational rents.

It is simplest to consider the case where M is perfectly informed about the costs of the two agents. Then the delegated organization reduces to the problem of P contracting with a single consolidated agent, who produces both inputs (a_1, a_2) at a cost of $\theta_1 a_1 + \theta_2 a_2$ (because this will be the cost that M incurs in procuring these inputs from the agents). Hence, the comparison

3. There is a third alternative $(P^* - (M, A_1, A_2))$, in which P retains control and treats M as a supervisor rather than a manager. In the absence of collusion, P can costlessly acquire M 's information and then use it to contract with the agents. However, for the reasons provided by Tirole (1986), this arrangement would be vulnerable to collusion between M and the agents. In the presence of collusion, which we consider in Section 3.5, it turns out that this alternative is closely related to the one we are considering now, where authority is delegated to M .

is between P contracting with two separate agents, each of whom produces one of the inputs, with a consolidated agent, who produces both at the same aggregate cost.

This problem has been considered by Baron and Besanko (1992), Gilbert and Riordan (1995), Mookherjee and Tsumagari (2004), and Severinov (2008). The main result is the following. *If M is perfectly informed about agents' costs, delegation to M is better than P managing the firm herself without involving M , if the two inputs a_1 and a_2 are complements in the sense that $\frac{\partial^2 B}{\partial a_1 \partial a_2} \geq 0$ and the costs have iid exponential distributions with a lower bound of 0. The converse is true if a_1 and a_2 are perfect or near-perfect substitutes (i.e., infinite or near-infinite elasticity of substitution).*⁴

The intuitive explanation is the following. When P contracts with separate suppliers, each supplier exerts an externality on the other supplier through their cost reports. This information is internalized when the suppliers are consolidated into a single entity. If the inputs are near-perfect substitutes, then the two agents are competing suppliers, and a lower cost report by one agent tends to decrease the production target awarded to (and hence the payoff earned by) the other agent. Internalizing this externality implies that cost reports will tend to become higher—which lowers P 's profits. Consolidation here suppresses competition. However, when the two inputs are complements, a lower cost report by one agent expands the production target and the payoff of the other agent. Internalization of this externality results in lower cost reports—which works to P 's advantage. Here consolidation fosters cooperation.

There is another effect of consolidation: two one-dimensional adverse selection problems are replaced by a single multidimensional problem. The consolidated agent can consider coordinated deviations of cost reports along the two dimensions that was not possible when the agents were separate. This adds to the problems of control of M . These problems are not severe when the two agents are ex ante symmetric and have exponentially distributed costs (this scenario contains uniformly distributed cost as a special case).⁵

3.5. Delegation and Collusion

How are the preceding results modified in the presence of collusion among agents? One heuristic view is that centralized contracting is generally vulnerable to collusion (e.g., it undermines P 's efforts to induce competition among agents when they supply substitutes), whereas delegation is not vulnerable, as the latter already incorporates a form of side-contracting between agents. Hence, collusion increases the relative value of delegation and renders it optimal in a wider class of circumstances. Extending the models considered above allows us to appraise the extent to which this view is correct. In fact, once we allow for collusion among agents, the Revelation Principle no longer applies. Is it possible that delegation can then be superior to centralization?

4. Again, this result holds for the case of continuously distributed costs. The result as stated is an implication of Proposition 5 in Mookherjee and Tsumagari (2004). Severinov (2008) considers the case of a discrete set of cost types and provides detailed results concerning how the comparison depends on the degree of substitutability and asymmetry across agents. However, the results are broadly similar to the continuous distribution case.

5. Da Rocha and de Frutos (1999) and Severinov (2008) provide examples where delegation performs worse than centralization, owing to asymmetries between the agents, even when they perform complementary tasks.

The first note of caution is that the results concerning the incentive-constrained optimality of delegation ($P - A_1^* - A_2$) described above relied on particular assumptions regarding the nature of side-contracting that are inconsistent with collusive behavior. For instance, P must be able to observe side-payments between the two agents or their relative contribution to the firm's revenues. The profit center arrangement implies A_1 's compensation increases by less than a dollar for every dollar's increment in payments to A_2 . This will tempt A_1 to pad costs or payments to A_2 , in exchange for under-the-table kickbacks. The manager must be prevented from communicating with the subordinate before contracting with the owner. Preventing either of these actions will typically be difficult for P . In the absence of the ability to monitor side-payments between the agents, I have already noted that the firm will be prone to the empire-building tendency of the manager, and delegation is then no longer a second-best option.

However, centralization is also vulnerable to collusion. For instance, consider the case of a procurement auction designed by P between two competing and ex ante symmetric agents. The second-best mechanism is a second-price auction, which creates strong incentives for the suppliers to enter into a hidden agreement to raise their cost reports. Whether centralization or delegation is more vulnerable to collusion is therefore a nontrivial question.

The answer depends partly on the precise way that collusion is modeled. Most of the literature follows Tirole (1986) and ignores possible problems with the enforceability of side-contracts. The usual handwaving justification offered for this assumption is that the agents are engaged in a long-term relationship with one another and can thus enter into self-enforcing agreements. Additional problems arise with the allocation of bargaining power within the coalition of colluding agents. Owing to asymmetric information among the agents regarding their respective costs, the Coase Theorem does not apply to the analysis of ex ante optimal side contracts: the allocation of bargaining power affects decisions they make concerning the cost reports they decide to send P in a coordinated fashion. This is one complicating feature of this class of models compared with the context studied by Tirole (where there was effectively complete information within the coalition of the agent and the supervisor, so that their joint behavior could be represented simply by that of a consolidated entity earning the sum of their respective payoffs). There is a nontrivial contracting-within-contracting aspect to the problem.

A related question concerns how the allocation of bargaining power between colluding agents varies between the centralized and decentralized contracting regimes. Laffont and Martimort (1998) postulate that it is symmetric in the centralized regime and asymmetric in the decentralized one. This idea seems intuitive, insofar as the two agents are at the same layer of the hierarchy in the centralized world and at different layers in the decentralized one. However, the idea seems to be based on the notion that the structure of unobserved side-contracting (which is hidden, illegal, or informal) reflects the structure of the regular or permitted contracts in the respective hierarchies. Their theory provides no account of why this may be so.

The Laffont and Martimort (1998) model focuses on the restrictive case of the standard model with two agents (i.e., where costs take two possible values for each agent, and tasks are perfectly complementary). In centralization with collusion, the two agents enter into an ex ante side-contract, which agrees on a coordinated set of cost reports submitted to P and associated hidden side-transfers between themselves. This side-contract is chosen to maximize the sum of their ex ante payoffs, subject to incentive and participation constraints within the coalition. The incentive constraint states that each agent has an incentive to report his cost truthfully

within the coalition; the participation constraint states that each agent must attain at least the expected utility he would attain by not entering the collusive agreement and playing the mechanism designed by P noncooperatively.

In contrast in the delegation setting, Laffont and Martimort assume that A_1 makes a take-it-or-leave-it offer of an unobserved side-contract, in which the agents again coordinate the cost report that A_1 makes to P on their joint behalf and enter into side-transfers unobserved by P . There are two main differences in the nature of this side-contracting problem. First, the objective function is different: it is the expected utility of A_1 alone. Second, the participation constraint is different. Because P does not offer a formal contract to A_2 and delegates this authority to A_1 , A_2 does not have the option of participating in another mechanism, should he refuse the side-contract offered by A_1 .

Using the restrictive version of the standard model with *ex ante* symmetric agents, Laffont and Martimort (1998) find that delegation and centralization both achieve equivalent (second-best) profits for P , irrespective of whether there is collusion. This is no longer the case when there is an additional constraint of symmetric treatment of the agents—which they interpret either as a “fairness” requirement or the result of communication or information processing costs (wherein P can only keep track of the aggregate cost $\hat{\theta}_1 + \hat{\theta}_2$ reported by the two agents, rather than their separate cost reports). They find then that delegation still achieves second-best profit, but centralization does not. The control of collusion requires asymmetric treatment of the two agents, which is not permitted in the centralized regime but is possible in the delegation setting owing to the asymmetry in bargaining power that it allows through a side-contract.

Bargaining power shifts to A_1 in the delegation setting for two reasons in the Laffont and Martimort (1998) theory. The first results from the assumption that the implied welfare weight on A_2 's expected payoff is zero under delegation but is equal to that on A_1 's payoff under centralization. This consideration is based on an implicit assumption of a change in the bargaining protocol itself as a result of a shift in the formal contracting regime. The second reason for a diminution of A_2 's relative bargaining power is that he no longer has a backup option of participating noncooperatively.

This second reason for the reduction in bargaining power of A_2 is intrinsic to the nature of the contracting: delegation gives no back-up noncooperative option to A_2 should he refuse to collude, unlike centralization. The first reason is less intrinsic: it seems conceivable that the bargaining protocol itself does not change as a result of the formal contracting regime. For instance, if the two agents belong to a union, cartel, or industry association with fairness norms, which require equal treatment, and this association mediates the collusion, the allocation of welfare weights would not change across the two regimes. Therefore, it seems more natural to keep the bargaining protocol itself unchanged by the contracting regime and focus only on the second reason for alteration in bargaining power, which is entirely intrinsic to the regimes concerned.

For this reason, most of the subsequent literature assumes that welfare weights do not change between centralization and delegation; only the participation constraint for the side-contract differs. It is assumed that in both regimes, the same agent A_1 makes a take-it-or-leave-it offer of side contract to A_2 .

If collusion is modeled in this way, it is evident that delegation cannot outperform centralization. A version of the Revelation Principle reappears: any outcome achieved by delegation can be replicated under centralization with P designing a contract that is null for A_2 (i.e., of-

fers no transfers or production assignments to this agent). Then the nature of the constraints in P 's contracting problem are exactly the same, because the induced side-contracting games are identical.

The question to be resolved, then, is whether delegation is costly relative to centralization. In other words, is it valuable for P to contract with both agents rather than just one of them? Doing so allows her to manipulate the bargaining power within the coalition.

One additional ingredient of the models need to be mentioned: the treatment of participation constraints in the contract offered by P . Some authors (e.g., Mookherjee and Tsumagari 2004) assume these are *ex post* (i.e., the agents decide whether to agree to participate after exchanging cost reports within the coalition). Others, such as Faure-Grimaud et al. (2003) and Celik (2009), assume these constraints are *interim*: participation decisions must be made at the outset, before the agents have had an opportunity to communicate with each other.

Mookherjee and Tsumagari consider the standard model with continuous types with two agents; they compare centralized contracting ($P^* - (A_1, A_2)$) with delegation to one of the productive agents ($P - A_1^* - A_2$) and to delegation to an intermediary ($P - M^* - (A_1, A_2)$), who is perfectly informed about the agents' costs.⁶ Using *ex post* participation constraints (in the sense described above, where agents can collude on their participation decisions as well as on reports), they find the same rankings between these regimes hold as in the case of no collusion. Specifically, centralized contracting is always superior to delegation to one of the agents, while the ranking of the former vis-à-vis delegation to M depends on whether the two agents supply substitute or complementary inputs. Similar results also obtain in the discrete types case, where M is not perfectly informed about the agents' costs, provided M is sufficiently well informed. These results provide an explanation of Chandler's (1962) observation that authority tends to be predominantly delegated by owners to managers who are pure intermediaries and not personally involved in productive tasks; their principal responsibility is to supervise and coordinate complementary tasks carried out by different workers.

Faure-Grimaud et al. (2003) and Celik (2009) consider analogous questions in a setting with one agent A and one supervisor M , a discrete set of cost types, and where M is better informed than P but not perfectly informed about A 's cost. Although both sets of authors assume participation decisions in the mechanism offered by P must be made at the interim stage, their models differ with respect to details of the information structure. Faure-Grimaud et al. study the two cost type case, where M receives a signal that also takes two possible values. They find that delegation to M (i.e., $(P - M^* - A)$) and centralization ($P^* - (M, A)$) achieve equivalent payoffs for P . In contrast, Celik considers a case with three cost types, where M 's information consists of a partition of the state space. He finds that delegation to M does strictly worse. Hence, the cost of delegation in these papers seems very sensitive to the fine details of the information structure.

The results of Mookherjee and Tsumagari (2004) and Celik (2009) are similar and have a similar intuition. Collusion renders inoperable the second-best optimality of delegation, owing

6. Baliga and Sjöström (1998) compare centralized contracting with delegation to one of the agents in a setting with moral hazard with limited liability, rather than adverse selection. They find that the two are equivalent in a wide variety of circumstances, though not in all.

to the DMR problem (i.e., the adverse selection problem between the manager and his subordinate). The incidence of this problem can be reduced by raising the bargaining power of the subordinate vis-à-vis the manager. This can be achieved by P contracting with both agents, so as to allow A_2 (or A in the case of the Celik model) a positive outside option if he refuses the side-contract offered by A_1 (or M in the case of the Celik model). However, it is not easy to provide a simple intuition for why the same does not happen in the case considered by Faure-Grimaud et al. (2003).

Motta (2009) argues that the analyses of Faure-Grimaud et al. (2003) and Celik (2009) impose the overly restrictive assumption that contracts offered by P in the centralized regime are always accepted by both M and A on the equilibrium path. He shows that if we continue to assume that both parties must decide on whether to participate in P 's mechanism at the interim stage (i.e., before they can collude), then a centralized mechanism exists in which the second-best outcome can be achieved. This result is true for either of the type or information structures considered by Faure-Grimaud et al. (2003) and Celik (2009). The mechanism constructed by Motta (2009) involves offering a menu of contracts to A in which some options selected by A are associated with M not being employed to supervise A . These are tantamount to allowing an amnesty scheme or self-reporting by A , which obviates the necessity of supervision. Motta shows that such schemes are useful in combating collusion, irrespective of how bargaining power is distributed within the coalition. Hence, using such mechanisms, which further augment the bargaining power of A , allows the problem of collusion to be completely overcome in the centralized regime, irrespective of the structure of information available to M . At the same time, delegation continues to be unable to achieve the second-best outcome, owing to the weak bargaining power of A in that regime. This observation suggests that centralization is superior to delegation in the presence of collusion, when agents cannot collude in their participation. Whether this continues to be so for the more relevant case, where agents and supervisors can collude in their participation decisions as well, has not yet been studied.

In summary, the dust has yet to settle on how to model collusion and what it implies for the optimality of delegation. If delegation and centralization do not change bargaining weights of colluding participants, delegation cannot be superior to centralization. Whether it is inferior to centralization depends on the context and fine details of the nature of collusion.

4. Contractual Incompleteness, Renegotiation, and Complexity

The preceding section considered contexts of complete contracts, in which the principal can commit to a comprehensive mechanism in which there are no restrictions on (1) the ability of agents to communicate their private information or (2) the principal to process this information, make decisions, and communicate corresponding instructions back to agents. These assumptions, combined with noncooperative behavior of agents, allow the Revelation Principle to hold, implying that delegation cannot outperform centralization. To understand the benefits of delegation, it is therefore necessary to explore settings where the assumptions underlying the Revelation Principle fail to apply. Because the last section showed that collusion among agents does not provide a convincing theory of the benefits of delegation, it is necessary to explore some of the other assumptions. This requirement confirms the well-known proposition (going back

to Williamson [1975] and reiterated by Hart [1995]) that one needs an incomplete contract framework to have a cogent theory of allocation of control rights in an organization.

Contractual incompleteness is, however, a very broad notion, and there are different approaches to modeling it. The simplest approach is to exogenously rule out complete contracts and impose “realistic” restrictions on contracts (e.g., limiting their duration or the kinds of contingencies they can incorporate). Aghion and Tirole (1997), Dessein (2002), Alonso et al. (2008), Bester and Kräbmer (2008), and Rantakari (2008) use this approach to model the costs and benefits of delegation. Most of these models model communication between A and P under centralization as a cheap-talk game, where the latter is unable to commit *ex ante* to decisions following any particular set of reports received. This restriction is the principal drawback of centralization, which limits the amount of information that the agent communicates, owing to the desire of the latter to manipulate the principal’s subsequent decision. In contrast, decentralization results in decisions that depend more sensitively on the agent’s information but tend to serve A’s personal interests rather than P’s. We pass over this interesting literature, because it is described in some detail in Bolton and Dewatripont (this volume). Hereafter I focus instead on theories where incompleteness arises endogenously from either of two additional frictions: inability of the principal to commit, and costs of communication or contractual complexity.

4.1. Commitment Problems

In many contexts it can be difficult for P to commit to deviate from *ex ante* promises and behave in a certain way in particular *ex post* contingencies, even though the latter can be anticipated and specified in advance. The reason is that *ex ante* decisions promised by P may not be optimal *ex post*, as the former may have been prompted by the need to provide certain kinds of incentives to A. Once the required actions have been chosen by A, then P may wish to revert to a different decision, which is in the subsequent *ex post* mutual interest of P and A. Delegation of authority to an independent third party may be a way to overcome this commitment problem.

Examples of this time-inconsistency problem in the context of monetary policy have been familiar to macroeconomists since the work of Kydland and Prescott (1977). Governments with a short-term interest in expansionary monetary policy tend to create excessive inflation when they possess discretionary control. This problem forms the primary motivation for delegation of monetary policy to an independent central bank (Rogoff 1985). The solution to the problem of commitment to an anti-inflationary monetary policy is for the government to delegate day-to-day policymaking to bureaucrats or technocrats with a known commitment to anti-inflationary policy and insulate them from short-term political pressure. Similar problems also arise in fiscal policy, such as the problem of bailouts of public sector firms or soft budget constraints (see, e.g., Dewatripont and Maskin 1995; Qian and Weingast 1997), and in income tax audits (Melumad and Mookherjee 1989). Crémer (1995) provides an interesting model of commitment problems in organizations along similar lines, in the context of design of employment contracts: owners will find it difficult to follow through on threats to fire high-quality agents detected shirking, if these agents are expected to be superior relative to others who might replace them. Delegation of employment decisions to a manager who is provided strong incentives to fire unproductive workers via an incentive scheme may be a way of committing to implement termination threats that induce workers not to shirk.

One problem with this explanation of delegation is that it is based on an implicit assumption that it is easier for principals to commit to delegating the allocation of control rights than it is to commit to detailed decisions if they retain the rights themselves. There may be problems arising even with these delegation arrangements, wherein P may seek to reallocate control rights *ex post* or attempt to influence the decisions made by agents to whom authority has been delegated (for a detailed analysis, see Katz 1991). In Cremer's model, for instance, if employment decisions were delegated to a manager who is supposed to be penalized for retaining unproductive workers, the owner would have an *ex post* incentive for not applying this penalty when the worker in question was discovered to be of high quality. Neither the worker nor manager would have an interest in opposing P's opportunistic intervention. Hence, there could be problems with the enforcement of commitments to delegate. It is not clear whether and why it is easier to commit to delegate authority than to actual decisions.

A tighter argument for the value of delegation on the basis of renegotiation problems is provided by Beaudry and Poitevin (1995) and Poitevin (1995, 2000) in the context of a standard principal-agent production problem. Opportunities for (*ex post* Pareto-improving) renegotiation are provided in both centralized and decentralized environments. They show that the decentralized regime is less vulnerable to renegotiation and can accordingly generate a higher level of payoff for P.

The argument is simplest in a single-agent setting. Suppose the agent A produces a at a cost of θa , which generates revenue $B(a)$ to P, and A is privately informed about the realization of θ . Under centralization the contracting game is as follows. In stage 1 P offers a contract $a(\theta), t(\theta)$. In stage 2 A observes the realization of θ , decides whether to participate, and submits a cost report to P. In stage 3 P can offer a new contract to A. If A accepts, the game continues with the new contract in force. Otherwise, the previous contract continues to apply. The output and transfer are then determined by the prevailing contract and the report already submitted by A.

Attention can be restricted to contracts that are not renegotiated on the equilibrium path. It can then be shown that the equilibrium renegotiation-proof allocation must be separating (i.e., P will learn the true cost of A at the end of stage 2).⁷ Hence, P will subsequently offer an *ex post* efficient allocation in stage 3. Thus, the second-best solution (i.e., the allocation associated with a commitment contract) cannot be supported in the presence of opportunities for renegotiation as long as it involves *ex post* distortions.

Now consider delegation, wherein P offers A an incentive contract $t(a)$ in stage 1. In stage 2 A observes θ , decides whether to participate, and selects a . In stage 3 P observes a and can offer a new contract. But given that a has already been chosen, the only scope for renegotiation is over the transfer payment. But there cannot be any scope for an *ex post* Pareto-improving renegotiation over the transfer payment alone. Hence, the second-best allocation can be implemented under delegation. It follows that delegation typically dominates centralization, as it is less vulnerable to renegotiation. The key difference is that under centralization, decisions over production and transfers are made by P following communication from the agent. Under delegation, renegotiation can happen after the production decision has already been made by A.

Does this difference suggest that delegation generally outperforms centralization? Poitevin (1995) points out that this is not the case when P also receives relevant information after signing

7. See Beaudry and Poitevin (1995: 315, proposition 5) for details.

the initial contract. Suppose P learns the value of a market parameter η that enters the revenue function $B(a; \eta)$ at the same time that A learns the realization of cost θ . Delegating production decisions to A without any communication from P regarding the realization of η would then imply independence of production decisions with regard to the realization of market information. Conversely, the benefit of centralization based on communication of cost information from A would be that production decisions would be responsive to market information, at the cost of being vulnerable to renegotiation with A . There are now four possible organizational alternatives: pure centralization (decisions are made by P without communication from A), pure decentralization without communication (production decisions are made by A without communication from P about the realization of η), and corresponding versions with communication (which Poitevin calls a “hierarchy”). A hierarchy is more responsive to information about both cost and market parameters, at the cost of being more vulnerable to renegotiation.

4.2. Communication and Complexity Costs

Melumad et al. (1992, 1997) explore the implications of costly communication or contractual complexity for the costs and benefits of delegation vis-à-vis centralization, in the context of the standard production model with one principal and two agents. Their 1992 paper focuses on communication costs, which are argued to arise from expertise of agents not shared by P , which makes it impossible for the agents to communicate all they know to the latter. Languages used by P and agents may not be exactly the same, and they could lack a rich enough shared vocabulary. There could also be limits on P 's ability to process the reports sent by the agents in a given time limit within which decisions need to be made.

Such restrictions are incorporated as an (exogenous) finite limit on the message set available to any agent for communicating with P (under either centralization or decentralization), while the agent's private information is real valued. Thus, full revelation is impossible: agents must compress what they know into messages in a way that entails loss of information. The finite limit could represent a common finite alphabet used for communication. Alternatively, if sending each bit of information takes one unit of time, then a given time limit for making decisions imposes an upper bound to the number of bits that can be communicated. This approach is similar to the one used in computer science to measure communicational complexity, that is, the tree complexity of communication protocols (Karchmer 1989; Segal 1995). Nevertheless, Melumad et al. (1992) do not model the underlying sources of the communication restrictions. Instead they impose a common restriction on the size of message sets that applies uniformly to both centralization and decentralization, and then they compare their performance under any given size restriction. This approach follows in the tradition of earlier models of Green and Laffont (1986, 1987). A similar approach was adopted by Laffont and Martimort (1998), in which P was assumed to only be able to receive aggregates of cost reports sent by different agents.

The Melumad et al. (1992) model imposes a number of additional restrictions on communication and contracting. Only one round of communication takes place, either sequentially or simultaneously. Other conditions ensure zero control loss from delegation in a full communication setting: risk neutrality, suitable monitoring, and sequencing of contracts to eliminate collusion and the DMR problem. Then for any finite message-set restrictions, delegation is shown to outperform centralization. A similar result is obtained in their follow-up 1997 paper,

in which restrictions on communication are derived from restrictions on complexity of contracts, where the latter is measured by the total number of contingencies (which correspond to message combinations under centralization, and message-action combinations under decentralization). The underlying idea is that finite communication restrictions prevent agents from fully revealing their real-valued cost realizations to *P* under centralization. Delegating decisionmaking authority to agents enables decisions to be based on more localized information, resulting in a flexibility gain. Offsetting this gain is the incentive (DMR) problem, which cannot be fully overcome, owing to limits on communication. The trade-off is then based on a comparison of the flexibility gain and the control loss, and the former prevails under the conditions stated.

At the same time, if *P* lacks the ability to monitor detailed production assignments or transfers between the agents, examples can be constructed where the control losses inherent in delegation may outweigh the gains in flexibility, ensuring that centralization is superior. Hence, the theory provides contexts in which either one of the two modes is superior, depending on the ability of *P* to monitor the side contract.

These results provide a rationale for studying conditions for delegation to be optimal with complete contracts: the very conditions that ensure this turn out to ensure that delegation is superior to centralization when communication or contractual complexity is costly. When delegation with complete contracts is inferior, it may also be so when contracts are incomplete, owing to communication or complexity costs. In general, there is a trade-off between the flexibility advantage of delegation (which arises only when contracts are incomplete) and its control loss (which also arises when contracts are complete).

Nevertheless, several problems remain with this theory, as discussed in a recent paper by Mookherjee and Tsumagari (2008). For one, the restriction to a single round of communication is ad hoc: most real-world organizations are characterized by interactive multistage communication between agents. The mechanism design problem includes the design of communication protocols. Mookherjee and Tsumagari consider a context in which agents take time to read and write messages, and production decisions need to be made within a finite time horizon, combined with time taken to read and write messages. This consideration allows a wide range of finite communication protocols, varying with regard to the number of rounds and message-set size at each round.

Mookherjee and Tsumagari (2008) develop a theory of mechanism design that allows a broad class of finite communication protocols with multiple stages, as well as a wide range of mechanisms where different components of contracting, communication, and production can be centralized or decentralized. Based on an assumption that messages exchanged between agents are costlessly verifiable by *P*, they show that centralized contracting can generally perform as well as decentralized contracting. At the same time, decentralized production and communication systems generally outperform centralized ones, owing to the greater flexibility they allow in the choice of production and coordination of information across agents. In other words, it indicates the optimality of an intermediate form of organization, where contracting and monitoring are centralized while production decisions are decentralized, as in the prototypical Japanese firm (e.g., Aoki 1990).⁸

8. However, when communication between agents is difficult to verify by employers, they provide an example where decentralized contracting outperforms centralized contracts.

5. More Complex Hierarchies

The preceding two sections have been concerned with foundational issues in the modeling of costs and benefits of delegating control to managers or intermediaries. Accordingly, they focused on simple contexts involving one principal or owner; one manager; and one or two agents, who play a productive role. In this section I describe models of more complex hierarchies, involving more agents or departments, which help address a number of additional questions concerning the organization of hierarchies. An example of such a question concerns the grouping of activities into different departments. In *Strategy and Structure*, Chandler (1962) described the evolution of many large, vertically integrated firms producing a multitude of products in various regions or markets from unitary (U-form) to multidivisional (M-form) organizations. In the former, departments are organized along functional lines: departments concentrate plants and activities producing the same input or intermediate good. In the latter, they are organized by product, market, or region, with each division being internally vertically integrated and relatively independent of other divisions (except for overhead, capital, or top management, which are allocated by top management across divisions). Socialist economies likewise can be organized by ministries producing specific intermediate inputs (as in the erstwhile Soviet economy) or by regions, each of which is relatively self-contained (as in the Chinese economy). Chandler argued that the shift away from the U-form freed up the time and effort of central management from day-to-day management of operations in each division, required by the need to coordinate the activities of different divisions. By using the M-form, they could delegate internal management of divisions to divisional managers and focus on long-range issues. However, this form meant giving up the advantages of scale economies and specialization made possible by the concentration of similar activities within the same division in the U-form.

Understanding this dimension of organizational design requires extension of the models described in previous sections to incorporate multiple divisions and problems of horizontal coordination across these divisions. The previous models can be thought of as organizations consisting of a single division, with a focus on problems of vertical control and coordination.

Rotemberg (1999) provides an interesting model in which the key trade-off between a U-form and a M-form hierarchy involves coordination versus control. A firm produces two products A and B and two associated intermediate inputs 1 and 2, each of which is required in the production of either good. There are four agents or plant managers, represented by a combination of a product and an input used for that product. Rotemberg assumes that a pair of agents will have a common supervisor and will thereby form a division. Implicit here is an exogenous upper bound on the span of control: a supervisor cannot oversee more than two agents. This restriction rules out a fully centralized firm with a single division that contains all four agents. Rotemberg assumes, therefore, that the firm has two divisions and two corresponding supervisors, who jointly own it. Another important assumption is that the supervisors operate independently and cannot share any information with each other.

In the U-form, divisions are organized by the inputs produced: division i produces input i and includes the two plants iA and iB producing this input, where $i = 1, 2$. In the M-form, they are organized by products: division j produces product j and includes the plants $1j$ and $2j$ producing the two inputs needed for this product, where $j = A, B$. Each plant ij has to choose a level of activity x_j^i and a method m_j^i . The inputs used in the production of each product need to be coordinated: there is a loss function for each product j that depends on the difference in

activity levels x_j^1 , x_j^2 . The M-form allows better coordination, because it groups different plants involved in the same product group into the same department.

The optimal method of producing the same input across different products is the same. Incentive problems arise with respect to the choice of method, about whose costs the respective plant managers are privately informed. The main advantage of the U-form is that the supervisor controls two agents producing the same input, thus allowing the report of each agent to discipline the other. Hence, the U-form allows for better control of incentive problems.

The model has a number of interesting predictions. The U-form involves less high-powered incentives for plant managers, owing to the better information available to the corresponding supervisor. As the firm expands in scale, it adds more plants in each division. In the M-form there are now multiple plants producing the same input, which helps reduce the incentive problem. But the U-form continues to be subject to coordination losses. Hence, for sufficiently large scale, the M-form must dominate. This result helps explain how American firms shifted from one form to the other as described by Chandler (1962): the coordination problems with the U-form became worse relative to the control problems as firms grew in scale.

Mookherjee and Reichelstein (1997, 2001) provide a model of hierarchies that generalizes the standard production model of preceding sections to the context of many agents, departments, and products. They provide general sufficient conditions on the structure of the organizational production function or technology for a hierarchy with an arbitrary number of branches and layers to be able to achieve second-best profits for P. The mechanism they use extends the profit or cost center mechanism described in Section 3 for the case of two agents who form a single division. With multiple divisions that constitute different branches of the hierarchy at any given layer, the mechanism has to ensure horizontal coordination across these branches as well as vertical coordination and control across layers in any given branch. In addition to the assumptions concerning the sequencing of contracts and absence of collusion and of risk aversion or limited liability constraints, the key assumption required is that the organization of the hierarchy is consistent with the technology being used. This stipulation means that the technology is recursively decomposable into the production of intermediate inputs at different stages of production, and each plant has constant returns to scale.

Absent incentive problems, this consistency condition implies that an optimal production plan can be formed for the firm as a whole, with (one-dimensional) cost reports (or budgets or forecasts) sent by agents that flow up the hierarchy, which are aggregated at each layer and passed up by each manager to his manager in turn. Subsequently, production targets are formed at the top of the hierarchy, and these then flow down the hierarchy. Each divisional manager forms a contingent production plan, allocating production responsibility across subordinate divisions on the basis of their respective cost reports and the aggregate production target assigned to the division. Mookherjee and Reichelstein (1997, 2001) show that the same kind of mechanism can be used even in the presence of incentive problems, where each agent is self-interested. It requires an initial phase to be added wherein contracts flow down the hierarchy; the manager at any layer offers a contract to each subordinate, which the latter must respond to prior to offering contracts to their subordinates in turn. The assumptions required are the same as those that ensure optimality of delegation in a three-layer hierarchy: top-down contracting, monitoring of costs, and risk neutrality of all agents. The construction resembles the Calvo and Wellisz (1978) method of replicating the three-layer hierarchy to accommodate

more layers and branches. Under these conditions, then, there is no limit to the size of the hierarchy.

Applied to the question of U-form versus M-form, this model provides conditions when either can be optimal. The U-form is optimal if it is consistent with the technology being used—as would be the case if the firm produces a single product by combining different inputs, each of which is produced by multiple plants. Each division then corresponds to the production of a particular input. The M-form is consistent with the technology if the firm produces multiple products, each of which combines a number of inputs (some of which are used in different products). The divisions are then organized along product lines. Each division is independent of the others, except for allocation of some overhead facilities or capital resources by headquarters. When the technology takes this form, it is evident that the U-form is not consistent with it. This approach thus suggests the role of changing technology and product variety in explaining evolution from U-form to M-form organizations. With the emergence of multiple products produced by the same firm, the U-form would experience problems relative to the M-form in coordinating production of different inputs used in any given good. Specifically, it would no longer be possible to use a budgeting system based on one-dimensional cost and quantity aggregates for each division.

An alternative perspective on U-form versus M-form organizations is provided by Maskin et al. (2000). Their theory abstracts from coordination issues altogether and focuses on the informational and incentive implications of these alternatives. Similar to the basic Rotemberg (1999) model, the Maskin et al. model has a three-layer hierarchy producing two products $i = 1, 2$ in two different regions $r = A, B$. There are four plants, corresponding to a combination of a product and a region. Productivity shocks arise at the economy, regional, and industrial levels. The organizational structure assigns responsibility to managers to devote costly effort to improving productivity. Observed performance levels are the confluence of effort and shocks, giving rise to moral hazard problems. In both the U-form and M-form a top manager deals with the economywide shock. The essential difference arises at the middle layer of the hierarchy. In the U-form the departments are organized by industry, so there is a manager at the middle layer in each department whose effort affects the productivity of the two plants in the corresponding industry. In the M-form the departments are organized by region, so the middle manager's effort affects the performance of the two plants in two different industries, which happen to be located in the same region. Bottom-level managers' efforts affect the plants they are assigned to. In the U-form (resp. M-form), these correspond to different regions (resp. industries) within the same industry (resp. region). The two organizational forms thus differ in the assignment of tasks across managers. In the M-form, for instance, only one manager (located in the middle tier) in the organization is dealing with the regional shocks, whereas there are two managers in the U-form (located at the bottom layer in two different industry divisions) who deal with regional shocks.

Managers are risk averse, giving rise to a trade-off between risk-sharing and effort incentives in the design of their compensation schemes. "Yardstick" competition is an important way of dealing with these incentive problems, wherein an agent's performance is measured relative to that of peers whose performance is subject to similar (i.e., correlated) shocks. Maskin et al. (2000) show that the U-form and M-form offer identical opportunities for evaluating performance of managers in the top and bottom tiers, but they differ with regard to managers in the middle

tier. If performance at the regional level (aggregating across industries) is more comparable (i.e., correlated) across regions, rather than performance at the industrial level (aggregating across regions), then the M-form allows more effective use of yardstick competition for middle managers. For top managers, there is no opportunity for yardstick competition (as in the model, this is the only firm in the economy). And for bottom-level managers, there exists one other manager in the firm whose performance provides a comparable yardstick in both organizations. The model thus predicts that performance differences will arise owing to differential managerial effort incentives at intermediate levels of the hierarchy. Maskin et al. (2000) go on to provide empirical evidence from Chinese firms that the structure of productivity shocks is such that performance is more comparable across regions than across industries. This result suggests the superiority of the M-form, thus providing a potential explanation for superior performance of the Chinese over the Soviet version of socialism.

6. Conclusion

The literature overviewed in this chapter pertains mainly to the microfoundations of an incentive-based theory of hierarchies. The holy grail of this field has been a formalization of Williamson's (1967) ideas of control loss in hierarchies based on incentive problems, and how it affects the size and structure of organizations. This effort has proved difficult, mainly because addressing this question requires understanding what managers do and the costs and benefits of delegating authority to them. Only when a basic model of management exists can the theory be used to address detailed questions concerning the nature of control loss and how it varies with the size and structure of the organization.

The models described in this chapter focus on a particular source of control loss in hierarchies: that arising from incentive problems associated with supervision and delegation of authority. They address questions about the design of compensation for supervisors, how these designs relate to the compensation of production workers, and attendant problems of collusion. The models help pose the question of choice among different organizational designs, highlighting the different dimensions involved in these designs even in the simplest contexts involving one or two productive agents and one manager: breadth (span of control) and depth (number of vertical layers); the extent of responsibility delegated at each level and related compensation rules and monitoring systems; and how contracts, communication, and production planning are sequenced. So far most of the models have been rudimentary, with only one or two production workers, one manager, and one owner. At the next step one expects these models will be used as building blocks for more complex organizations and design issues in the presence of more agents, managers, products, and intermediate goods.

Despite their simplicity, the models enable the age-old question of centralization versus decentralization to be posed in different concrete ways. They have also generated a wide range of applications in fields as diverse as management accounting (profit centers and budgeting [Mookherjee and Reichelstein 1997], transfer pricing [Edlin and Reichelstein 1995; Vaysman 1996, 1998; Baldenius and Reichelstein 2004], and auditing [Melumad and Mookherjee 1989; Kofman and Lawaree 1993]), fiscal decentralization (hard versus soft budget constraints [Devatripont and Maskin 1995; Qian and Roland 1998], treatment of externalities [Klibanoff and Poitevin 2009], or accountability in local governments [Seabright 1996; Bardhan and

Mookherjee 2000, 2006]), procurement and regulation (Baron and Besanko 1992; Gilbert and Riordan 1995; Severinov 2008), and comparisons between Soviet-style and Chinese-style socialism (Qian and Weingast 1997; Maskin et al. 2000; Jin et al. 2005).

Nevertheless, much remains to be done. There is considerable scope and need to use these models to address more applied questions in industrial organization and enable closer integration with empirical work on the internal organization of firms. What are the effects of changes in information technology, competition in the product market, or openness to trade on the internal structure of firms? These issues have been discussed extensively in fields of management (e.g., Hammer and Champy 1993) and have been the subject of recent empirical studies (e.g., Brynjolfsson and Hitt 2000; Caroli and Van Reenen 2001; Bresnahan et al. 2002; Acemoglu et al. 2006; Rajan and Wulf 2006). With the exception of Acemoglu et al. (2006), most of this literature lacks a theoretical framework. A closer integration of theory and empirics would enrich these analyses and permit better understanding of normative implications.

Even in the context of purely theoretical analysis, significant challenges and open questions remain. An integration of incentive issues with costly information processing would represent a major step forward at the conceptual level. It would help formalize hierarchy design as a trade-off between information processing advantages with the incentive and control disadvantages of delegating authority. Issues concerning the design of more complex hierarchies still remain to be addressed, for example, models of delegation that address questions of size and structure of hierarchies and related implications for compensation, rents, and performance at different levels. The simple models described in this chapter suggest roles for collusion, limited liability, or managerial risk aversion as sources of control loss in hierarchies. They need to be embedded in more complex settings to develop detailed predictions concerning how the size and structure of firms are affected by technology and market parameters. This effort would then help realize the goal of constructing a Williamsonian model of hierarchies with secure microfoundations that can be empirically tested.

Strategy and Organization

John Roberts and Garth Saloner

1. Introduction

A firm's business strategy is a set of choices about what business it will be in, which products and services it will offer, which customers it will seek to serve, where it will operate, and which of the activities that are needed to realize these plans it will undertake itself rather than leave to others. A strategy sets direction and provides a standard against which later options can be evaluated. It is not a complete specification of all the decisions a firm must make, but it does fix enough of these choices to facilitate coordination of later decisions. It also can have a role in motivation.

Strategy has a central role in business management and, correspondingly, in business schools. It has not featured very much in economics, however, although industrial economics and game theory have had major influences on the study—and even the practice of—strategic management.¹

In particular, organizational economics has largely developed without paying much explicit attention to strategy. Most chapters in this volume can be thought of as studying how to organize to maximize profits in a very general context. However, realizing a firm's strategy implies that it needs to carry out certain activities (product development, production, sales, etc.), and different strategy choices lead to different required activities. It seems likely that what the firm is trying to do might have a significant impact on how it is organized. The purpose of this chapter is to examine the (mostly very recent) research that has paid attention to the connection between strategy and organization and to point to what seem to be interesting issues for organizational economists in this area.

The fundamental assumption on which this chapter is based is that firm performance is determined by three broad factors: the economic, legal, regulatory, social, and technological *environment* in which it operates; the *strategy* it adopts to deal with that environment; and the

The authors are indebted to Robert Gibbons and Heikki Rantakari for numerous helpful comments and suggestions and to the participants in a meeting of the NBER Working Group in Organizational Economics devoted to reviewing early drafts of chapters from this handbook.

1. Popular treatments and textbook expositions include Dixit and Nalebuff (1991), McMillan (1992), Brandenberger and Nalebuff (1996), Saloner et al. (2001), McAfee (2002), and Besanko et al. (2009).

organization it puts in place, through which it seeks to implement its strategy. High performance involves finding “fit” among these three, where one cannot assume that there is a single best choice of strategy and organization for all environments. Success also requires maintaining alignment over time by altering the strategy and organization as the environment changes (Lawrence and Lorsch 1967).

This chapter is organized as follows. Section 2 is devoted to establishing what strategy is, the roles it serves, its connection to some related managerial concepts, and how it comes about and changes. Section 3 examines what we mean by organization, some central issues and trade-offs in organizational design, the problem of establishing fit, and the basic connection between organization and competitive advantage at the level of a single-business firm or business unit. Section 4 looks at the multiproduct firm, its reasons for existence, and the connection between organization and corporate strategy.

2. Strategy

We begin by establishing what we mean by strategy. The management literature has offered a variety of definitions. We start by looking at the concept historically.

2.1. What Is Strategy?

While we do not propose to provide a history of the field of strategic management here, some background is useful in setting the context for this chapter. As a field of academic study the genesis of modern strategic management can be found in the Harvard Business School’s general management approach to the subject of business policy. In 1912 Harvard Business School introduced its first course in the subject, designed to recognize the interrelationship among problems faced in specialized functions and the need for coordination among departments to achieve broad company objectives (for a more detailed discussion, see Ghemawat 2006). In the 1950s C. Roland Christensen and others stressed the notion that the firm’s strategy should fit with the competitive environment, and by the late 1950s Kenneth R. Andrews was proposing an approach to strategy that called for a broad view of the firm and its objectives.

In his 1971 classic, *The Concept of Corporate Strategy*, Andrews wrote:

Corporate strategy is the pattern of decisions in a company that determines and reveals its objectives, purposes, or goals, produces the principal policies and plans for achieving those goals, and defines the range of business the company is to pursue, the kind of economic and human organization it is or intends to be, and the nature of the economic and noneconomic contribution it intends to make to its shareholders, employees, customers, and communities. [Andrews 1971: 13]

The role of the general manager in this perspective is to set direction; to establish organizational structure, commitment, and policies to pursue the company’s goals; and to ensure that the entire process is managed with an eye to corporate social responsibility and good corporate governance.

The next major innovation in the field occurred with Michael Porter’s development of systematic frameworks for the analysis of industry structure and the firm’s competitive positioning,

culminating in his *Competitive Strategy* (Porter 1980). Although a great deal of economics bears on issues of relevance to Andrews's concept of strategy, it was the direct overlap of the domains of Porter's competitive strategy and the economics of industrial organization that caused the first major infusion of economic thinking (and economists) into the field of strategic management.

Although many still equate strategy and competitive strategy, here we take a broader view, perhaps closer in spirit to Andrews than to Porter. In particular, we consider not only the product market competitive forces that are the focus of Porter but also the firms' choices of the resources to acquire and the productive capabilities to develop.² We take this perspective, because it is a more natural vantage point for a discussion of strategy and organization, but also because we believe, though relatively neglected, it is arguably more important for a comprehensive general management perspective of the firm. At the same time, we adhere to Porter's fundamental position that strategy is about winning. While Andrews begins with strategy at the level of a corporation as a whole, we begin with strategy at the level of an individual business unit and build up to corporate strategy.

Recent research has begun to offer formal definitions and models of strategy, and we examine these below. However, for now, we proceed on a less formal, more practice-oriented, level to develop a clear understanding of the phenomena under discussion.

For practical purposes, a well-considered statement of a business unit's strategy has four main elements (Saloner et al. 2001).³ First is a specification of the *goal* that that firm is trying to achieve—what it means to win. This is important, because it suggests the appropriate measures to collect. In economics we usually assume that profit maximization is the goal, but it need not be. For example, through the 1980s, large Japanese firms acted as if their principal objectives were to maintain and expand their employment. Moreover, firms often find it useful to adopt more proximate, less formulaic, objectives. For Komatsu, the Japanese heavy equipment company, the stated goal was to “Encircle [Beat] Caterpillar!” (Bartlett and Rangan 1988).

The next element of a strategy statement is a specification of *scope*: what products or services the firm will offer; which customers it will try to attract; how it will select and deal with suppliers; where it will do business geographically; what technology it will use; and which of the activities that must be carried out to realize these plans the firm will do in-house, and which it will leave to others. Economics has investigated aspects of many of these choices, but typically not the first one, of what business to be in.⁴ Yet that is one of the most crucial decisions that the people leading a company must make.

The third element is an indication of why customers will deal with the firm on terms that let it achieve its goals—a statement of its *competitive advantage*. In a commercial setting, competitive advantage often comes down to how the firm will create value. Most often, it does so by offering a combination of low costs and perceived quality that allows it to serve its target market uniquely well (Porter 1980; Saloner et al. 2001). Sources of competitive advantage are typically thought to include the firm's position in the markets in which it deals, the capabilities it has to undertake various activities well, and in some contexts, the resources it controls. For example, being a

2. The input-focused approach to strategy is often called the “resource-based” view of the firm. See Section 3.6.

3. See Collis and Rukstad (2008) for a more recent, but similar, experienced-based specification.

4. Granted, the literature on entry treats the decision to enter a business, but it rarely considers alternative businesses among which a choice must be made.

monopolist in a business with significant barriers to entry is a strong positional advantage. Enjoying large cost advantages because of learning effects or economies of scale allows charging attractively low prices that are still profitable. Having particular expertise in key aspects of business (e.g., in developing great new products, as at Apple) is a capability that gives competitive advantage. A crucial patent or a particularly productive mine are resources that can convey competitive advantage.

Finally, the strategy should have an explicable *logic*: why the firm will be able to realize its claimed competitive advantage within the scope of its strategy and thereby achieve its goals. This logic requires that there should be coherence among the firm's goals, competitive advantage, and strategic scope; that the organization through which it seeks to implement its strategy should be fit for its purpose; and that these factors should all fit with the environment (e.g., customers, competitors, suppliers, legal and regulatory policies, and social concerns) in which the business operates.

If a strategy is to succeed more than briefly, it must involve a sustainable competitive advantage; one that will endure despite the efforts of competitors. We return to this subject in Section 3.6.

At the level of the corporation, a strategy is a specification of the array of businesses in which the firm will be active, supported by a theory of how, by having the constituent businesses under common ownership and management, the firm will add value over what they would generate on their own. We return to corporate-wide issues in Section 4.

2.2. Relationship to Other Common Strategy Notions

CEOs often talk about future directions for a business in terms of their "vision." By this term they mean a description of a desired future state. As Bennis and Nanus (1985: 89) stated: "a vision articulates a view of a realistic, credible, attractive future for the company." A vision typically paints a picture of the future competitive landscape and a position the business in question might attain in it. Because strategy is fundamentally about winning, the putative future position is a favorable one, achieved by choosing the products and services the business offers in a way that creates advantage for the firm over the products and services offered by its rivals.

Nokia's leaders in the first years of the 1990s had the vision that "voice will go wireless," and they focused their firm, which had been a remarkably diverse conglomerate, completely on mobile telephony (Doornik and Roberts 2001: 4). Bill Gates's somewhat tardy recognition in the middle of that decade of the potential significance of the Internet led Microsoft as well to reshape its business fundamentally.

As the term suggests, a vision is often suggestive rather than specific. By describing a desired future state, it incorporates some sense of what part of the product space the business will occupy and how it will achieve competitive advantage relative to its rival when it does so. So vision contains at least some elements of objectives, scope, and competitive advantage. Moreover, to be at all compelling, it must contain at least some defensible rudimentary logic. But because it is nonspecific, a vision typically falls short of fully describing a business strategy.

A compelling vision is neither necessary nor sufficient for a successful business strategy. A firm that is well positioned with clear competitive advantage can succeed by tweaking its current strategy at the margin. And a CEO with a dazzling vision but without a coherent plan for pursuing it is unlikely to be successful.

Instead, a vision is typically the starting point for coming up with a novel strategy. By articulating what the business might become, it provides the basis both for an analysis of the product and service definitions and requirements that will be needed and for an examination of whether the business has the capabilities, resources, and organization—or can develop them—to pull it off. More importantly, coming up with the vision provides the creative spark that drives a new business strategy.

Coming up with an innovative vision can account for a significant fraction of the value a firm creates by propelling it down an entirely new path it might not otherwise have taken. It is harder to be enthusiastic about the much more ubiquitous mission statement. In contrast to the business strategy, the mission statement is a public declaration of whom the firm aspires to serve and how. In principle, therefore, the mission statement might be expected to share many elements with the business strategy. In particular, the mission statement might contain useful elements of objectives, scope, and competitive advantage.

In practice, however, mission statements tend to be bland and largely uninformative. Because they are public documents, their crafters often lack the courage to place any class of stakeholders above any others, so that the business appears to serve customers, employees, shareholders, and the public equally. And because they are typically designed to be enduring statements of purpose, they are far more general than are descriptions of strategic scope, for example, “to develop people to work together to create value for the Company’s shareholders by doing it right with fun and integrity”⁵ could be the mission statement of any number of companies.

Still, mission statements are interesting, because they belie a kind of collective corporate need for definition around why the business exists and who it serves. These issues would seem to be salient in a not-for-profit organization, where there is often a natural ambiguity about its *raison d’être* and the identity of its primary stakeholders. Their ubiquity in for-profit firms, where shareholders’ value maximization is often the unambiguous overarching goal, suggests executives share a common struggle to put even basic parameters around their businesses. Often the creation of the mission statement is a response to uncertainty and even conflict within the organization about whom it will and will not serve and, more generally, about what the company is trying to do; elements that ought to be clear from the objectives and scope of the strategy.

In the short term, at least, one might expect that this kind of uncertainty and conflict would be adjudicated in an agreed-on plan of action. Indeed, most businesses are guided by a *strategic plan* (or business plan) that sets goals with horizons of perhaps 1 year and 5 years for sales, by product and region, for existing and still-to-be-developed products and services. As well, the plan usually describes specific actions to be taken to meet those goals. The strategic plan also typically translates the hoped-for business performance into a set of pro forma financial statements and financial requirements for the business. Finally, the functional areas of the business typically develop functional strategic plans (a marketing plan, financial strategy, etc.) to support the business strategy.

We discuss in Sections 2.4 and 2.5 the process by which plans are developed and how strategy evolves. For now, suffice it to say that, although one might expect a strategic plan

5. The quotation is from the Canadian Natural Resources Limited website, www.cnlr.com/about (accessed November 5, 2006).

naturally to include a goal, scope, competitive advantage, and logic, it is not uncommon for these plans to neglect at least some of these elements. In what follows we use the term “strategy” as incorporating those elements, as distinct from vision, mission, or the strategic plan.

2.3. The Role of Strategy

As the above discussion of ambiguity, uncertainty, and conflict suggests, there is a role for strategy in ensuring that the members of an organization take actions that advance the goals of the business. There are fundamentally two ways in which strategy can serve this role that have been discussed in the literature: by facilitating the coordination of decisions and by providing motivation in the absence of complete contracting.

2.3.1. Coordination

In the presence of interdependencies among the functions of the organization, even in the absence of disagreement or of conflict of interest, strategy can serve to coordinate. For example, a firm with a choice between providing top-quality products aimed at the high end of the market and low-cost mass-produced products aimed at the low end will need to coordinate product design, pricing, marketing, sourcing, manufacturing, and channel strategy to support the choice it makes. Even if everyone in the business has the same information about all options facing the firm, the same beliefs about the outcomes that will result from any set of actions, and the same ability to calculate costlessly the profitability of every course of action, there still will typically be multiple equilibria: one in which everyone coordinates on the high-end approach and another in which coordination occurs on the low-end approach. In this case the strategy that picks which coordinated approach to pursue helps avoid Pareto-dominated outcomes (Milgrom and Roberts 1992).

In most practical settings the coordination problem in the firm concerns much more than simply which of a set of well-defined coordinated outcomes to choose. In most businesses of any size, for example, manufacturing does not possess the knowledge of customer wants and willingness to pay that the sales organization has, and sales has little information about the costs of production of different products at varying volumes. So managers in neither area even understand what coordinated outcomes are possible. In the presence of significant costs of communicating and processing all such information, the role for central coordination increases in significance.

However, it is not clear that this enhanced role for coordination should take the form of a statement of strategy in the way that we have defined it above. For example, one could imagine a structure in which decentralized information is communicated to a center, with a complete set of optimal actions being communicated back, but strategy is definitely not such a comprehensive plan. The sort of thing we have been calling a “strategy” would make more sense if additional decentralized decisionmaking is desired even after some aspects of a coordinated outcome have already been specified. In the military analogy, once it has been decided which hill is to be taken (and whether from the ground or from the air), it can be left to the commanders in the field to decide precisely how to do it.

Van den Steen (2011) has recently offered a formal model of strategy as a coordination device that captures much of this discussion and yields additional implications. For him, a Strategy⁶ is a specification of a minimal set of choices that are sufficient to guide all other choices that the members of an organization must make to reach an objective. The above discussion treated these choices as involving the (proximate) goal, aspects of the scope of the firm's activities, and how it plans to compete successfully (the competitive advantage, supported by the logic).

To model this idea, Van den Steen considered an organization with K individuals, each of whom can make a binary decision $D_k \in \{A, B\}$. Each decision may be right or wrong, depending on the state $T_k \in \{A, B\}$. In addition, pairs of decisions i and j can be complements or substitutes, depending on a state variable $V_{ij} \in \{S, C\}$, where $V_{ij} = V_{ji}$, so there are $K(K - 1)/2$ such pairs. If the two actions are substitutes, then the decisions AB and BA are aligned; in the case of complements, then the decisions AA and BB are the right ones. Each state has probability $1/2$ and the states are independent. All agents share these beliefs. Payoffs are separable. A correct decision $D_k = T_k$ yields payoff $\alpha_k > 0$ to all individuals. Incorrect decisions yield zero. If a pair i, j of decisions are aligned, then they generate $\gamma_{ij} > 0$ for everyone; if they are not aligned, they yield $-\gamma_{ij} < 0$. All this is common knowledge. Let θ denote a realization of the $K + K(K - 1)/2$ states. Given a particular subset of the states S , we write (θ_S, θ_{-S}) to represent the whole vector.

The correctness of individual decisions is meant to model the need for fit with an external environment; the patterns of alignment model internal coherence. The common payoff focuses the model on coordination rather than on incentives.

There is also an additional agent, called the "strategist," who shares the common payoffs of the K decisionmakers. Before any actions are taken, the strategist may obtain signals on any number of the states. Having done so, she can fix any subset of the decisions and communicate her choices to the other agents. These actions by the strategist are assumed to have infinitesimal costs: everyone lexicographically prefers that the strategist make fewer investigations and also fewer decisions and announcements, but the actual payoffs from the decisions are overwhelmingly more important. Once the strategist has acted, then each individual k receives a signal about the state pertaining to his decision D_k and about the $K - 1$ interaction states involving decisions D_k and D_j , j different from k . For simplicity, assume these signals are the same as the ones the strategist would see if she investigated. So, in particular, both members of any pair of agents see the same signal about the interaction between their actions. Then those agents whose decisions have not been fixed by the strategist all simultaneously make their decisions, and the payoffs are realized.

Note that, without the first stage (no strategist), this is a game of incomplete information.⁷ Players' strategies in the game map their private information (their signals) into their decisions. From the point of view of each agent k , every other agent j is equally likely to have seen A as B as the signal on j 's choice D_j and to have seen C as S on each of the interactions that j 's choice has with other actors' choices (except that k knows that j saw the same signal as he did on the jk interaction). In this context, a very salient equilibrium involves each party k conjecturing

6. In this discussion only, we capitalize "Strategy" in the sense it is being used in this chapter to distinguish it from players' strategies in the game Van den Steen (2011) analyzes.

7. As is the game after the strategist has made her choices.

that every other party j follows the signal j received for his individual decision, so everyone effectively is expected to play A with probability 1/2 and B with probability 1/2. Then playing in this way is actually optimal for each player. In this case, the choices end up being coordinated only a fraction of the time (half the time when $K = 2$). This result indicates the nature of the coordination problem that the strategist is meant to help solve.

Van den Steen (2011) then formally defined a Strategy as a nonempty set X of choices by the strategist of states to examine and decisions to specify such that, given the objective $D(\theta)$ being pursued, the signals that she receives, and the beliefs of the other agents once they have observed her choices:⁸

1. the choices the strategist makes in X are those that realize the target $D(\theta_X, \theta_{-X})$ for any possible realization θ_{-X} of the states she has not examined;
2. for each individual decision k not in X and any θ_{-X} , it is an equilibrium of the game specified above for individual k to choose the decision that realizes his part of $D(\theta_X, \theta_{-X})$; and
3. there does not exist a strict subset X^* of X such that conditions (1) and (2) hold with X^* in place of X .

So the Strategy achieves coordination on the desired outcome and is a minimal set of choices that can do so.

The first result is that, in any equilibrium of the full game, the choices of the strategist define a Strategy in the above sense that induces the (common) payoff-maximizing outcome. The proof is simple. With only infinitesimal costs to inspection and announcements, the strategist can achieve essentially the joint maximizing outcome by her own actions alone. Further, whatever choice she makes must implement the optimal outcome in any subgames starting after her choices are announced: otherwise, it cannot be equilibrium behavior, because she shares the payoffs. Finally, given her lexicographic preferences, she will pick a minimal set of decisions achieving these goals.

Van den Steen (2011) then examined the comparative statics of his model, focusing on the case $K = 2$ but allowing for a third stage in the game in which any decision can be reversed at a cost c , where c measures the irreversibility of choices. The parameters are the payoffs from the individual decisions and from alignment, the precision of the signals, and the cost of reversing. The first result is that the value of developing a Strategy (i.e., the expected payoff to the game when it includes the first stage less the payoff to the game without the first stage) is increasing in the payoff to alignment, the precision of the signals about the nature of the interaction, and the cost of reversing. In addition, these three features are complementary: raising any of them enhances the effect of increasing the others on the value of developing a Strategy. If there is little gain to aligning choices or the form of the interaction is very uncertain, then there is little to be gained by trying to coordinate: decisions might just as well be made on their own. And if it is cheap to achieve coordination ex post, in the third stage, then coordination ex ante through a Strategy is relatively less valuable. As Van den Steen suggested, these results should

8. These beliefs about the actual state of the world may depend on the individuals' beliefs about what the strategist has seen, given her observed choices.

probably be thought of as a check that his formulation is reasonable. Yet they yield an interesting point: having a Strategy is really important only if there are both important interactions and significant irreversibility. Also, because we think of strong interactions as creating multiple coherent patterns of organization features (see Sections 3.2 and 3.3), Strategy really matters only when internal alignment—finding a good pattern—is important. To the extent we think of external fit in terms of decisions being well adapted to markets and internal alignment as a matter of organizational coherence, Strategy in this sense matters only when the organizational design problem is relatively complex. If interactions are unimportant, individual decisions can be made reasonably well on the basis of individual signals about the external environment: they need no Strategy to guide them.

Van den Steen (2011) also investigated a rich set of issues about when particular decisions will be part of the Strategy, what form the Strategy takes, and the role of process and leadership in Strategy, but these issues are not so relevant here. The key results here are those relating to the value of Strategy in coordination and its link to organization.

In a more dynamic coordination context, Strategy can play an ongoing role in helping those inside the firm know which new opportunities to ignore without undertaking extensive investigation—because they clearly do not fit with the Strategy—and which to explore more thoroughly. To our knowledge, this idea has not been modeled, although some of the models we discuss next about strategy as a motivational device have something of this flavor.⁹

2.3.2. *Motivation and Commitment*

The above discussion of coordination assumes no disagreement or incentive issues within the firm. The presence of either issue introduces an additional role for strategy. One reason is that if it is difficult for the firm to provide incentives for employees to take actions that are dependent on the firm's adhering to particular products and markets approached in a specific way, it might be advantageous to commit to a specific strategy. As Aguilar (1988: 71) put it:

Consistency of word and deed on the leader's part is absolutely necessary if others are to commit themselves to the personal and business risks associated with new and unproven courses of action. The general manager who runs hot and cold will fail to encourage confidence in others . . . Nobody wants to go out on a limb and risk being abandoned at the first sound of cracking wood.

Rotemberg and Saloner (1994) offered a model of when it may be valuable for senior management to commit to a narrow business strategy—one that excludes some things the firm may already have been doing. They contemplated a setting in which employees must exert costly effort to generate innovative ideas for the business. They further supposed that, because of the difficulty of contracting on either effort or the ideas themselves, employees reap the rewards of their innovative efforts only when their ideas are actually implemented. Rotemberg and Saloner considered two settings in which the strategy the firm pursues can affect whether the ideas are implemented. In one the firm is not able to pursue all the directions in the future that it has in the past (because, e.g., it faces financial constraints). Knowing that, employees working in each

9. We are indebted to Heikki Rantakari for this point.

of the directions currently being pursued may doubt that their efforts will be rewarded, because their innovations will not be implemented if the firm changes direction, and they then will be reluctant to exert costly effort to innovate in the first place. In the second case employees in one line of business may generate innovations that render innovations made by those in the other less valuable. Knowing that, the latter have less incentive to innovate. In either case it may be in the interests of the firm to commit to a narrower range of future paths to credibly convince employees that their innovative ideas are likely to be implemented. The authors argued that if strategy commits the firm to a specific scope for at least some time, it can achieve this goal (see also Rotemberg and Saloner 1995).

In a related paper, Rotemberg and Saloner (2000) argued that an alternative way to achieve commitment, and hence motivation, is to hire a CEO whose “vision” for the company favors certain directions over others. They modeled this predilection on the part of the CEO as a bias in favor of certain kinds of projects over others. A biased CEO can be relied on to consistently implement projects he favors, leaving employees with little doubt that their innovations in those directions will be implemented. Rotemberg and Saloner argued that a company with a visionary CEO of this kind can actually outperform one that simply follows a narrow strategy, because the latter completely eschews certain potentially profitable directions in the interests of commitment, whereas a biased CEO will ultimately implement highly profitable projects if they are sufficiently good to overcome his bias.

The essence of these arguments is that if employees earn rents when the projects they have worked on are implemented, and if their innovative efforts are not contractible, they will be more likely to put forth effort if they believe the top executive’s strategy or vision favors the direction into which their projects fit. Van den Steen (2005) showed that one need not rely on some unexplained bias on the part of the CEO to make the managers’ and employees’ expectations about future direction matter. In his model, because he did not impose common prior beliefs about the likelihood of various states of the world, people simply disagree about the likelihood of success of possible projects. Van den Steen showed that in such a setting employees will work harder for managers who hold beliefs that agree with their own about what sort of projects are more likely to succeed, because they know their ideas will be more likely to be implemented. Further, if they agree with the manager on which state is more likely, they will work even harder the more certain the manager is in his beliefs, because his expected payoff from adoption is higher, and so he adopts more projects. Interestingly, employees will work hard even for managers with whom they disagree, as long as the managers’ convictions are very strongly held. At least they know where they stand and that implementation of projects the manager likes is assured, even though they personally have little confidence in the likelihood of these succeeding. Even so, if we back up a stage and consider the employment decision, employees will choose to work for firms whose managers hold beliefs similar to their own, so that sorting then creates organizational alignment around the direction that is favored by the manager. As a result, employees working for a strongly visionary manager will work harder and be more satisfied than others. Then it is worthwhile to hire such a manager, even if one believes the manager is too much of a “true believer.” The resulting shared beliefs are an aspect of corporate culture that emerges quite naturally in this model (see Van den Steen 2010a,b).

Just as alignment of beliefs about strategy between those who take actions and those who must implement them can increase motivation, so, too, can alignment of preferences. CEOs

who put weight on what their employees want (even at the expense of profit) give employees the confidence that the firm will continue to pursue strategies that allow the employees to bring their nascent efforts to fruition. Whether the reason that senior managers act this way is because the CEO is “fair minded” and follows through on her implicit promises (Shleifer and Summers 1988), is empathic and cares about the utility of the employees (Rotemberg and Saloner 1993), or is “enthusiastic” and cares about the direction of the firm and about the benefits of like-minded workers (Hart and Holmström 2002), motivation is enhanced through alignment of preferences.

In Rotemberg and Saloner (1994) firms limit themselves to narrow strategies because it is a commitment that induces employees to work harder. It is also possible that firms might benefit from narrow strategies for precisely the opposite reason: fear that the firm might later broaden its strategy if the current strategy is unsuccessful might cause employees to work harder to ensure continuation of the current strategy. For that fear to be founded, senior management must have the flexibility to change strategy in the future rather than being committed to the current one.

This alternative motivation for hard work can happen if the value of employees’ human capital itself is strategy-specific, or at least there are complementarities between the human capital employees develop (or come with) and the strategy the firm is pursuing. For example, salespeople nurture networks that are complementary to the products and services that the firm is providing, and access to those networks is more valuable if the firm continues to provide those products and services. If the value of employees’ human capital is strategy-specific and the rents they receive are greater if the firm continues with its current strategy, the employees then have an incentive to work hard to ensure the continuation of the strategy. Fear that the firm will change strategy will induce effort.

This point is demonstrated by Mailath et al. (2004) in a model where the firm considers a merger between two related businesses. In their model if firms A and B are in related businesses producing competing differentiated products, if A does not perform well in its current strategy, senior management might be tempted to shift in the direction of B’s products. If management does so, A’s current employees would suffer a reduction in the value of their strategy-specific human capital. Consequently they will work hard to ensure the success of the current strategy. If, however, the firms were to merge, an *ex post* shift in A’s strategy would be less profitable, as it would come at the expense of B, a cost that the merged firm would internalize. Thus, in a merged firm a change in A’s strategy is less credible, with the result that the fear of changing the strategy is less of a disciplining device.

The difference between the motivations for pursuing narrow strategies in these two lines of research is that in the Rotemberg-Saloner and Van den Steen models the firm wants to induce employees to make new strategy-specific investments, whereas in Mailath et al. (2004), the employees, as a result of existing human capital, have a vested interest in the status quo.

Finally, Ferreira and Rezende (2007) offered a model in which publically announcing a strategy to outsiders can induce commitment to it, because changing an announced strategy causes the managerial labor market to reduce its estimate of the manager’s ability. In their setup, the strategy is a plan about how business will be conducted in the future, and the problem is to induce noncontractible investments that are specific to that plan. Commitment to the plan makes inducing the investment easier.

2.4. The Process of Strategy Formulation

There is a great deal of variety in way that strategy is formulated in practice. This variety reflects the differing needs of firms of different sizes and in different industries, but it also reflects the lack of a single accepted best practice in this area.

2.4.1. *Large, Established Single-Business Firms*

These firms are the most interesting place to start, because size introduces significant issues of communication and delegation, and usually of ownership and control as well. It is common in these settings to ascribe the responsibility for coming up with a vision for the business and translating it into a business strategy to the CEO. Quigley (1993) gave credence to this top-down view, citing a Korn/Ferry International study of 1,500 senior managers in 20 countries, in which 98% say the most important CEO trait is the ability to convey a strong sense of vision, and the most important skill (by a margin of 25% over any other) is strategy formulation to achieve the vision.

Some strategic management scholars ascribe a much smaller role to senior management. Mintzberg has repeatedly argued that the role of senior management is much closer to that of formalizing and documenting strategic changes that have already been brought about by others in the organization. He uses the term “emergent” strategy to capture the idea that strategy grows from small initiatives spread throughout the organization undertaken at the discretion of employees, rather than as the result of a master plan (e.g., Mintzberg and Waters 1985). Of course, “small initiatives” might be consistent with the existing strategy and could advance that strategy in the spirit of the formal models described above. However, in contrasting “emergent strategies” with “deliberate” ones, Mintzberg suggests that strategy is better described as a “bottom-up” than a “top-down” phenomenon.¹⁰

Burgelman (1983, 1991) attempted to reconcile the top-down and bottom-up views of strategy formulation, based on his observations of different companies, most notably Intel. In his formulation senior management does indeed specify a strategy, but managers lower down in the organization sometimes use their delegation of authority to explore initiatives that are outside the stated strategy. If these initiatives are successful, they sometimes later become incorporated in the formal strategy. Burgelman’s framework incorporates a curious mix of behaviors: senior management that directs strategy and junior managers who flaunt those directives and take actions outside the scope of the current strategy that ultimately change the strategy.

However, this combination of behaviors arises naturally in models in which the firm employs visionary leaders who are biased, enthusiastic, or have strong beliefs of the kind described above. The strength of the visionary leader in those models in motivating employees to exert effort that is consistent with the vision is tempered by the fact that objectively good initiatives might not be undertaken for fear that they would not be implemented, and indeed, employees wishing to

10. The organizational ecology literature in sociology (Hannan and Freeman 1984) proposes an even smaller role for senior management in determining the strategic course of the firm. In that literature firms of different organizational forms are inherently suited to pursuing particular courses of action (the way that they compete is a function of inherent firm attributes). In that sense the strategy *is* the organizational form. Some firms win and others lose, not because senior management has chosen and implemented a winning strategy, but because the competitive environment selects the organizational forms that are better suited to the industry context.

pursue such initiatives might be starved of the resources to do so. It might then be better to have an intermediate layer of middle managers who have an objective view of the world (“professional managers” in the terminology of Hart and Holmström 2002). Such managers understand that senior management will not favor initiatives that are inconsistent with their idiosyncratic or biased view of the world, but they might provide the resources for promising initiatives outside the scope of the current strategy. The point is that these initiatives, if sufficiently successful, might overcome the predilections of the bosses and be adopted, changing the course of the strategy in the process.

A formal model of such a hierarchy was developed in Rotemberg and Saloner (2000). In addition, although he did not formally develop the role of the middle managers in such a setting, in Van den Steen’s model (2005) employees with strong opinions that differ from their boss’s will pursue their own inclinations, and if sufficiently successful, will have their projects implemented despite being outside the preferred strategy of the CEO. For middle managers to be objective, their appointment must be supervised by a group that does not share the CEO’s bias—a board of directors, perhaps.

2.4.2. *Start-Ups*

Strategy in small companies is more straightforward, because top management is both well informed about strategy-relevant characteristics and in a position to monitor employees’ actions. In these settings strategy does tend to spring from the mind of the CEO—a top-down view is clearly the relevant one here—and tends to be formulated without a formal or inclusive process.

Start-ups, by which we mean nascent organizations assembled to pursue a novel idea or business approach, are small companies that introduce different issues, because the strategies that most start-ups end up pursuing are either completely different from what was originally conceived or are significant modifications thereof. Yet the provision of critical resources—capital, labor, channels of distribution, etc.—will in part depend on an assessment of the likely success of the strategy. Consequently, although start-ups are compelled by resource-providers to be able to articulate strategy even at an early stage, they often exhibit two features not always seen in more established companies (at least not to the same degree). First, the strategy is a work in progress, often evolving rapidly as the founders learn about their markets, their competitors, and the tastes of resource providers. Second, whereas disciplined, more mature businesses often drive toward focus by ejecting elements of scope that will be distracting, even start-ups that are resource-poor often explicitly experiment among several strategic alternatives because of the high value of the real options they have, resulting from the uncertainty inherent in matching a start-up’s potential to its market. This lack of initial focus also means that young firms are sometimes unable to align their human capital to their strategies as closely as more established entities can, and they may require more generalist skills. (This view is consistent with Lazear [2005], who argued that entrepreneurs are jacks-of-all-trades, although in that paper the reason given—that entrepreneurs must tackle diverse tasks—is different.)

2.4.3. *Corporate Strategy*

Strategy in multibusiness firms must encompass both the complexity of strategy formulation for each individual business, discussed above, and the alignment and coordination of strategy across businesses. We defer discussion of this topic to the section on multibusiness firms in Section 4.1.

2.5. Strategic Change

Organizations must manage a natural tension between immutable strategy and change. The benefits to coordination and motivation described above can be realized only if the firm sticks to its strategy. Employees lower down in the organization know what to do, and they know that their initiatives will be implemented, only if the strategy they are following in taking those actions is not a moving target. At the same time, in the presence of changes in the firm's environment and its own internal capabilities, a given strategy will not remain optimal forever. One might imagine that the firm might adapt the strategy to optimize continuously against such changes, but in practice it takes time to communicate strategy effectively. This, plus limitations on the kinds of subtleties that can be effectively communicated, tend to lead to infrequent but significant changes to strategy.

This line of thought suggests a kind of "punctuated equilibrium" view of strategy, in which periodic changes to strategy are significant events, between which strategy is stable. In this view of the world the general manager is expected to manage, on the one hand, as though the strategy is fixed (at least for now) while, on the other, continually assessing whether environmental or internal developments are such that a significant shift in strategy is needed.

The frequency with which strategy should be changed must be industry and firm dependent. In more rapidly changing industries, firms will find the balance between the benefits of responding to changes in their external environment and the costs of strategic change tilting in favor of more frequent changes. The same will be true of firms that are smaller (because they are less complex and can execute change more quickly) or have more centralized structures (so change is more easily coordinated).

Some strategic change will consist of small, local adjustments in response to changes in internal and external factors. Although the changes may be sporadic because of the adjustment costs described above, they may well approximate a continuous process. However, the most interesting episodes of strategic change involve discontinuous realignments of strategy and organization. Because a strategy involves a coherent goal, scope, competitive advantage, and logic, and an execution of that strategy that is aligned with organization structure (as discussed in more detail in Section 3), strategic change may require a set of people, policies, products, positioning, etc. that is at once different from the status quo yet internally consistent. Strikingly, however, the issue is not continuous versus discrete change, because the abilities to do each are complementary: being able to make large changes is more valuable the better one is able to fine-tune after the major shift, and vice versa (Milgrom and Roberts 1995b).

A final potential motivation for strategic change that one hears, at least among practitioners, is to "shake things up." As described above, a firm that steadfastly pursues a given strategy for a long time will tend to align its organization, processes, and people around that strategy. Sorting is likely to result in people with like beliefs, and the only innovations that are undertaken are ones that are consistent with the direction the company has been pursuing. It is sometimes suggested that opening the firm up to a process of strategic change can result in increased innovation, creativity, and motivation, both through the process of thinking through change and its implementation.

This whole area of the meaning of strategic change, its frequency, and nature has not been the subject of much formal economic analysis.

3. Organization

Choice of a strategy determines a set of activities that must be carried out to implement it. Executing these activities requires putting in place an organization through which decisions and actions of the people involved can be coordinated and motivated: managed organizations exist to coordinate and motivate.

3.1. The Elements of Organization

A useful typology of the features of any formal, managed organization involves four elements, each of which affects coordination and motivation (Roberts 2004). The first is the people who belong to the organization, with their knowledge, skills, preferences, and individual beliefs, and with their networks of relationships with others, both inside and outside the organization. Next comes the organizational architecture, including such matters as the specification of the organizational chart with its information about who reports to whom, how tasks are collected to define jobs and how people are assigned to them, how jobs are collected together into units and units into larger entities, how broad the spans of control are, and how deep the hierarchy is. Architecture also involves such matters as the allocation of authority over various decisions; the financial, ownership, and governance structures of the organization; and its formal boundaries and relationships with other, cooperating entities. The third set of features involves the routines, processes and procedures, both formal and informal, official and actual, through which information is gathered and disseminated, decisions are made, assets are acquired, resources are allocated, work is done, performance is tracked, and people are rewarded. Finally, there is the culture of the organization, involving shared beliefs and values, mental models, special vocabulary, and behavioral norms. Each of the many features of the organization is at least partially controllable and so may be used to influence behavior and affect the realization of the strategy.

Various chapters in this volume deal with specific aspects of organizations in detail. For example, Baron and Kreps (this volume), Lazear and Oyer (this volume), and Waldman (this volume) deal with human capital and personnel issues; Gertner and Scharfstein (this volume) study resource allocation; Bresnahan and Levin (this volume) examine the vertical boundaries of the firm; Garicano and Van Zandt (this volume) and Mookherjee (this volume) study hierarchy and delegation; Hermalin ("Culture and Leadership," this volume) reflects on culture in organizations; Gibbons and Henderson (this volume) look at routines and capabilities; Bolton and Dewatripont (this volume) study authority; Gibbons et al. (this volume) examine organizational decisionmaking; and Gibbons and Roberts ("Economic Theories of Incentives in Organizations," this volume) study motivation and incentives. Thus, rather than dig into these issues here, we instead focus on higher level issues, except in the specific context of multiproduct firms in Section 4.

There are two extreme views on the connection between strategy and organization. One is encapsulated in Alfred Chandler's dictum: "Structure follows strategy" (Chandler 1962: 14). Chandler's theory arose from his studies of the emergence of the multidivisional form in the early twentieth century. More ambitious strategies—operating over an unprecedentedly broad geographic expanse or in multiple product or factor markets—implied much more complex problems of coordination and motivation than had previously been encountered. Confronting

these problems led to the development of new organizational models that would permit execution of the new strategies.

In the other view, in ongoing companies the organization that is in place constrains strategic choice and may even determine it, so that strategy follows structure. First, it is obvious that the people in the firm limit its options: a steel manufacturer cannot easily convert to being an investment bank, no matter how profitable banking might be, because the steelmakers lack the skills and relationships to be bankers and the capital stock of the company is ill-suited to the new role. Culture has similar inertial effects. In addition, the capabilities on which competitive advantage may rest are embedded in the routines of the organization (Nelson and Winter 1982), so what the firm can do depends on who its members are and what it has done before. Moreover, because organizational change is hard and dangerous (Barnett and Carroll 1995), the existing organizational design affects the attractiveness of any new strategy through the costs of adjustment. Finally, and most fundamentally, the existing organizational architecture, routines, and culture will shape the decisions that affect strategy: the information that those empowered to make decisions have and the explicit and implicit incentives they face will lead them to make choices that will, in effect, determine the emergent strategy (Bower 1970; Burgelman 1983). In this context, John Browne, former Group Chief Executive of energy giant BP, has said, “our organization is our strategy.”¹¹

In fact, both positions have an element of truth. In established firms, the extant organization does influence what is possible. In contrast, Chandler’s dictum is often right in the context of new ventures: the entrepreneur decides what to do, then how to do it. But even here matters are not crystal clear. As discussed above, actual start-ups often go through an extended process of exploratory learning as they attempt to figure out what the market actually wants, and the nascent organization influences the path and scope of this learning.

Ideally, the strategy and the organization are developed together in a holistic fashion and are jointly determined, so they fit each other and also fit the economic, technological, legal, regulatory, and social environment in which the company operates.

3.2. Fundamental Trade-Offs in Organizational Design

Organizational design involves fundamental trade-offs, two of which we highlight here as illustrative of some of the basic issues.

3.2.1. Initiative and Cooperation

In thinking of the organization as a mechanism to coordinate and motivate in pursuit of the strategy, Holmström’s conception of the necessity of inducing two sorts of behavior—initiative and cooperation—is useful. Initiative is the clever, diligent, honest pursuit of one’s own responsibilities. Cooperation is behavior that advances others’ interests or overall organizational success, as opposed to contributing to one’s own assigned responsibilities. High levels of initiative are almost definitionally valuable in any organization. At the same time, because managed organizations tend to arise in contexts where interdependencies abound and that are problematic for formal contracting, cooperative behavior can be extremely valuable as well. The difficulty is that

11. Private discussion with John Roberts, circa 1999.

often the two compete for peoples' time, so that inducing one makes it more costly to induce the other. Thus, for a given level of resources being dedicated to motivating behavior and a given state of managerial technology, there will be some maximum amount of initiative that can be induced for any level of cooperation, and one expects that this frontier is downward sloping. This framework can be a useful tool for analysis (Roberts 2004).

In some organizations, initiative is paramount. The trading desk of an investment bank might be an example, although some of the risk taking that went on in the run-up to the financial crisis of 2008 does seem to have shown a lack of concern with the success of the overall organization—a shortage of cooperation. In other contexts, motivating cooperation may be of greater value. For example, a company facing similar operating issues in many different locations might get great value out of managers' sharing their experiences with different possible solutions to common problems.

One approach to modeling motivating the provision of both cooperation and initiative would naturally be done in the context of a multitasking agency framework (Holmström and Milgrom 1991; Baker 1992; see also Gibbons and Roberts, "Economic Theories of Incentives in Organizations," this volume). The key would be that providing formal, explicit incentives for initiative should typically be much easier than for cooperation, because the former may be easily measured, whereas the latter may be subject only to very noisy or easily manipulable measures. For example, in many situations, cooperation consists simply of avoiding opportunism aimed at others inside the firm, and determining when someone has passed on such an opportunity will be hard. Or if cooperation is providing help in solving a problem in another part of the company, it will be hard to determine whether someone did not contribute because of lack of cooperation or lack of anything useful to offer.

In this case, the logic of multitasking indicates that any formal incentives for both activities must be quite muted if the marginal cost of providing the one is increasing in the amount of the other (Holmström and Milgrom 1991). Two other alternatives seem possible, however. One would be to rely on a boss's subjective evaluations on the provision of cooperation while providing explicit formal incentives for initiative. The other would be to develop norms of cooperation in situations where, even if the boss cannot observe enough to form useful subjective evaluations, peers are aware of one another's behavior. This was done at BP to encourage the sharing of resources and knowledge across business units (Roberts 2004). Both approaches presumably would involve relational contracts in a repeated setting.¹²

Van den Steen (2006) looked at a closely related trade-off—between motivating individual effort and coordinating decisions—that arises in situations where the parties fundamentally disagree about what the right decisions are.¹³ He considers a setup very much like that in Van den Steen (2011) discussed above, where a principal and an agent must each make a binary decision, and the agent can exert costly, unobservable effort. The payoff from the project depends on the individual decisions (whether they match the state or not), on whether the two decisions are the same (coordination), and on the agent's effort. The principal can either make both decisions just on her own or make one and leave the other to the agent, who then observes

12. Baker et al. (1994) in fact carry out a related analysis when the supply of each activity is unaffected by the amount of the other being provided. This assumption generally simplifies the analysis considerably.

13. Formally, they have differing prior beliefs about the likelihood of various states of nature.

the principal's choice. Letting the agent make his own decision motivates him to provide effort if the quality of the decision and effort are complements, because he believes the decisions he makes are better than those the principal makes (by revealed preference plus differing beliefs). As for coordination, one obvious potential way to achieve it is to use monetary incentives (which would work in a setting where there was simply a common prior, but the agent received private benefits from making decisions). Here it does not, because although giving the agent more residual income increases his interest in coordination, it also intensifies his interest in making the right decision (from his point of view), even at the expense of coordination. In the present setup these two effects cancel out, and monetary incentives are useless. So if coordination is to be assured, the principal must make both decisions, although this reduces the agent's effort incentives. The result is a trade-off and, for a given share of the project returns paid to the agent, a downward-sloping frontier relating motivation and coordination.

3.2.2. *Exploration and Exploitation*

March (1991) identified two fundamental learning processes in organizations. One involves exploitation: realizing the opportunities inherent in the current strategic, organizational, and environmental contexts. The second is exploring for new opportunities outside the current agenda. Effective exploitation is needed to succeed in the ongoing business, but exploration is also vital in a world of change, where competitive advantage can erode and demand may disappear. Perhaps this search need not always be pursued intensely, instead being concentrated in times of crisis, when there is a great need for redefinition and renewal; see Tushman and O'Reilly (1996, 2011) for examples. Still, at least sometimes the firm must both explore and exploit.

The difficulty is that the two compete for resources and, further, organizational designs that support exploration are typically inimical to exploration (Roberts 2004). The competition for resources is often an uneven one, because the resources are being generated by the current business—the exploiters—who are likely to resist resources being shifted away from the uses they have for them to pay for the explorers. Also, all the normal measurement, control, and reward systems will show the exploiters in a better light compared to the explorers. The former can demonstrate immediate, measurable results that are easily understood. The explorers offer little but hope and dreams while burning up cash. To support exploration, the measures should be in terms of milestones and growth—not cost, revenues, and efficiency. The reward schemes and the culture should favor risk taking, imagination, and innovation—not the rigor, discipline, and focus that mark exploitation—and they must avoid punishing well-intentioned failure. Taking a multitasking point of view, it is clear that it is much harder to induce exploration than exploitation (Roberts 2004).

At the same time, the exploratory efforts must be linked back to the business. Otherwise the glorious, sad history of Xerox's Palo Alto Research Center (PARC) may be repeated. PARC invented a remarkable list of technologies, including the computer mouse and graphical user interfaces that Apple Corporation copied for the Macintosh, yet Xerox was never able to figure out how to use any of them profitably.

Management scholars have identified a set of actions that appear to be conducive and perhaps even necessary to support exploration. These include setting up separate new business units outside the existing business, having the new units report to top-level executives directly, and

allowing them to develop their own organizational designs (see the references in Tushman and O'Reilly 2011).

A variety of economics papers have investigated the problem of motivating innovation, but only one apparently has looked at the problem of exploration and exploitation. Manso (2011) considered a repeated agency problem where, in each period, the agent has three choices: shirk; try the established way of carrying out his responsibilities, which has a known probability of success; or try a new way, whose probability of success is unknown. Each option carries a positive probability of success and of failure, but the new way is, in expectation, inferior to the old. So exploitation is favored in a one-shot game. However, suppose that if the new way is tried and it succeeds, then the updated posterior on its probability of success exceeds the known probability of success of the established way. In this case, the principal may want the agent to explore the new way, with the intention of adopting it in the second period if it is a success and otherwise reverting to exploiting the old way.

To motivate exploitation of the old way optimally involves a contract design that is absolutely standard from the literature on unobservable, costly effort. However, motivating exploration necessitates muted first-period incentives, because success is more likely if the agent exploits, and so success is bad news about his choice. In fact, it may even be necessary to reward first-period failure if the agent finds it easier to exploit than to explore.

3.3. Finding Fit

For success, the strategy and organization need to fit each other. What is involved?

3.3.1. *The Problem*

Sometimes fit questions are simple, even if firms do not always come up with the right answers. For example, suppose a firm adopts a strategy that calls for very high service being provided to a group of customers with whom it wants to build long-term relationships and from whom it will seek to learn about their evolving preferences to develop new offerings. Then it would be unwise to pay salespeople significant commissions based on short-term sales revenues, although such incentives would be ideal in a context where current sales were all that really mattered (Anderson and Schmittlein 1984; Holmström and Milgrom 1991). Financing the firm predominantly with debt may be desirable in a stable, mature industry, where the firm has few good options for investing its cash flow but where managers might prefer not to pay out the cash to shareholders (Jensen 1986). Yet equity may be preferred in a more volatile environment with better growth opportunities.

Despite such examples, the task of finding the best fit among all the elements of organization and of the organization as a whole with the strategy and environment is, in principal, arbitrarily complicated, because the elements of strategy and organization interact in potentially complex ways that affect performance.

For example, consider Southwest Airlines and Singapore Airlines. Both are in the passenger airline business, and both are very successful, but they have radically different strategies and organizations. Singapore Airlines focuses on long-haul, international flights through its hub in Singapore and provides extremely high levels of service, especially to business and first class customers, with little discounting of prices. To support this approach, it requires that its female

flight attendants be slim and physically attractive, trains them extensively not just in service but also in grooming, and requires them to retire at a young age. (Male flight attendants receive training in service but are not subject to the other conditions.) It also makes a point of having the most modern fleet of airplanes (it was the first to buy the Airbus 380), equipping the airplanes with every luxury, having luxurious lounges in airports, and offering excellent food and drinks on board. Meanwhile, Southwest is purely domestic, operating point-to-point flights with only economy seating and very sharp prices. Service is friendly but not in any sense outstanding (there are no assigned seats, and no food is offered on the planes). Flight attendants appear to be selected for good humor and a willingness to work hard. Costs are kept low by a variety of measures, including especially high utilization of the aircraft, achieved in large part by fast turnarounds at the gate. To facilitate quick turnarounds, the aircrew and flight attendants will clean the plane rather than waiting for cleaners, and they even handle baggage. To further economize by eliminating variation, Southwest operates only one type of aircraft, the Boeing 737, a small single-aisle model whose design dates back almost 50 years. In each case, the strategy and organization fit together, and the success of each enterprise can be attributed to this fit. But crucially, until very recently no airline has managed to match either Singapore's strategy and organization or Southwest's, despite the presumptive gains from doing so in an industry where most participants fail to earn their cost of capital. Finding fit is apparently hard, even when models are available.

In fact, recent empirical work on organizations and management indicates tremendous heterogeneity across various elements of design. For example, Bloom and Van Reenen and various coauthors (e.g., see Bloom and Van Reenen 2007; Bloom et al. 2010, 2011b) have found extensive differences in the extent of delegation and decentralization (e.g., authority to hire various sorts of employees and spending limits for buying spare parts) in particular populations of establishments around the world. They have also examined various management practices (e.g., promotion on merit or future promise versus other criteria, setting goals and providing feedback, and recording quality problems and acting on the knowledge) and have found wide divergences in practice. Whether to decentralize or not involves important trade-offs, so that either answer on this dimension might be correct, if not obvious. However, for most management practices they study, there is clearly a right way to do things in most circumstances, but relatively few firms do it. Again, finding fit is apparently hard.

3.3.2. *Rugged Landscapes and the Difficulty of Finding Fit*

This logic has been captured in the "rugged landscapes" literature that begins with the work of Levinthal (1997). Levinthal's model, which is based on work by Kauffman (1993) on complexity, treats the choice of organization as selection of the values for N different binary (0 or 1) attributes, so there are 2^N different possible organizational designs. The payoff to a particular choice of the n th variable is a random number drawn from a uniform distribution on $[0, 1]$ that depends on the value of the choice of that variable as well as the specification of the values of K other variables. So in the $N = 3$, $K = 2$ case, the payoff to, say, $x_1 = 1$ is a different random number for each possible specification of x_2 and x_3 , whereas with $K = 0$, the payoff to x_1 depends only on the value of x_1 . Then the overall performance for a given organization is the average of the payoffs across the N variables.

If $K = 0$, then changing the value of one attribute does not change the payoff of any others, so the maximum change in the overall performance is $1/N$. In this case there is typically a unique

optimal organizational design. As K increases, changing a single attribute's level changes more and more of the payoffs to other attributes, and thus the overall performance can change much more. If $K = N - 1$, then any change in a single variable changes the contribution of all the others. Thus, with $K > 0$, adjacent points can have very different performance levels, and the graph of the performance function can be uneven and irregular: a "rugged landscape." Moreover, the number of local maxima increases probabilistically with K .

In such a setup, local search is of limited value, because improving performance by changing the value of one variable gives no information on the effects of any other changes, and as N and K become large, global search becomes very complex.¹⁴ These factors suggest that firms that happen upon "good" configurations may have a lasting competitive advantage, because imitation will be hard: even getting one element of the design wrong may give radically different performance. Less positively, firms may also find replication of their success in another location or line of business very difficult, because altering one element of the strategy and organization (location, product) may change the effectiveness of all other elements. And finding fit again after the environment has changed may be very difficult.

The rugged landscapes modeling of the problem of selecting strategy and organization is about as far as possible from the standard models of economics that yield nice, smooth, concave optimization problems. This newer model has pluses and minuses. On the one hand, dropping unwarranted but conventional assumptions of divisibility and decreasing returns is clearly desirable. On the other hand, the approach assumes that there is no logic or theory that can be used to guide the selection. This conclusion seems to be too nihilistic.

3.3.3. Complementarity and Fit

In a series of papers, Milgrom and Roberts (e.g., 1988b, 1990, 1995b) have argued that finding fit will often involve recognizing and exploiting complementarities that exist among elements of strategy and organization. Two elements of choice are complementary when increasing one weakly increases the return to increasing the other. Complementarity ideas accord with the rugged landscape in accentuating the possibly multitudinous interactions among organizational design variables. They also are consistent with the design problem involving indivisibilities and nonconcavities. So the complementarity approach shares key features of the rugged landscapes framework, namely, that multiple local optima are normal and that improving performance may require changing many aspects of design simultaneously. But crucially, this approach assumes that there are important regularities in the interactions among the attributes of the organization and a resulting recognizable logic to organizational performance and design.

In particular, with complementary choice variables, any change in the environment that favors increasing a particular variable will also favor increasing all other variables that are complementary to it. Further, increasing them all will yield a greater change in payoffs than would be estimated by looking at the individual changes in isolation. Thus, there is a tendency for all or none of a set of complementary practices to be adopted together. In addition, the search for performance improvement is simplified, because at least half the gains from moving from any particular specification of the choices to the optimum can be found just by searching over those quadrants where all variables are higher than at the base point and where all are lower (Milgrom

14. The problem is NP complete (Rivkin 2000).

and Roberts 1995a). Yet, as in the rugged landscapes literature, failure to adjust even one variable optimally may lead to large losses relative to the overall optimum, and local improvements may not find the overall optimum. Thus, some of the difficulties of imitation survive.

There is now a wealth of papers using complementarity in studying strategy and organization. Milgrom and Roberts (1988b) argued that the strategic issue of the breadth of the firm's product line is complementary with such organizational choices as producing to order (rather than for inventory) and communicating more closely with customers. Milgrom and Roberts (1990) argued for complementarities among the frequency of new product introduction, the flexibility of the manufacturing system, reduced inventories, and the extent of outsourcing, with greater reliance on these being driven by improvements in information and communications technologies. Milgrom and Roberts (1995a) added a group of human resource management practices to the "modern manufacturing" nexus. These practices include long-term employment, high investment in training, finer pre-employment screening, worker empowerment, and increased horizontal communication. The same paper also points to complementarities among Lincoln Electric's low-cost strategy and many of its distinctive organizational features: piece rates, bonus payments for quality and cooperation, no layoffs, internal ownership, open communication, no executive perks, and large inventories of work in process.

Testing empirically whether choices are actually complementary is tricky, because of unobserved heterogeneity problems (Athey and Stern 1998; see also Brynjolfsson and Milgrom, this volume). However, numerous empirical studies have observed patterns of payoffs to differing or changing strategic and organizational designs that are consistent with complementarity. For example, MacDuffie (1995) found that a distinctive set of human resource management practices was associated with the move to Toyota-style lean production in U.S. auto assembly plants, as Milgrom and Roberts's models had suggested. Ichniowski et al. (1997) found that a bundle of human resource management practices positively affected performance in steel finishing only when they were all adopted. Whittington et al. (1999) found the payoffs to changing elements of strategy and organization in a broad survey of European firms had a similar pattern: only by making all the changes was performance improved, but then the improvements were significant. Bresnahan et al. (2002) found that investments in IT were much more productive when matched with changes in organization that are arguably complementary. See Brynjolfsson and Milgrom (this volume), Lazear and Oyer (this volume), Ichniowski and Shaw (this volume), and Waldman (this volume) for other examples of complementarity among features of strategy and organization.

3.4. Some Dynamics

Of course, establishing alignment among strategy, organization, and the environment is not a once-and-for-all proposition. As the environment changes, the strategy and organization may need to be adjusted to maintain performance. This raises the issue of how finely the strategy and organization ought to be crafted to perform in a single environment. If some organizational designs will deliver reasonably good performance across a range of environmental conditions, while others perform exceptionally well over a limited range but badly if the environment changes more substantially, then there can be a trade-off between maximizing performance in a given environment and achieving good performance over time in the face of environmental

change (so long as organizational change is costly). This trade-off is similar to that noted by Stigler (1939) for the choice of cost curves in the face of variable demand. We are not aware of formal efforts to model the trade-off.

Although changing environmental conditions may call for organizational change, numerous observers have noted an apparent tendency for organizations to alternate between centralized and decentralized modes. Typically, these oscillations are taken by business commentators as reflecting managerial failure. A more positive approach has been suggested by Nickerson and Zenger (2003). A version is the following: Suppose the behavior that drives performance is not observable, and further suppose that the relationship between action and outcomes is so subtle and complex that agents cannot easily figure out how to behave to improve performance. Thus, inducing the right behavior is not possible using normal means. However, suppose that the formal organizational architecture and the associated routines and processes shape behavior over time. For example, when the organization is decentralized, initiative might tend to increase but cooperation tend to decrease. Now suppose there are only two coherent patterns of organizing: decentralized or centralized. Either a decision is made at the center or at the operating level; there is no half-way option. Thus, if we let the behavior be indicated by $a \in [0, 1]$, we specify that da/dt is positive if the organizational choice x is centralized ($x = 1$) and is negative if it is decentralized ($x = 0$). Further, suppose that $\lim_{t \rightarrow \infty} a(t, x) = x$, so behavior drifts to extremes. Finally, suppose that the performance is concave in a , that the optimal behavior is somewhere between that induced by centralization and decentralization, and that changing x is costly. Then just like a thermostat or an (s, S) solution to an inventory problem, the solution is to set $x = 1$ for a period of time, so that a drifts up, eventually reaching a critical level at which it is too far above the desired level, then to switch to $x = 0$ for a time, during which a drifts down until it has fallen to another critical level, whereupon x is reset to 1. So the organizational design optimally bounces back and forth.

3.5. Recent Trends in Organizational Design

For at least two decades, scholarly, journalistic, and practitioner observers of business organizations have been describing a broad pattern of changes. Here we present the perceived trends, as noted largely in case studies, and then look at the econometric evidence for them.

3.5.1. Perceived Trends

Architectural elements of the changes include reducing the overall size of the organization (downsizing, downscoping, outsourcing, and reliance on alliances); breaking up units into smaller sizes with more focused responsibilities; decreasing the number of hierarchic layers (delayering); increasing spans of control (the number of direct reports to an individual manager), especially at the top of the hierarchy; increasing operational and strategic delegation and, sometimes simultaneously, increasing authority at the center (via assumption of some powers previously held by the delayed middle managers); developing cross-functional and cross-business teams; and adopting more flexible, project-oriented structures. Routines and process changes include increased communication (horizontally among units and within teams; vertically across the hierarchy; and externally with suppliers, customers, and allies); heavy investment in information and communications technologies; and altered human resource practices, including tighter

pre-employment screening, more training, greater reliance on (often group) performance pay, more flexible job designs, greater encouragement of linkages among people, and greater reliance on frontline employees' using their own knowledge, judgment, and intelligence.¹⁵ Generally, the drivers of these changes are seen to be increased competition through globalization of markets and industries and changes in information and communication technologies. Increased competition requires firms to be able to change more quickly and respond faster to market developments. Technology enables operating and managing in new ways to meet the new challenges.

3.5.2. *Econometric Evidence*

Most patterns described above are drawn from individual case studies and/or small-numbers studies. The first systematic empirical examination of these changes on a broad scale appears to be Whittington et al. (1999). They surveyed a group of medium to large British and European manufacturing firms, receiving responses from about 450 CEOs. Their questions asked about current (1996) organizational practices on ten of the dimensions noted above¹⁶ and about changes since 1992. They found broad support for the asserted patterns of change but significant variation in the range and extent of actual changes. Strikingly, after bundling the changes into three groups—changing structures, changing processes, and changing boundaries—they found evidence that making changes in only one or two of these tended to be associated with weaker financial performance, whereas changing all three was associated with stronger performance.

Bresnahan et al. (2002) examined U.S. data from a similar period and found that information technology investment was associated with increasing decentralization; increased employee empowerment; an increased value to employee skill, leading to more screening and training; and on the strategic side, increased new product introduction. Also like Whittington et al. (1999), they found feedbacks consistent with complementarity among these features.

More recently, several empirical studies have examined more specific aspects of organizational and strategic change, sometimes linking these to increased competition. Rajan and Wulf (2006), Gaudalupe and Wulf (2010), and Gaudalupe et al. (2012) all examined changes in the hierarchical structure of firms, using U.S. data. Rajan and Wulf studied a sample of 300 very large U.S. firms from 1986 to 1998. Their first finding was that the number of people reporting directly to the average CEO rose significantly, from an average (median) of 4.4 (4) in 1986 to 8.2 (7) in 1998. They also found that the number of layers in the hierarchy between the CEO and the lowest level manager with profit and loss responsibility (division heads) fell by more than a quarter over the period, while the number of division heads reporting directly to the CEO increased three times, and many of these frontline managers were newly appointed as corporate officers. These changes took place despite little change in the size of the divisions they headed. Instead, the delayering involved removing middle managers, such as chief operating officers, whose number fell by 20% during this period. Finally, the compensation of the division heads rose as they moved closer to the CEO, suggesting that their responsibili-

15. See Whittington et al. (1999) for references to the management literature describing these changes and Roberts (2004) for more detailed descriptions of the changes.

16. The dimensions queried were delayering, project structure, operational decentralization, strategic decentralization, human resource innovations, information technology, horizontal linkages, outsourcing, strategic alliances, and downscoping.

ties were increased. Rajan and Wulf (2006) discussed several possible drivers of these changes, but did not test any of them. Potential drivers included increased product market competition requiring quicker responses, improved corporate governance driving out slack and dismantling empires, and improved information technology allowing a broader span of control at the top.

Guadalupe and Wulf (2010) explicitly identified increased competition as leading to these changes, utilizing a quasi-natural experiment. They studied the effect of increased Canadian competition for U.S. firms occasioned by the passage of the North American Free Trade Agreement, which removed U.S. tariffs on imports from Canada. Using a multi-industry panel of more than 300 firms during 1986–1999, they employed a differences in differences strategy made possible because different industries had enjoyed different levels of tariff protection before the tariffs were removed. They were able to show that increased competition led to decreased numbers of hierarchical layers and larger CEO spans of control.

Most recently, Guadalupe et al. (2012) looked at the composition of the set of executives reporting directly to the CEO in a panel of 300 large U.S. firms from 1986 to 2006. They found that the number of such executives doubled on average, but that three-quarters of this growth was among senior functional managers (e.g., chief marketing officer, chief information officer), rather than among general managers responsible for pieces of business. We return to this paper in our discussion of the organization of multiproduct firms in Section 4.2.1.2.

At a lower hierarchic level, Colombo et al. (2007) examined the effects on profitability of adopting high-performance work practices, including plant-level profit sharing, pay for skills, total quality management, team work, job rotation, and employee involvement in decisions, in a panel of single-plant Italian metalworking firms in the 1990s. (Many studies have documented the spread of such practices over the past decades, but few have measured their impact on performance.) They also looked at the effects of reducing the number of supervisory layers between the plant manager and the workers and of delegation of operational and strategic authority to the plant manager. In doing this, they controlled for the adoption of various advanced manufacturing technologies. The sample was relatively small (109 firms), and there seem to have been significant selection issues associated with it. Still, they obtained some interesting results.

In particular, they found that, among the high-performance work practices, only profit sharing and total quality management were individually significant in affecting profitability, with both having positive effects. However, there was significant colinearity in their data, because the practices tended to be adopted in bundles, making estimating individual effects tricky. In any case, the null hypothesis that the collection of high-performance work practices together had no effect was easily rejected. The effect of involving the plant manager in decisions rather than holding them all with the manager's superior was also positive and significant, whereas the number of layers had an inverse-U shaped effect: bureaucratic firms with many layers gained by delayering, but those with few layers gained by adding intermediate levels.

In two recent papers Cuñat and Guadalupe have investigated the effect of increased competition on incentive compensation inside firms. The first of these (Cuñat and Guadalupe 2005) examined data from the 1990s on the compensation of the highest-paid executive (director), other executive directors, and the average employee from a panel of more than 22,000 U.K. manufacturing firms, ranging in size from the largest firms in the country to ones with only five

employees. They utilized a quasi-natural experiment, namely, the sharp and sudden appreciation of the British pound in 1996, which increased foreign competition for these firms (but differentially so for firms in more open sectors). Their differences in differences estimations found a strong effect: increased competition led to greater sensitivity of pay to firm profit at all levels, but especially at the top of the firm.

Cuñat and Guadalupe (2009) used a matched employer-employee panel of 831 large U.S. manufacturing firms and 7,571 executives from 1992 to 2000. The data involve detailed information on firm characteristics and on the base and performance-related pay of the five highest-paid executives in each firm. Foreign competition is measured by import penetration in different lines of business. The results are that increased foreign competition lowered base pay and increased the sensitivity of pay to performance. In addition, the in-firm dispersion of total pay among executives increased, largely through greater increases in performance sensitivity for higher ranks, and executive total compensation increased. Further, increased competition led firms to hire more able executives. Together these studies point to a strong role for competition in driving compensation and staffing decisions, a key aspect of organizational design.

Although competition's impact on organization is beginning to be documented, there is much less work examining its effects on strategy. Exceptions are case studies, such as Skil's withdrawing from the mass market channels for power tools in the face of competition from Black & Decker (Porter and Ong 1988), Intel's decision to abandon the dynamic random-access memory business it had created and focus only on microprocessors in the face of Japanese competition (Burgelman 1994), and IBM's move to accentuate services over hardware sales (Applegate et al. 2009). There are also a few studies at the industry level. Notable are Freeman and Kleiner (2005), Bartel et al. (2007), and Bugamelli et al. (2008), each of which showed manufacturing firms in particular industries increasing innovation in response to competition from low-wage countries.

The first cross-industry study in this area appears to be Bloom et al. (2011a). They examined the impact of Chinese imports from 2000 to 2007 on strategy and aspects of organization in a set of many hundreds of European firms.¹⁷ During this period, following China's entry to the World Trade Organization, the share of imports from China to the United States and Europe more than doubled. These products were typically technologically unsophisticated, mass produced, and of basic quality.

The authors found that imports from China to a given country and product market reduced employment in the importing country, as many domestic firms contracted or went out of business. However, those firms that stayed in business shifted to a strategy emphasizing innovation (higher quality) by increasing their patenting and research and development expenditures. They also increased their total factor productivity growth and their investments in information technology. Meanwhile, on the organizational side, they improved their management practices on the 18 dimensions first identified in Bloom and Van Reenen (2007): monitoring (do firms continuously collect, analyze, and use information); targets (do firms have balanced, well-understood, and binding targets); and incentives (do firms reward high-performers and retrain and/or sanction poor performers). The attention to both strategic and organizational features makes Bloom et al. (2011a) especially notable.

17. The number varied across different datasets related to different dimensions of the estimated effects.

3.6. Organization and Competitive Advantage

As discussed in Section 2.1, competitive advantage is the set of reasons that other parties will deal with the firm on terms that let it realize its goals. As also noted, at any point in time, competitive advantage is likely to lie in the firm's mix of quality and price that attracts its target customers, because they prefer this offer to the alternatives in the market. However, for such an advantage to be sustainable in the face of competition, the firm must have some advantages that are not replicable. Lasting competitive advantage is inconsistent with everyone having access to the same production and market opportunities.

A favorable market position can be a significant source of sustainable advantage. Examples are a monopoly position protected by barriers to entry or uniquely low costs arising from learning economies that resulted from being a first-mover. Porter's (1980) application of industrial organization economics to strategy accentuated positional advantage and market power as the source of rents.

The resource-based view of the firm, originating with Rumelt (1984) and Wernerfeldt (1984), accentuates looking at input markets over the output markets that are the focus of Porter-style work. It sees the sources of rents in the unique resources and capabilities that the firm has at its disposal.

Unique resources, such as patents or access to particularly productive ore deposits, can be a source of lasting advantage. There is, however, always an issue of whether the firm is getting the most out of these resources by using them itself rather than selling or licensing them. Moreover, human resources are a particularly difficult source of lasting competitive advantage, because employees' ability to seek alternative employment means they are apt to claim a large share of the rents they generate. Interdependencies among employees, which imply they need to move together to carry their rent-generating potential elsewhere, combined with problems coordinating their bargaining with alternative employers, may restrict their ability to seize the rents they generate (Mailath and Postlewaite 1990). But Wall Street's experience with teams of hot traders moving to other banks, Hollywood's history of star performers and directors collecting the bulk of the returns that the studios cannot hide, and Silicon Valley's norm of engineers moving en masse to create new companies are all suggestive of the problems with making money on the basis of unique human resources. Clearly, to the extent that unique human resources are the source of profits, the recruitment, retention, and motivation of these people are crucial activities to which the organization must be shaped.

The other widely recognized source of competitive advantage are the unique capabilities of the firm that let it produce better or cheaper products or services and develop superior new ones. In standard economic models, these capabilities are black-boxed in the production function. Once we start to unpack the box, the connection between capabilities and organization emerges. Capabilities rely on the knowledge and skills of different people in the firm (not any single individual, or that person alone would be the source of rents). Thus, to cite a standard example, Sony's capabilities in miniaturization in the 1970s and 1980s that let it develop breakthrough products did not reside in any one person but in a collection of people inside the firm and in the standardized routines it had for developing compact products. Activating the capabilities relies on these people working together, so the capabilities depend on the networks among individuals as well as the formal architecture of teams, departments, and divisions. Motivating people may draw on numerous other aspects of the organizational design. Finally, as

emphasized by Nelson and Winter (1982), the capabilities become encoded in the routines of the firm.

From this point of view, the strategic question is not so much which markets to enter and how to position the firm's offerings in those markets, but rather what resources to acquire and which capabilities to build. Of course, neither formulation stands on its own: deciding on developing a capability requires evaluating the uses to which it could be put, and choosing a product strategy depends on being able to generate the product in question. Yet the focus on capabilities seems better suited for considering a variety of issues, such as the persistence of performance differentials among apparently similar firms (see Gibbons and Henderson, this volume). It also leads to conceptions of the fundamental problems facing firms that are quite different from the industrial organization approach, because skill development and acquisition, knowledge management, and the management of innovation and learning are key activities. It further puts the focus much more on the organization—people, architecture, routines, and culture—than is natural under Porter's industrial organization approach.

The economics literature contains streams of work that connect to these issues. For example, Prendergast (1993) examines how promotion policies can affect the development of firm-specific human capital. Meanwhile, a variety of organizational approaches have been studied in the context of encouraging innovation. These include incomplete ownership contracts in Aghion and Tirole (1994), agency contracts in Manso (2011), and the allocation of authority in Rantakari (2012a). See Lazear and Oyer (this volume) and Waldman (this volume) for more on human resource management and see Azoulay and Lerner (this volume) on innovation.

4. The Multiproduct Firm, Corporate Strategy, and Organization

The previous sections focused on strategy and organization for firms operating in a single market. Now we turn to multiproduct firms. Of course, almost all firms are "multiproduct" if products are defined as in Arrow-Debreu by the date, location, and state of the world in which they are available, as well as by their physical characteristics. However, we focus on situations where more common notions of market definition mean that the firm is operating in several distinct (possibly unrelated) markets. These might be defined by the set of physical products or services being offered or, in the case of a multinational firm, by geography.

Corporate strategy is about multiproduct firms. It involves answering two questions. First, which businesses should be created or brought inside a single firm? To answer this, in turn, we need to explain how having these businesses under common ownership and management will allow them to do better than they could do on their own (or bundled with some other group of businesses). The organizational issues at the corporate level are then to figure out how to structure the connections among these businesses to realize the opportunities for better performance and how to allocate decisionmaking and rewards within the firm. These issues involve the role of corporate headquarters and its relations with the units. At least until recently, formal economic theory has had little to say on these questions.

4.1. Why Are There Multiproduct Firms?

Chandler (1969) documented that corporate diversification occurred on a major scale in the United States during the 1930s. He seems to have believed that this broadening of scope arose

from the desire to maintain growth when the markets in which the firms were already active showed no growth prospects (Chandler 1969: 275). After World War II the United States experienced the development of conglomerate mergers—ones involving unrelated products, such as bringing baking and telephone service provision inside one firm. Early attempts to explain these combinations (Marris 1964; Mueller 1969) rested on “managerialist” theories. Today these would be modeled as moral hazard on the part of managers who prefer (for whatever reason) that their firms grow faster than shareholders’ interests would warrant and faster than can be achieved in the market(s) in which they are already active.

4.1.1. Teece’s Theory of the Multiproduct Firm

The first attempt to build a systematic theory of firm scope based on profit-maximizing behavior is due to Teece (1982). Strikingly, although Google Scholar lists more than 1,300 references to this paper, only a handful of the referencing papers are in economics journals and only a couple, all appearing recently, are in the most-cited journals: economists have largely ignored the issue of the horizontal scope of the firm. This is quite remarkable, given the huge amounts of attention devoted to explaining vertical integration.

Teece wrote in the spirit of Williamson (1975) and of Nelson and Winter (1982). There is no formal model, but much serious theorizing and good sense. He began by arguing that, under standard assumptions, many arguments that might be adduced to explain the existence of multiproduct firms are not valid. Economies of scope plus efficiency lead to joint production, but if contracts are complete, there is no need for this to occur inside a single firm. Instead, the producers of the various goods can contract over the shared inputs giving rise to the scope economies. Bringing two random income streams together by merging the corresponding companies may reduce variance, but shareholders can achieve that gain for themselves if the capital markets are working properly. Similarly, the merging of income streams does not increase the value of the firm by reducing default risk: all that happens is that bondholders gain and stockholders lose, with the total value being unaffected. The fall in the stockholder wealth comes from the reduced value of the option that stock represents, where this reduced value is occasioned by the reduced variance.

Teece’s (1982) arguments to explain the existence of multiproduct firms focus on the existence of excess resources in firms—resources that would not be efficiently used in the current line(s) of business. These may be indivisible physical assets; financial assets; human resources; or, importantly, knowledge. Machine capacity may exceed the demands of the current business, so the machine is often idle. The firm may be generating cash in excess of what can profitably be reinvested in its current business. Experience may have increased the productivity of workers or managers, meaning that they are not fully occupied in the current business. Knowledge and knowhow often have the character of a public good that allows them to be used repeatedly without being “used up.”

These excess resources should be put to other uses. If they cannot be efficiently transferred to other users contractually, they may be better used within the firm by its diversifying into new lines of business.

Teece (1982) then presented transaction cost arguments concerning the likelihood that particular resources can or cannot be effectively transferred contractually. Although nonspecialized indivisible assets can be shared contractually, specialized physical assets are subject to hold-up.

Protecting them may then be the basis for diversification, if they can be used in multiple products. Knowhow with multiple uses that is embodied in human assets is hard to transfer for a variety of reasons: not only is it subject to all the usual problems with selling information, but also much of it is likely to be tacit, so its transfer may necessitate moving people (at least temporarily). Finally, following Williamson (1975), Teece argued that internal capital allocation may be better than what the market can achieve, because the managers may have deeper knowledge and may have better incentives than do bankers (see Gertner and Scharfstein, this volume). In any case, multiproduct firms may be efficient.

We might note that industrial organization economics provides some other potential advantages to a multiproduct firm, but again Teece's arguments about the role of contracting apply. For example, static Nash behavior between providers of substitutes (or complements) will lead to prices that do not maximize total joint profits. Bringing the two firms under common control would then be profitable. But if the firms can contract over the prices they will charge, this alternative might be at least as effective as merger. Similarly for situations of multimarket contact: two multiproduct firms might coordinate better than two pairs of standalone enterprises, but again, contract may be an alternative.

What is missing from Teece's (1982) theory is an analysis of the limits of the multiproduct firm. He starts from an existing firm with excess assets, which enters new businesses presumably until it runs out of spare resources. But many multiproduct firms grow by acquisition. Perhaps this behavior is a matter of buying assets to use with other assets already inside the firm that are in excess supply and are not easily transferrable. This story was one given for conglomerate mergers: the managers of the conglomerates were supposedly better than those outside the firm and had the capacity to manage more assets better than outsiders could. Ultimately, however, there must be some cost to adding new businesses inside a single firm. Otherwise, we face a version of Williamson's selective intervention problem (Williamson 1985). If the managers of a multiproduct firm can mimic the market when that is appropriate, but manage internally assets that cannot be transferred efficiently through contract, then there is no limit to the scope of the firm.

4.1.2. Limits on the Scope of the Firm

Williamson (1985) presented a variety of arguments against the possibility of a comprehensive policy of selective intervention that would limit the size of firms. In the case where an owner-managed firm is being absorbed, the primary one is the difficulty or inadvisability (for multitasking reasons) of committing to marketlike incentives. If two organizations where ownership and management are already separated are being brought together, he focuses on the costs of bureaucracy, including an excessive propensity to manage, excessive forgiveness, and log-rolling, all of which might be more extensive in a merged organization.

Milgrom and Roberts (1988a) identified another potential cost of having decisions made inside an organization: the affected parties would have strong incentives to try to influence the decisionmaker in ways that would not be possible if the decision were made in another organization to which both parties did not belong. These influence activities could be expected to be greater as the range of decisions being taken and the number of interested parties increase, so they would increase with the size and possibly with the complexity of the organization. These activities can be costly in a variety of ways: resources are expended on them, decisions may

be affected by them in ways that do not promote efficiency, and organizational processes may be twisted to reduce the extent of influence activities (see Gibbons et al., this volume). These influence costs could then put a limit on the (horizontal) scope of the firm.

Meyer et al. (1992) then developed an explicit influence cost-based argument concerning horizontal scope as an explanation of the trend in the 1980s for multiproduct firms to shed businesses that had become poor performers, even if their weakness was public knowledge, so they could not fetch a high price. They argued that divisions that had fallen on hard times would be especially likely to exert influence in attempts to grab corporate resources to keep themselves going, to the detriment of overall efficiency. If separation into distinct companies limited or prevented this influence activity, this would give a reason for spinoffs or sale of such weak units. (For further discussion of these issues, see Gertler and Scharfstein, this volume.)

Although such arguments as those adduced by Williamson (1985) and by Milgrom and Roberts (1988a) for the cost of integration may eminently plausible, it would be more theoretically appealing if the costs and benefits of integration were to emerge in a single model. In a recent contribution, Friebe and Raith (2010) offer such a theory of the multiproduct firm. Like that of Teece (1982), their approach rests on difficulties of contracting, but it has a much more organizational flavor.

4.1.3. *Friebe and Raith on the Multiproduct Firm*

Friebe and Raith (2010) modeled the choice between having two separately owned firms (each run by a manager, who contracts with the unit's owner) and a consolidated firm (where the two managers are still in charge of their divisions and there is also a central owner and/or CEO who contracts with the two managers). The advantage of the multiproduct firm is that it can potentially allocate resources better than the separate firms can.

Specifically, contracting problems are assumed to prevent transferring assets between separate companies, but the bringing the assets under common ownership eliminates the need for contracting over them. The CEO can then allocate the resources as seems fit, leaving them in the divisions where they were initially lodged or moving one unit's resources into the other.

The costs of consolidation are informational and incentive ones. First, the manager of each unit can exert costly, unobservable effort to increase the value of resources used in that unit. To motivate this effort, managerial compensation, even in the standalone context, should be tied to the performance of the manager's unit. In fact, bringing the two firms under common management partially alleviates this moral hazard problem, because the possibility of resources being transferred increases the returns to effort more than the threat of losing resources decreases effort incentives. However, some own-performance pay is still needed.

Second, the consolidated firm faces another problem. Specifically, the value of using resources in each division is private information to the unit's manager. Thus, the managers need to be induced to provide accurate information to headquarters to allow efficient reallocation between the divisions of the merged firm. But now the own-unit performance pay creates problems. In particular, the managers must get some nonnegative return when admitting that the value of resources in their units are low rather than claiming the value is high and that they should be receiving resources, not giving them up. If the managers' pay were independent of their units' performance, they would presumably be willing to report truthfully. With the performance pay, however, the incentives are to hang on to resources. The performance pay generates an

endogenous incentive for empire building, because having more resources helps generate better returns and rewards. To offset this and generate incentives for correct revelation, rewards must also be linked to overall firm performance (or, equivalently, the performance of the other unit). Doing so raises the cost of providing incentives. These problems are avoided if the firms are distinct and each unit's resources are certain to be used there. Thus, the gain in the efficiency of capital allocation comes at organizational costs of misaligned incentives for effort and truthful communication.

Depending on the magnitudes of these incentive costs and of the benefits of reallocation, either single or multiproduct firms may be better. In particular, if the difference in the productivity of resources between high- and low-value uses is increased, then the gains to reallocation are greater. This situation favors bringing the units under common direction. Also, if the economies of scale in the use of resources increase, common management is favored for similar reasons. This might be the case if the two units are more similar in their production processes, so that their resources are more likely to be complementary. Further, stepping outside the formal model, if the managers can be held accountable for their reports, then the multiproduct solution is favored, because the cost of inducing correct revelation falls. Such accountability might be possible in a repeated framework corresponding to an ongoing venture.

4.1.4. *Other Approaches*

The possibility of transferring resources more effectively presents one clear motive for multiproduct firms, but surely not the only one. For example, if there are economies of scope in marketing, then product line extensions would seem attractive. If the salespersons are employees of the firm for multitasking incentive reasons (Anderson and Schmittlein 1984; Holmström and Milgrom 1991), then the line extension must be done inside a single firm. The countervailing costs might be the diminishing returns to more finely segmenting markets. More generally, formal models building on the difficulty of contracting to share assets (versus reallocating them) would be potentially interesting, with knowledge sharing being a particularly obvious candidate.

There is a huge literature, largely in finance, that studies mergers and acquisitions, a major mechanism through which multiproduct firms are created and expanded. It seeks to understand whether mergers create or destroy value (as they would if driven by executives' enjoying private benefits from having larger empires), when they occur, and what the characteristics of the targets and acquirers are. This literature is too large to address here. For a recent paper with extensive references, see Basu (2010).

4.1.5. *Multinationals*

The particular case of the multinationals as multiproduct firms has received separate attention from the scholarly communities in international trade, economic geography, and international business. The first issue here is why firms become multinationals, that is, make foreign direct investments by acquiring or establishing facilities and subsidiaries in other countries. The existence of foreign markets for the firms' products is not enough, as there are options of exporting (perhaps using a local distributor for sales and service) and of licensing a foreign affiliate. The literature here, growing out of the work of Dunning (1977) and ably surveyed by Markusen (1995), focuses on shared excess resources, mostly knowledge, originally held in the home country, and on the difficulties of contracting on the transfer and use of knowledge. These factors

lead firms to establish their own production facilities in foreign markets. Formal models of such “horizontal internationalization,” wherein firms produce goods in different locations to be sold either locally or exported, begin with Helpman (1984) and Markusen (1984). The issue of vertical internationalization, with firms establishing plants in foreign countries to supply inputs, is a different matter that takes us too far from the chapter’s subject of strategy and organization.

The second issue with multinationals is their internal organization. Again, the literature on this subject is largely separate from organizational economics but is relevant to its concerns. We now turn to this topic.

4.2. Structuring the Multiproduct Firm

The literature considers two broad questions about how to organize a multiproduct firm. First, how should activities be grouped for purposes of coordination and motivation? This issue was first addressed by Chandler (1962), who described the replacement of functional organizational designs by multidivisional architectures. More recent work has examined when each of these may be optimal and when even more complex designs may be best. We examine this topic in this section. The second issue is, where should the authority to make various decisions be lodged? In the context of centralization versus decentralization, this question goes back for decades, but there has been recent work of substantial note explicitly in the context of a multibusiness firm. This is the subject matter of Section 4.3.

When modern corporations first emerged in the nineteenth century, they were organized functionally (Chandler 1962). All manufacturing activities were grouped together and reported to a head of manufacturing, who in turn reported to the CEO; similarly for sales, marketing, procurement, engineering, and so on. Williamson (1975) dubbed this the unitary or U-form organization.

Beginning in the early years of the twentieth century companies developed and adopted the multidivisional or M-form of organization (Chandler 1962). In this model, “business units” are established that, in the first instance, offer a particular product. The business units take fundamental responsibility for all activities directly necessary to bring their products to market (later versions of the model have had business units defined by customer segments, technologies, geographies, and probably other criteria). Thus, each business unit handled its own product development, engineering, procurement, manufacturing, marketing, sales, and service. Meanwhile, finance, accounting, legal, and possibly other support services stayed under the control of headquarters, as well as the definition of the scope of the individual businesses, the establishment of strategic direction, and monitoring of division performance.¹⁸ The prototypical example is General Motors under Alfred P. Sloan. Each of the divisions—Chevrolet, Pontiac, Oldsmobile, Buick, and Cadillac—had its assigned target market, was to avoid competing with its brethren, and was measured on its performance, much as if it were a standalone company. The divisions developed, manufactured, and sold their own models within these mandates, while headquarters allocated capital, monitored performance, and set strategy, avoiding involvement

18. Earlier there were also holding companies that owned several distinct businesses (each arranged functionally), but the headquarters of a holding company played a very limited role relative to the role it played in the M-form.

in operating details. This organizational design ultimately spread across American industry and then to Europe and Asia, eventually becoming the dominant form for large, complex firms around the world.

4.2.1. *U-Form versus M-Form*

Chandler (1962) and Williamson (1975, 1985) both discussed the U-form and M-form as alternatives. Chandler argued on the basis of historical observation, to which Williamson added transaction cost insights, that it was increasing size and complexity in multiproduct, multilocal firms that rendered the U-form incapable of coordinating effectively at reasonable cost. With only the CEO having authority and responsibilities across functions, the top became overloaded. At the same time, the need for coordination across what were to be the divisions meant that a holding company, with a headquarters that took only the most minimal role, was also inadequate. Structure then followed strategy: the more ambitious strategies required a new organizational design.

The relative attractions of the U-form versus the M-form were first modeled by operations researchers in the 1980s. A notable example is Malone and Smith (1988), who considered a model of the production of m products, each of which requires that a common set of tasks be undertaken. Product orders arrive randomly and must be assigned to workers who are capable of handling the necessary tasks. Among the several organizational alternatives considered by Malone and Smith are (1) a product-based hierarchy in which the m product managers (who decide on the tasks to be undertaken) directly assign workers who are under their individual commands to the tasks and (2) a functional hierarchy in which all workers capable of carrying out a task report to a functional manager, with the functional managers being told what tasks need doing by a top-level product manager (the CEO). The analysis, based on queuing theory, evaluated the design options on the length of the average queue, the amount of communication necessary for coordination, and the costs of disruption when a worker is unavailable. The model suggested that if production became more efficient and coordination more costly, then the product hierarchy would be favored, because it involved lower communication costs. The authors suggested this as an explanation for the shift from U-form to M-form.

Aghion and Tirole (1995) developed the first formal model in economics of U-form versus M-form and the first to adduce incentive reasons as a key element in the choice. The authors built a model of how overload at the center leads to the choice of the M-form that is based on their well-known model of real versus formal authority (Aghion and Tirole 1997).¹⁹ There are two products, production of each of which requires the carrying out of two different activities (say, manufacturing and sales). Each agent can perform two tasks. Thus, the principal hires two agents and assigns each to two specific tasks. The U-form has each agent performing one activity (sales or manufacturing) twice, once for each product, and the M-form has each agent perform both of the two activities associated with one of the products.

Performing each activity involves a search over a number of alternatives to determine the unique best way to undertake the specific activity. Search involves effort, and both the principal and the agents can exert effort to increase the probability of learning the values of all alternatives and thus determine which is best. The agents' efforts are not observable, and incentive pay

19. This model is discussed in detail in several chapters, including Bolton and Dewatripont (this volume).

is ruled out. Instead, the agents are motivated to provide effort by career concerns related to potential outside employers' inferring their search abilities. The cost to the principal of exerting effort E is $g(E, k)$, where k is a parameter affecting the marginal cost of effort, with $\partial g / \partial E > 0$ and $\partial^2 g / \partial E \partial k > 0$. There is also a cost for training the agents that is assumed to be strictly lower for the U-form, because each agent must learn how to undertake only one activity.

If the principal is successful in determining the best alternative for all four activities (which occurs with probability E), she will produce both products (she has formal authority in terms of Aghion and Tirole 1997). In this case the market learns nothing of the agents' abilities. If the principal is completely uninformed (which occurs with probability $1 - E$), then she may rely on the agents' possibly being informed and suggesting the way to do things. The payoffs to different alternatives are such that it is worthwhile to produce a product only if the best way to do each of the two associated activities has been found. In the M-form, if either agent learns the best ways to carry out both his responsibilities, then the corresponding product will be produced and the market will raise its beliefs about the agent's abilities. Failure to produce a particular product is thus bad news about the corresponding agent's ability. However, failure to produce a product in the U-form can occur because either agent failed to find the best way to carry out his activity associated with that product. Thus, failure to produce is not as bad news about either agent as it is under the M-form, and so the implied incentives are weaker. From this logic, it follows that the agents in equilibrium will work harder in the M-form for any given E .

Aghion and Tirole (1995) placed assumptions on the curvature of the agents' effort-cost functions and on the payoff increase for the agents in the U-form from two goods being produced rather than one. They then showed that as the parameter of the principal's cost function k rises, increasing the marginal cost of E (which is meant to model the principal becoming overloaded), it becomes more valuable to induce more effort from the agents. This situation favors the M-form. Then, for any specific advantage in training costs (scale economies) that the U-form enjoys, there is a cut-off k^* beyond which the M-form is preferred.

This Aghion-Tirole model is a sensible rendering of the overloaded hypothesis, but (as the authors note) the main conclusion is not very robust to variations in the modeling. Further, the reputation mechanism and wage setting mechanism are not modeled, so the assumption on the relative returns to having two products produced rather than one is ad hoc. In addition, one would want to allow for incentive contracts. Still, this model is a valuable first step that deserves to be better known.

Rotemberg (1999) offered a different take on the issue. In his model, the U-form has an advantage in control: the functional manager, observing more people doing a given job, can more effectively determine the best way to do that job (of which the workers have private knowledge) and require that it be adopted. The M-form has better coordination across functions within a division (in fact, by assumption, within-division coordination is perfect). Rotemberg showed that making compensation more dependent on division performance in the M-form can overcome some of the incentive problems, making workers more willing to reveal their private information. Still, despite the superiority of the M-form at coordination, the U-form can be superior if the importance of getting things done the right way is great enough. However, as the number of employees increases, the M-form ultimately becomes superior, as solving the coordination problem becomes more important.

Maskin et al. (2000) built a model of M-form versus U-form in which different organizational designs generate different information that affects the incentives that can be provided to middle managers. Thus, this approach does not link very directly to the size-complexity-coordination arguments on which earlier modelings were based. The M-form is modeled as a two-function, two-product, three-level hierarchy with a top executive and two mid-level executives, each of whom is responsible for one product and has two frontline functional people reporting to her, one from each function. In the U-form, the managers in the middle have functional responsibilities, and each has two frontline reports, one involved with each product. Each of the various agents can exert nonobservable effort and has a separable utility function over income and the cost of effort. The output of any frontline worker is simply the sum of the unobservable efforts across the three levels plus random noise attached to each effort:

$$y_{ij} = e + \eta + e_i + \delta_i + e_j + \theta_j,$$

where $i = 1, 2$ denotes the function, and $j = A, B$ denotes the product.

Maskin et al. (2000) showed that the provision of incentives at the top and bottom of the hierarchy is unaffected by the choice of U-form or M-form. However, the problem of motivating the middle manager does depend on the architecture. Specifically, the M-form involves relative performance evaluation between the two business unit managers, whereas the U-form has relative performance evaluation between the two functional managers. Which is better depends on how effective this relative performance evaluation is in each case, which is a matter of the amount of residual noise in the performance measures left after the comparison. If it is more effective to compare two division managers than to compare across functions, the M-form is favored. The authors suggested that this might reasonably seem be the case: comparing two product managers is likely more informative than comparing the head of manufacturing's performance to that of the head of marketing (because the corresponding noise terms are more correlated in the former case). This observation does not, however, offer much insight into why the M-form has historically become more important and the U-form less so.

Other approaches to the issue of M-form versus U-form include that of Besanko et al. (2000), who assumed that the M-form permits more effective performance pay but argue that the U-form may be superior if it is sufficiently important to manage cross-product spillovers within functions and there is enough asymmetry in the system. Another approach is that of Qian et al. (2006), who examined how the organizational structure affects the information available for coordination and thus the effectiveness of different sorts of experimentation and innovation.

4.2.2. *Matrix Structures*

In recent years firms have developed more complex organizational models. A major innovation is the matrix form. In it, at least two dimensions into which the business can be divided are identified. The most frequent are geography and product. Then a particular business in a particular region reports both to a manager with responsibility for that product across geographies and also to a manager responsible for that geography across products. A prime instance is one of the most-studied examples of matrix organization, ABB (Asea Brown Boveri) in the late 1980s and early 1990s (Bartlett 1999). ABB was in a broad range of businesses, from railroad engines to electrical transformers and factory automation equipment, and it operated in

most European countries and later also in the Americas and Asia. Its organization design had a global product manager for each of its dozens of product areas (e.g., high-voltage transformers or steam turbines) as well as a country head for each of the countries or regions in which it operated. Then each product area in each geographic area was set up as a separate company, with its own balance sheet and income statement, and the president of that company reported to both the country head and the product manager. The latter was charged with coordinating across countries, determining where investments would be made, and which countries would handle exports to countries without their own manufacturing capabilities. The country head had responsibility for coordinating across businesses in the country, particularly with regard to human resources, labor relations, and governmental affairs, as well as for profit and loss in the country. Both managers were involved in setting performance standards and carrying out performance evaluations for the company presidents. Other multinationals, including Citibank, have had even more complex matrices, involving three or more dimensions.

The importance of these more complex forms is suggested by the recent work of Guadalupe et al. (2012). They examined the changes in the titles (and pay) of the executives who reported directly to the CEO in a sample of U.S. firms. They found a doubling of the number of direct reports from 1986 to 2006, but crucially, much of the growth was from central functional managers being brought into the top executive team, rather than general managers of business units. Presumably, the functional managers were charged with coordination across the companies' businesses on a functional basis. Yet business managers remained an important class of direct reports. This trend certainly suggests strongly that large U.S. firms are moving away from the pure U-form and M-form.

The first attempts to explore formally the relative merits of the matrix form of organization versus a simple product structure or a geographic structure are due to Baron and Besanko (1996, 2001). They considered a firm selling P different products in G geographic areas. Demand for good i in geography j is a linear function of the quantity of the good and of the total amounts of other goods sold by the company in the region and of this good sold in other regions. Similarly, the marginal cost of each good in each region depends on its quantity and the sum of the quantities of other goods sold in the region and the total amount of this good sold in other regions.

Each product in each region has an associated frontline manager. There is also potentially a manager for each region, overseeing all products in the region, and a manager for each product overseeing all regions. Finally, there is a top manager. The top manager designs the organization—which comes down to determining how much influence each middle manager will have over the pay of the frontline managers—and instructs the two middle managers to design bonus contracts for the front line to coordinate the spillovers in the dimension for which that manager is responsible. The payoff to the frontline manager is then a weighted average of the bonuses offered by the two middle managers. The design solution depends on how the spillovers interact.

If all markets are symmetric, a matrix is optimal if coordinating the geographic spillovers requires changing outputs in the opposite direction to that required to coordinate the product spillovers. In this case, both the product and geography managers have a positive influence on the frontline managers' pay. An example would be where there are economies of scale for a particular product, calling for increased production in each individual geography beyond what would

otherwise be produced, and competition within a product across geographies (perhaps from customers going to other regions to buy), which calls for reducing output in each geography. In contrast, if the spillovers work in the same direction, then either a pure product or a pure geographic organization is optimal (one or the other middle manager's weight in determining the local manager's pay is zero). Which one should prevail depends on the strength of the two types of spillovers. In particular, the simultaneous existence of both scale and scope economies, which is often suggested as a basis for multinational, multiproduct strategies, is inconsistent with a matrix organization being optimal. Baron and Besanko (1996, 2001) also examined the effect of asymmetries across markets and of local or global competition.

Harris and Raviv (2002) offered another approach to the issue of matrix organization based on coordination along different dimensions rather than the incentive issues that drive the Baron-Besanko model. Coordination of spillovers across activities requires managerial expertise, which is costly. The trade-off is then between the costs of coordination and its benefits. Different organizational designs permit more or less coordination but involve different demands on management.

Reinterpreting the Harris-Raviv setup in terms of the Baron-Besanko formulation, consider a firm that offers two physical products $i = 1, 2$ in two geographic markets $j = A, B$. Product i in market j , denoted P_{ij} , is produced by a local manager. There are four potential bilateral interactions across pairs of markets and products: between P_{iA} and P_{iB} , $i = 1, 2$, each of which occurs with probability p , and between P_{1j} and P_{2j} , $j = A, B$, each of which occurs with probability r . All the random variables are independent. Finding and coordinating a pairwise interaction brings a benefit of 1. Additionally, if all four pairwise interactions are present, there is also an additional benefit of s to coordinating across all four pairs.

The organization consists of a CEO, who is capable of coordinating any interactions and is uniquely able to coordinate across all four pairs, plus zero, two, or four middle managers, each of whom can coordinate a single pairwise interaction. The middle managers each cost F , and the CEO's expenditure of time on coordination has an opportunity cost $Q < s$ to the firm. If there are no middle managers, the local managers report directly to the CEO, who may or may not attempt coordination. This flat organization is called "centralized" if coordination is attempted and "decentralized" if it is not. With two middle managers there can be either a product organization, with one manager coordinating P_{1A} and P_{1B} and the other handling interactions of product 2 across the two markets, or a geographic organization, with one manager coordinating across products in region A and the other handling region B. In either of these cases the CEO may or may not coordinate the interactions not covered by the middle managers and the companywide interaction. These hierarchies are accordingly labeled "centralized" or "decentralized." Finally, with four middle managers we have a matrix structure, with each pairwise interaction handled by a middle manager and, because $s > Q$, the CEO coordinating the companywide interactions if the four managers have each discovered a pairwise interaction.

The authors determined the optimal structure as a function of the costs F of middle managers and the opportunity cost Q of involving the CEO. For high values of F , the flat structure without middle managers is used, and whether the CEO attempts to coordinate depends on how large Q is. For low values of F , a matrix is favored, with the upper boundary of the set of parameters leading to a matrix form being a convex piecewise linear set. It is also possible to have

the two hierarchical forms with the CEO involved in coordination, and also the decentralized hierarchy involving middle managers coordinating the more likely interaction (i.e., a product organization if $p > r$).

The Baron-Besanko model is all about incentives and Harris-Raviv ignores them entirely to focus on coordination via managerial expertise and costs. It seems likely that both effects are in fact at work, and a model of matrix organization that encompassed both would seem a natural next step. Drawing on the literature on common agency (Bernheim and Whinston 1986) would seem an obvious step.

4.2.3. Other Forms

Beyond the basic U-form, M-form, and matrix structures, firms are adopting other designs that would seem worthy of formal modeling. For example, Bartlett and Ghoshal (1998) describe an organizational design for multinational corporations that they call the “transnational model.” It involves a significant amount of delegation to national business units (to facilitate adaptation to local conditions), differentiated assignments to different local business units and coordination across them (to achieve economies of scale), extensive horizontal communication among business units, and a managerial center that sets broad strategy and coordinates and allocates resources across units. They contrast this model with two earlier ones. In one, decision authority and most activity was highly centralized and standardized with the aim to maximize global efficiency through economies of scale. This model was exemplified by Japanese multinational corporations, such as Matsushita and Toyota in the 1970s. The other involved extreme decentralization to national business units in search of effective adaptation to local conditions. This model was common among European multinational corporations, such as Philips and Unilever, after World War II. The first example of the transnational identified by Bartlett and Ghoshal was ABB in the 1980s (see Section 4.2.2), although other examples are now available.

One such is Tenaris, the leading manufacturer of high-quality seamless steel pipes and tubing globally. As described in Catalano and Roberts (2004), Tenaris has an elaborate “front-and-back” model involving production units—factories as organizational units—in various countries; geographically defined sales units for the countries in which it has production facilities; global, customer-defined sales units; several administrative functions that are managed globally; a global procurement operation; and a “supply chain” unit that manages the allocation of production among factories and the fulfillment of orders. This remarkably complex design was the result of explicit planning, not accretion or uncoordinated variation, although the geographic dispersal of production resulted from acquisitions. It was meant to provide responsiveness to local market conditions, efficiency across markets, and a high level of coordination.

4.3. The Optimal Locus of Decisionmaking in Complex Organizations

There is a large literature on the allocation of authority over decisions between hierarchical superiors and lower levels, much of which is discussed in other chapters in this volume (see Bolton and Dewatripont; Garicano and Van Zandt; Gibbons et al.; Mookherjee, all in this volume). Here we limit consideration to analyses that focus on the particular context of multibusiness firms.

4.3.1. *A First Pass at the Problem*

Athey and Roberts (2001) offered one of the first formal investigations of the interactions among businesses within a multiproduct firm and how these might affect organizational design. Their analysis is incomplete but quite suggestive.

They considered a firm with two divisions.²⁰ Each is headed by a manager, who must exert unobservable effort to create value in his individual division plus make a decision, about which he is privately informed, that may have noisy effects on the performance of both units. Crucially, contracting is constrained by there being only a single (noisy) performance measure for each manager ("unit profit"), and this measure confounds the effects of that manager's effort and the two managers' decisions. Athey and Roberts noted that if the decisions had no performance effects, then the optimal pay scheme would have each manager's pay depend heavily on own-performance and, if the noise in the performance measures is positively correlated, would also have each manager's pay depend negatively on the other's performance (relative performance evaluation). In contrast, if effort is not productive (or can be observed), then the pay system should simply focus on making the managers internalize the externalities in their decisions. This approach would tend to make pay depend positively on both performance measures if there are spillovers. There is thus a conflict: good incentives for effort create very bad incentives for decisions, and good incentives for decisions are bad ones for effort.

For the more general case, where both effort and decisions matter, Athey and Roberts (2001) argued that a number of organizational adaptations may be desirable in different contexts. In particular, they suggested that it may be desirable to centralize decisions, either with one of the managers or with a third agent who does not need to exert effort and so can be straightforwardly motivated to make good decisions. Athey and Roberts assumed in this context that the managers' information about the decisions can be made verifiable at a cost. In particular, they did not model the process of communication that would need to occur if the managers' decision-relevant information cannot be communicated verifiably. These issues are picked up in later work.

4.3.2. *The Alonso-Dessein-Matouschek and Rantakari Model*

Among the first papers to model strategic communication in the context of allocating decision authority are Alonso et al. (2008) and Rantakari (2008). These both considered models of whether decisions in two businesses should be centralized with a single decisionmaker in light of two factors: (1) a need to coordinate decisions between the two units because of externalities and (2) a need to adapt the individual decisions to local conditions that are specific to that business. Informational constraints that limit communication possibilities and differing interests between the two units together create incentive problems. The optimal organization solves the problem of maximizing total profits across the two units.

4.3.2.1. The Symmetric Case. For simplicity, we initially focus on the Alonso et al. (2008) version, which examines only a symmetric case, as opposed to Rantakari's (2008) richer model that explicitly allows for some asymmetries across units and considers a richer set of organi-

20. Athey and Roberts (2001) did not explain why the divisions are within a single firm, although the externalities they assume between divisions might provide a basis for an explanation.

zational designs. We return to the Rantakari version later to examine some further alternative organizational structures that can arise there.

Even for the simpler case, the analysis is complicated. Alonso et al. (2008) considered a model with two businesses, each led by a manager, whose payoffs v_i , $i = 1, 2$, depend on both the fit of their individual decisions d_1 and d_2 to local conditions (independent random variables θ_1 and θ_2) and the fit of the two decisions with each other:

$$v_i(d_i, d_j) = -(d_i - \theta_i)^2 - \delta(d_i - d_j)^2.$$

Here δ measures the relative importance of coordinating the two decisions as opposed to responding to local conditions. The payoffs of manager i are exogenously fixed at $\lambda v_i + (1 - \lambda)v_j$, where $0.5 \leq \lambda \leq 1$. Here $(1 - \lambda)$ measures the extent to which the manager cares about the other unit.

The issue Alonso et al. (2008) addressed is when it is best to decentralize and let the two managers make the decisions on their own and when the decisions should be centralized with a third agent (headquarters), whose payoff is simply the sum of the two managers' payoffs, $v_1 + v_2$. In either case, they allow for communication: between the managers when the decisions are decentralized to them, so they can coordinate their choices, or between the individual managers and headquarters, to inform the central decision. In both cases, the communication is cheap talk (Crawford and Sobel 1982): manager i can claim any value m_i for θ_i in $[-s_i, s_i]$, the interval over which θ_i is uniformly distributed, because neither the other manager nor headquarters can observe θ_i , although the distributions are common knowledge. There are no contracts allowed over the decisions or communication protocols. All that can be chosen is who will have decision rights, and once this is set (which is before the managers learn their private local information), these rights cannot be changed.

Although the interactions are relatively complex, the final performance under either structure is determined by the quality of the final decisions, which in turn depend on (1) the amount of information made available to the decisionmaker regarding the local conditions and (2) biases, if any, in the actual use of that information. These factors differ across the two structures.

The analysis proceeds in several steps. First, the decisions that result from any given set of beliefs about the θ_i values are derived. In the centralized case, these values are the ones that maximize the expected value of the headquarters' payoffs. The decision d_i turns out to be a weighted average of the expected values of θ_i and θ_j conditional on the messages received. The weighting on θ_j in determining d_i is 0 if δ is 0, when no coordination is required, so d_i is just the expected value of θ_i conditional on the message m_i . As δ goes to infinity, the weighting converges to 1/2, so each d_i is just the expected value of $\theta_1 + \theta_2$, conditional on m_1 and m_2 .

In the decentralized case, the decisions are the Bayesian Nash equilibrium choices by the two managers, given the beliefs they hold after communicating with each other and knowing their own θ_i values. Manager 1's decision is a convex combination of his local conditions θ_1 , his posterior belief about θ_2 , and Manager 2's posterior belief about θ_1 . The weighting depends both on λ and δ . As δ increases, each manager puts less weight on his private information and more weight on a weighted average of the posterior beliefs. As δ goes to infinity, the division managers rely only on the communicated information and set $d_1 = d_2 = E(\theta_1 + \theta_2 \mid m_1, m_2)$. Note that,

for given posteriors, these are exactly the same decisions that headquarters implements as δ goes to infinity.

The next step is to determine the communication strategies. Each player has an incentive to exaggerate his private information, with $m_i/\theta_i > 1$ as long as $\theta_i \neq 0$. This is because both the headquarters (in the centralized case) and the other manager (in the decentralized case) have incentives to take decisions that are smaller in magnitude than the given manager would like. From the point of view of manager i , the headquarters puts more weight on coordinating d_i and d_j (instead of adapting d_i to θ_i) than i wants. Because $E(\theta_j) = 0$, if i were to report correctly, then the headquarters' tendency would be to make decisions that are smaller in magnitude than i wants. So manager i exaggerates. When decisionmaking is decentralized, manager j puts more weight on adapting d_j to θ_j rather than coordinating the decisions than manager i wants, and again i is led to exaggerate. Thus, the incentives for misrepresentation are qualitatively similar in both cases. However, under centralization, manager i 's incentive to exaggerate is increasing in the own-division bias and in the need for coordination, whereas under decentralization, manager i 's incentive to exaggerate is increasing in his own-division bias but decreasing in the need for coordination.

In equilibrium, the private information is not completely revealed. Instead, equilibrium communication is characterized by a collection of intervals in (θ_1, θ_2) space in which the information lies, with a given value of the private information θ_i leading to an announcement that it lies in a certain interval. These intervals become smaller with decreases in the magnitude of the value of the sender's private information, with $m_i = \theta_i$ if $\theta_i = 0$. There are multiple equilibria, indexed by the number of intervals. The most efficient one obtains as the number of intervals grows without bound.

In this most efficient equilibrium, the difference in the quality of information transmission under the two decisionmaking regimes (as measured by the difference of the inverse of the residual variance of θ after communication has occurred under decentralization versus centralization) is decreasing in the own-bias λ and increasing in the need for coordination δ . If $\lambda = 1/2$, then the two regimes are equally effective, as they are as δ goes to infinity. For $\lambda > 1/2$, the centralized regime has better decisionmaking, because an increase in the own-division bias λ has a more detrimental effect on horizontal than on vertical communication. This difference arises because, under centralization, an increase in λ increases the bias of the senders but does not affect the decisionmaking of the receiver. In contrast, under decentralization, an increase in λ also leads to more biased decisionmaking by the receiver. Meanwhile, for any value of the bias, centralized decisionmaking performs better than decentralized, but the two coincide in the limit.

The difference in the precision of communication in the two regimes is essentially driven by the qualitatively different purpose of communication in each. Under centralization the managers communicate to headquarters to induce it to adapt the decisions to their local needs, whereas under decentralization the managers naturally know their local needs but need to communicate with each other to achieve better coordination between the decisions.

The expected profits are now determined through the interplay of the incentives governing the decisions and the quality of the communication. Alonso et al. (2008) showed that the performance of the centralized regime compared to the decentralized one can be written as the difference in performance due to worse adaptation to the local conditions under the centralized

regime plus 2δ times the performance advantage due to better coordination that the centralized regime enjoys.

The simple intuition is that decentralization always achieves better adaptation, because the information needed for adaptation is directly available to the division managers, whereas some of it is lost when transmitted to headquarters. Meanwhile, coordination will be better under centralization. By being in control of the decisions, headquarters always achieves the right level of coordination. In contrast, imprecise communication between the division managers under decentralization leads to some coordination failures. Further, these effects are amplified by the own-division biases of the division managers, making their decisions inherently excessively adaptive at the expense of coordination, even given perfect information.

The expression for the relative efficiency turns out to be highly nonlinear in the parameters λ and δ . If $\lambda = 1/2$, so the managers are not biased toward their own profitability, then the two regimes perform equally well. The same is true if coordination does not matter ($\delta = 0$) or, in the limit, if all that matters is coordination: $\delta \rightarrow \infty$. However, because of the complex interplay of the effects on communication and on decisionmaking, the effects of increasing the importance of either adaptation or coordination are not monotonic. For positive values of λ that are close enough to $1/2$ (very small bias), decentralization is superior for any δ . This is because the quality of information utilization is good (and similar) under either regime, and so the collocation of information and decisionmaking under decentralization is definitive. Thus, great need for coordination does not necessarily lead to centralization if the individual manager's incentives are good. Similarly, decentralization is superior for any positive λ if the value of coordination is small enough. Essentially, even when the need for coordination is very small, communication is noisy under both structures. Under centralization this noise affects the ability of headquarters to adapt the decisions to the local conditions, whereas under decentralization it affects the ability of the division managers to coordinate their actions. Because for small δ coordination is much less important than adaptation, the centralized structure suffers more from imperfect communication than the decentralized one does. Thus, strong bias is not a problem if the need for coordination is small.

However, for higher values of each variable, centralization can be best. If the division managers are very biased, vertical communication is much more efficient than horizontal. In addition, because increases in own-division biases distort decisionmaking by the division managers but not by headquarters, decisionmaking under centralization is significantly more efficient than decisionmaking under decentralization when the bias is large. Because of these two factors, centralization outperforms decentralization when the division managers are very biased and coordination is important.

This model indicates that the organizational design problem in the multiproduct firm involves extremely complicated trade-offs. Still, Alonso et al. (2008) suggested that their results are consistent with two classic cases of organizational change in multiproduct firms instigated in response to strategic change, namely, General Motors in the 1920s under Alfred Sloan and British Petroleum's Exploration and Production stream in the 1990s under John Browne. In both cases, an increase in the need for coordination led to the creation of mechanisms to facilitate horizontal communication and a rebalancing of incentives toward group versus individual incentives.

4.3.2.2. Allowing for Asymmetries. Rantakari's (2008) model is very similar to that of Alonso et al. (2008), except the unit i 's payoffs are

$$\Pi_i = -k_i((1 - r_i)(\theta_i - d_i)^2 + r_i(d_j - d_i)^2),$$

so the two units may differ. Here, r_i measures the relative importance of coordination to division i . It is called the "dependency" of i . The parameter k_i measures the overall importance of decisionmaking to unit i and is related to its size. In parallel with Alonso et al. (2008), the θ_i are independently distributed over $[-s_i, s_i]$, where s_i measures the environmental volatility faced by unit i . In contrast with Alonso et al., each manager is interested only in the profits of his own division (in terms of Alonso et al. [2008], $\lambda = 1$).

Rantakari (2008) investigated the two alternatives of centralization and decentralization studied by Alonso et al. (2008) but was also able to examine the effects of situations where the sizes of the units differ and, more centrally, where the importance of coordination differs between them. Generally, except for low values of both r_1 and r_2 , where coordination does not matter much, the decentralized regime does worse than the centralized one, because the latter coordinates better. He also studied two further organizational options that are of interest in the asymmetric case. One, partial decentralization, involves the center choosing d_i , while d_j is left to division j . The other, directional authority, involves subjugating one division to the other, with manager i making both decisions. Shifting the decision authority changes both the decision rules and the equilibrium communication, and each of these forms may be optimal. In particular, Rantakari provided two examples. One involves IBM's managing the PC business in the 1980s, where the partial decentralization model was initially employed, with the PC group allowed to have its head and the mainframe business controlled by the center. Later the PC business was centralized, too. The second involves Microsoft's belated refocusing on the Internet and the development of Internet Explorer. This new business was centralized initially, then brought into one of the main business units in an example of directional authority. In each case, the behavior is in line with the model's predictions.

4.3.2.3. Dynamics. A more recent paper by Rantakari (2012b) uses a version of this same basic model to look at the impact of environmental volatility on several aspects of organizational design: the allocation of decision rights to the managers or headquarters, managerial compensation contracts, managerial investments in learning their local conditions, and the extent of operational integration. The divisional payoff function now is

$$\Pi_i(\theta_i, d_i, d_j) = K(\beta) - \beta(d_i - d_j)^2 - \alpha(d_i - \theta_i),$$

where β is the measure of operational integration. The payoff increases in β through K , reflecting gains from standardization, but the need for coordination also increases with β . The importance of local adaptation is measured by α . Managers now are initially uninformed about their local conditions, but each can get a signal about his θ_i in $[-s, s]$, at a cost that is increasing in the accuracy of the signal. Also, the total profit can be distributed linearly between the two managers in any way. In particular, each might be paid on only his own division's performance, they could share total returns equally, or anything in between. The problem is to select the

degree of operational integration, whether the decisions are centralized or decentralized, and the compensation of the managers to maximize expected total returns.

The analysis proceeds in a similar fashion to Alonso et al. (2008) and Rantakari (2008), allowing for the extra choice variables. The key results are in how the solution responds to changes in the uncertainty or volatility in the environment, as measured by the length of the interval $[-s, s]$. In particular, Rantakari showed that an increase in volatility decreases the level of operational integration, decreases the use of firmwide incentives for a given governance structure, and increases the preference for decentralization. If the increase in volatility leads to decentralization, the use of firmwide incentives can increase. In addition, centralization arises as the preferred governance structure only when information is sufficiently costly relative to volatility and is always coupled with a significant level of operational integration and significant use of firmwide incentives.

This model is especially interesting in the context of multinationals. It shows that if the world is well understood and stable, the optimal organization will tend to be centralized in its decisionmaking, with a great deal of operational integration and many firmwide incentives. This specification corresponds to the model Bartlett and Ghoshal (1998) described that aimed at global efficiency through standardization and coordination. In contrast, if conditions in the two markets can differ significantly, then a model with decentralized decisionmaking by the local business units, less operational integration, and pay based more on individual unit performance is favored. This is the model Bartlett and Ghoshal described for trying to achieve high levels of local adaptation.

4.3.3. *Horizontal Boundaries of the Firm*

The analyses by Alonso et al. (2008) and by Rantakari (2008, 2012b) potentially provide the basis for alternatives to Teece's (1982) theory of the emergence of the multiproduct firm. Such theories would be driven by the effectiveness of communication and of decisionmaking within versus across firm boundaries. If there were only one firm, it could select the incentives for both division managers. If it makes pay depend only on total profits ($\lambda = 1/2$), then the firm would avoid any costs of misaligned incentives. Thus, a useful theory that would allow separate firms to be optimal (and one that would generate both decentralization and centralization in a multiproduct firm) would have to involve some mechanism that makes it valuable for pay to be biased toward own-division results. Inducing effort is an obvious possibility.

Almost by definition, having two separate firms involves the decentralization regime. However, one could imagine allowing the firms to communicate about their local circumstances and also to coordinate their pay systems if there is still value to coordinating decisions (but see Holmström 1999). To make the two-firm alternative interesting, there would again need to be some reason to keep them from agreeing on setting each λ to eliminate own-unit bias. An obvious option is whatever element in the theory prevents a single firm from simply setting $\lambda = 1/2$. In addition, it would be natural to assume that the firms' contracting over each other's actual pay might be problematic, and so only Nash equilibrium choices of pay systems might be possible.

A recent paper by Dessein et al. (2010) offers a related model that does provide an organizationally based theory of the multiproduct firm. They described their model as being concerned with the allocation of decision authority when there are benefits both to responsiveness to local variation in individual product markets in some dimensions or activities (e.g., marketing)

and also gains to standardization of other activities across markets (e.g., product designs). The choice is between having the two local managers handle both the marketing and design for their individual markets, in which case the opportunity for achieving gains to standardization is lost (these managers cannot coordinate with one another), or appointing a third manager to oversee the dimension on which standardization may be valuable. The former choice is called “nonintegration” and the latter “integration.”

Each manager must be motivated to supply unobservable effort, and they are risk averse, with exponential utility and quadratic costs for the effort applied to each activity. The gains to standardization (in terms of cost reduction) and its costs (in terms of lessened desirability of the product in the individual markets, resulting in lower revenues) are random. Initially these costs and benefits become public information once the organization design is fixed, but the authors also study the case in which they are private information to the manager concerned and so give rise to strategic communication.

Dessein et al. (2010) first computed the (second-best) effort contracts that prevail when the two divisions are not integrated. Each manager receives a fraction of any cost savings and revenue gains in that manager’s unit. If integration is attempted, then the manager charged with standardization determines the amount of effort to be put into cost reduction for each good, as well as whether to standardize. Paying this manager just for cost reductions, however, leads to excessive standardization, because the manager making the standardization decision does not bear the cost of the lost revenues. To offset this, the integration manager must also be paid on revenues. However, because the manager is risk averse, paying on revenues has a risk cost that leads to reducing the strength of cost incentives for this manager relative to the nonintegrated case.

Thus, there is an incentive cost to integration that may outweigh the potential gains of standardization. Having strategic communication about the costs and benefits of standardization increases the relative attractiveness of nonintegration.

Note that this model provides an alternative theory of the multiproduct firm if the gains from integration can be realized only by using a manager who needs to be motivated through pay.

5. Conclusion

We have examined the notions of business and corporate strategies and their connection to organization. Although an increasing amount of economic research, both theoretical and empirical, has addressed this subject in recent years, there is still much to do, and it is a fertile area for further work.

Vertical Integration and Market Structure

Timothy Bresnahan and Jonathan Levin

1. Introduction

Vertical integration occupies a central role in organizational economics. Williamson (2005) calls it the “paradigm” problem for explaining the distribution of firms and markets in modern economies. In this chapter, we review research on vertical integration decisions and their consequences, and offer some perspective on the current state of knowledge.¹

Our discussion bridges two very different literatures. Research in organizational economics generally treats vertical integration as an efficient response to contracting frictions. This approach is often associated with Coase (1937) and Williamson (1971). Research in industrial organization has taken a complementary approach, emphasizing patterns of integration at the market or industry level. Some of this work, following Stigler (1951), draws attention to scale and scope economies as rationales for integration, while other strands emphasize strategic motives and the idea that integration can be a tool for consolidating or extending market power.

Theoretical work in the first tradition argues that certain features of transactions create particular problems for arm’s-length contracting. These can include difficulty anticipating future contingencies, ambiguity in the nature of tasks and decisions to be carried out, the need to use specific assets, or an inability to measure and verify transaction outcomes. In Section 2, we describe some of the “building-block” models that link these types of transactional frictions to problems of hold-up, decisionmaking externalities, and incentive distortions, and offer explanations for when and why internal organization might lead to more efficient outcomes.

We thank the volume editors, Robert Gibbons and John Roberts, for helpful discussions and unusual patience, and the Ewing Marian Kauffman Foundation (Bresnahan) and the National Science Foundation (Levin) for their support.

1. Readers may also be interested in the surveys by Gibbons (2005), Joskow (2005), Klein (2005), Shelanski and Klein (1995), and Lafontaine and Slade (2007). Perry (1989) is an earlier survey of industrial organization research on vertical integration. Helpman (2006) and Antràs and Rossi-Hansberg (2009) review recent work on multinationals and cross-country integration decisions.

The ideas in these models have been the starting point for a long sequence of empirical studies dating back at least to Monteverde and Teece (1982), Masten (1984), Joskow (1985, 1987), and others. The typical strategy in the empirical literature has been to relate observed integration decisions to measures of contractual frictions, or more often, proxies for these frictions. In a very few cases, an attempt is made to link the integration decision to economic outcomes (e.g., productivity, investment, and innovation), or observed transaction costs (e.g., the incidence of disputes).

Many studies along these lines report statistically significant correlations between integration decisions and proxies for contracting difficulties. In Section 3, we discuss the extent to which these findings can be viewed as strong supportive evidence for the theory. We highlight a number of difficulties in relating the evidence to the theory. One is that the relevant theoretical variables (e.g., the importance of noncontractible decisions or the marginal returns to specific investments) can be inherently hard to measure (Whinston 2003). In other cases, the sources of variation that identify the parameters of interest appear to reflect important omitted variables. Finally, even if one accepts the directional results, the lack of evidence linking integration decisions to realized transaction costs makes it hard to assess the quantitative importance of the effects.

Empirical research also has faced a tension between testing specific predictions derived from the theory and trying to explain broad industry patterns of integration. Most contractual theories of integration aim to isolate particular mechanisms. The models tend to focus on simple environments, for example, two parties structuring a supply relationship with the surrounding market held fixed. Thus, the clearest empirical analogues are marginal decisions at the firm boundary, such as whether a firm should make or buy a particular input. Moving from this level of analysis to explain the organization of an entire industry requires additional steps, because the availability of suppliers or the existence of functioning markets or contracts needs to be treated as an outcome of the analysis rather than a fixed parameter.

This higher level industry perspective on vertical integration has been adopted in much of the industrial organization literature. Here, decisions about integration are often considered in the context of broader models of industry structure, competition, or technological change, but typically with much less attention to contractual issues and the ways in which vertical integration might differ from sophisticated contractual arrangements. In Section 4, we discuss this research, which has an empirical component as well, consisting most often of industry case studies or historical analyses of industry evolution. Using the case studies to communicate the key analytical themes, we distill three reasons industry structure and firm structure are interdependent.

The first relates to the presence of scale or scope economies. Many theories of industry structure are framed in terms of trading off the successful exploitation of scale economies versus the benefits of competition. If that trade-off calls for a large number of distinct firms in one or both of the industries where firms might be vertically integrated, the contracting problems emphasized in some organizational economics theories decline in importance. This leads to models in which market size or thickness is an important determinant of vertical integration.

Second, competitive strategy can be a key factor in vertical integration decisions. A rich set of models in industrial organization emphasize the use of vertical integration as a way to raise entry barriers in one or both of the associated markets. Another class of models focuses on mixed

structures, where a firm in industry A might be vertically integrated with a firm in industry B while also serving other firms in B as a disintegrated market supplier. Such structures create complex strategic problems of supplying, or being supplied by, one's competitor. These models lack foundational theories regarding why integration, rather than a complex contract, is needed to implement a particular strategy, but they nevertheless capture trade-offs that commonly arise in industry case studies and are discussed frequently in competition policy.

Third, the industrial organization literature has taken up the special case of vertical integration with complementary innovators. This literature deals with the trade-off between the benefits of coordination associated with integrated production and the benefits of getting multiple diverse draws, which favors separation into multiple independent inventors. The distinction has organizational implications, because contracting to coordinate *ex ante* calls for identifying and selecting a partner *ex ante*. Market organization of innovation can use *ex post* market selection. We use the production of scientific research as an example to illustrate this trade-off and how it brings together organizational and industry-level ideas.

We conclude our review by noting that the two literatures on vertical integration have remained largely separate despite the potential benefits of cross-pollination. We provide some suggestions for how insights from organizational economics might inform traditional analyses of market structure, and how a broader industry-level perspective at times might enrich organizational economics.

2. Contractual Theories of Vertical Integration

In his famous essay on the nature of the firm, Coase (1937) proposed to study why and how economic activity divides between firms and markets. He argued that firms exist to reduce the costs of transacting through markets. Their size and scope depends on the extent to which they offer a transaction cost advantage. Therefore, a decision to vertically integrate rather than sourcing inputs or selling outputs should reflect the respective transaction costs of internal and market organization.

To go further, one needs an explanation for why market transactions are inefficient and why the inefficiencies cannot be remedied with better contracts or pricing mechanisms. One also needs to explain why integration might yield an improvement in some cases but not all. Finally, a satisfactory theory should match observed patterns of integration and offer some hope for empirical testing and measurement. Essentially all contractual theories, from transaction cost economics to formal models of hold-up, decision rights, and incentives, reflect these goals.

2.1. Transaction Cost Theories

The transaction cost theory of integration was developed by Williamson (1971, 1975, 1985), Goldberg (1976), Klein et al. (1978), Joskow (1985), and others beginning in the 1970s. The theory expands on Coase's original idea by describing a wide set of transaction inefficiencies and potential organizational responses.²

2. Tadelis and Williamson (this volume) provide a more detailed account of transaction cost economics. See also Joskow (2005) and Williamson (2010) for recent overviews.

A starting observation is that market contracts are inherently incomplete. Parties can plan for some contingencies but not every one of them. Thus, in a great many transactions there will be room for opportunistic and inefficient behavior as the transaction proceeds. The concern may be especially severe when complexity or uncertainty make it difficult to specify contractual safeguards or when parties cannot walk away without incurring substantial costs.

Transaction cost theory argues that integration can be an effective response when these features are present. One reason given by Williamson (1971) relates to decisionmaking. When a dispute arises in an organization, it can be settled by a senior manager. In contrast, a dispute between separate entities must be resolved by negotiation or litigation. To the extent that managerial authority makes it easier to resolve disputes or make adaptations, integration can be the efficient response to uncertainty or contractual incompleteness (Williamson 1971, 1979).

A related rationale for integration is that it might mitigate potential hold-ups. If parties anticipate the possibility of future haggling or disputes, they may have little incentive to make specific investments for fear the investment could be wasted or expropriated (Klein et al. 1978; Williamson 1985). To the extent that integration allows a firm to protect specific investments, it again can be an efficient response to contractual incompleteness.

These stories provide a motive for vertical integration but not a corresponding cost. Williamson (1975, 1985) suggests a related but distinct set of inefficiencies inside organizations. These include low-powered incentives, and rent-seeking and informational bottlenecks that arise in managerial hierarchies. An implicit assumption in transaction cost theory is that these problems are relatively insensitive to the complexity, uncertainty, or specificity of particular transactions. So integration becomes optimal when hazards are more severe, but nonintegrated production may be preferred for relatively straightforward transactions.³

An important point in many transaction cost analyses is that the set of potential organizational responses to transaction frictions is very large. In addition to full vertical integration and spot contracting, responses can include contracts of varying duration and specificity, joint ventures, partial ownership through financial investment, partial control through seats on a board or voting arrangements, or shared ownership of assets or intellectual property. In fact, part of the appeal of transaction cost economics is that it offers such a broad and inclusive framework for matching organizational responses to transaction frictions. From an empirical perspective, however, this richness poses some challenges.

The sharpest predictions of the theory are that such transaction characteristics as specificity, uncertainty, and complexity should favor vertically integrated production. Perhaps the canonical example of specificity is a coal-fired electricity plant located next to a coal mine (Joskow 1985), which is also a good example to illustrate the subtleties of empirically testing transaction cost theories of integration. Coal-fired electricity plants are expensive to build, have a long lifetime, and are designed to burn particular types of coal. Before investing, the owners want to ensure a steady and reliable input supply. There are, however, a variety of ways to do this. Some plants vertically integrate, while others sign long-term contracts with the neighboring mine. There is relatively little evidence that the integrated plants outperform their counterparts

3. Williamson (1985) also emphasizes that the frequency of a transaction can be important, in the sense that one-time transactions are less likely to be integrated than repeated transactions.

(Kerkvliet 1991). So even in cases where specificity is apparent, vertical integration may be only one of several possible responses and not necessarily the most effective.

This same point can be seen in another classic example from the transaction cost literature: the acquisition of the Fisher Body Corporation by General Motors (Klein et al. 1978; Coase 1988, 2000; Klein 1988, 2000, 2007; Langlois and Robertson 1989; Casadesus-Masanell and Spulber 2000; Freeland 2000). Fisher Body supplied metal car bodies to GM in the early days of the auto industry. In 1919, GM acquired a stake in Fisher and the companies signed a contract committing Fisher to supply its output exclusively to GM. The contract was for 10 years, on cost-plus terms. After it was signed, production expanded as the demand for cars grew, and in 1926, GM purchased the remainder of Fisher Body, dissolving the contract and integrating the firms.

The question of why GM decided to integrate Fisher Body has been the subject of extensive debate. Klein et al. (1978) interpret the episode as a canonical example of a hold-up leading to integration. They observe that the relationship involved substantial specific investments in manufacturing and human capital. They also argue that rising demand raised Fisher's opportunity costs, so that they began to hold up GM by, among other things, using a relatively costly manufacturing process. This left GM with no option but integration. Coase (2000) and Freeland (2000) provide a very different interpretation. They point out that Fisher and GM had a tight relationship. A Fisher brother sat on GM's board, and GM paid for the construction of at least one Fisher plant. Rather than a hold-up arising from the cost-plus contract, Freeland and Coase argue that the cause of integration may have been a dispute about whether to expand an existing plant or build a new one that fit GM's expansion plans.

The episode demonstrates the subtleties in trying to formulate sharp empirical tests based on transaction cost theory. The historical research makes it clear that even before integration, Fisher and GM were closely intertwined. It is not obvious that things would have proceeded much differently if the companies had integrated in 1919 or not at all. Moreover, although different accounts are at odds over many issues, they are all consistent with the broad claims of transaction cost economics. In this sense, the same inclusiveness of the theory that makes it useful for organizing historical accounts also makes it difficult to reject.

A somewhat different issue, but one that turns out to be important for applied work, is that transaction cost theory tends to treat individual transactions in isolation, holding fixed the characteristics of the transaction and the surrounding market conditions. The difficulty in applied work is that transaction characteristics and market structure are often best viewed as endogenous variables. For instance, firms may have a choice about whether to use standard or customized inputs or to cooperate with other firms in their industry to create standardized contracts or technologies. We return to this point in more detail in Sections 2.5 and 4.3.

2.2. The Property Rights Model

The property rights model (Grossman and Hart 1986; Hart and Moore 1990; Hart 1995) is one of the first formal theories of integration that makes precise assumptions about the limits of contracting.⁴ The model focuses on how integration changes the incentives to make specific

4. Segal and Whinston (this volume) provide an overview of the property rights model as well as many extensions and related models.

investments. In the property rights theory, a firm is defined as a collection of physical assets. Decisions to integrate upstream or downstream are associated with shifts in asset ownership. An example would be a manufacturer that purchases a supplier and takes control of its physical plant or one that integrates downstream and takes ownership of distribution outlets. Contracts are assumed to be incomplete. When open issues arise, ownership strengthens a party's bargaining position. As a result, it has a stronger incentive to undertake *ex ante* specific investments.

The standard version of the property rights model has three stages. The relevant parties first decide who should own which assets. Other decisions, or some of them, are left to be decided later. Then the parties make investment decisions. The investments are specific—some of their value is lost if the relationship breaks down. After investments are sunk, the parties bargain over the outstanding terms and trade. Bargaining is assumed to be efficient, so the surplus-maximizing trade is made regardless of asset ownership.

Although bargaining leads to an efficient trading outcome irrespective of the distribution of assets, ownership does affect the terms of trade. Because it conveys the right to use an asset in the event of breakdown, ownership of an asset means that a party gets a larger share of the bargaining surplus. Under the typical assumptions about payoffs, this leads to sharp predictions about investment incentives. A move toward integration increases the investment incentives of the acquiring party but lowers the incentives of the acquired party. Determining whether integration is optimal, and which party should be the owner, requires a comparison of the costs and benefits, which can be complex.

Although the hold-up mechanism seems similar to transaction cost theory, the property rights model leads to distinct empirical predictions (Whinston 2003). For instance, transaction cost theory predicts that integration will be a response to specificity, where specificity refers (somewhat loosely) to a gap between the value of the ongoing relationship and the value of the parties' outside alternatives. In the property rights model, the gap *per se* is not consequential for predictions about ownership (Holmström and Roberts 1998). Instead, the relevant quantity is the degree to which ownership affects the marginal returns to noncontractible specific investments.

Perhaps because of these subtleties, the specific predictions of the theory have not received a great deal of empirical attention. Whinston (2003) emphasizes the difficulty in measuring or proxying for the marginal returns to investment. Moreover, ownership in the model conveys *residual* rights of control—that is, the right to make decisions that are not otherwise specified in a contract. In many settings, it is not obvious how to characterize or measure the importance of these rights. Similarly, the model focuses on investments that are both noncontractible and inalienable. Identifying important investments that are inherently nontransferable (e.g., investments in human capital) and yet important enough to drive vertical integration decisions can be tricky.

Holmström (1999) also has emphasized another issue with the property rights model, which may help explain why it has been more influential as a theoretical building block than as a framework for empirical work. Taken literally, the model suggests that individuals (e.g., the ones investing in human capital) should own the productive assets. Clearly, this is not the right frame of reference for thinking about large organizations that own many assets and coordinate many activities, where shares of ownership are often widely dispersed and separation of ownership and

control is common.⁵ One could associate the actors in the property rights theory with larger entities and still think about hold-up of specific investments as being a rationale for vertical integration, but in the context of the model, one then needs an explanation for why investments cannot be shared or contractually specified.

2.3. Decision Rights Models

One major contribution of the property rights model is that it offers a precisely formulated argument for why and when ownership conveys the right to make decisions. Many earlier accounts (e.g., Simon 1951) simply assume that managers enjoy a degree of authority to make decisions.⁶ In the property rights model, a firm's owner has to bargain with employees, who are free to walk away. If they do, however, they leave the firm's assets behind. This can give a firm's owner some degree of bargaining power over the firm's employees. In contrast, a supplier that walks away takes productive assets with it. Of course, in the property rights model, the key decision rights are never exercised because of the efficient bargaining assumption, so ownership matters only through ex ante investment incentives.

An alternative, and in some ways simpler, modeling approach assumes that bargaining is not efficient, or that there is no bargaining at all. Examples of this approach include Hart and Holmström (2010) and Baker et al. (2011). In these models, ownership is associated with the right to make certain residual decisions (the presence of physical assets is no longer very important). Roughly, these models predict that ownership should be allocated in a way that ensures more efficient ex post decisions (see Segal and Whinston, this volume).

In Hart and Holmström (2010), for instance, there are two business units that can benefit from coordinating their actions. Integration means that the units are placed under a single manager. The manager can force the units to coordinate, but (by assumption) may fail to respect the private preferences of the divisional employees. If instead the units operate under separate ownership, the respective managers will cater to their employees, but the units may fail to coordinate. There is a trade-off between the coordination benefits of internal organization and the incentive or appropriation benefits of nonintegration.⁷

This type of decision rights approach harkens back to a much older, although less contractually grounded, set of models in industrial organization. For instance, in the classic double

5. The separation of ownership and control in large organizations relates closely to many of the issues raised in this chapter, though we will not pursue it here. (Berle and Means (1932) is an early and classic reference.)

6. This view has been controversial. For instance, Alchian and Demsetz (1972: 777) write:

It is common to see the firm characterized by the power to settle issues by fiat, by authority, or by disciplinary action superior to that available in the conventional market. This is delusion. The firm does not own all its inputs . . . [An employer] can fire or sue, just as I can fire my grocer by stopping purchases from him or sue him for delivering faulty products.

7. Similar trade-offs also appear in the literature on internal capital markets (e.g., Stein 1997). A related model in Hart (2009) explores how integration might provide a way to avoid costly hold-ups, as in the transaction cost account of Klein (1996). In Hart's model, vertically related parties write a contract to trade at a future date. But they are unable to get the price right for every contingency. A situation can therefore arise where one party might threaten to walk away, triggering a (costly) renegotiation. The optimal ownership structure therefore is one that minimizes the likelihood of a hold-up.

marginalization model of Spengler (1950), a nonintegrated upstream supplier will choose its markup without regard to the profits of a downstream producer. The resulting trade is inefficient. Integration helps resolve the inefficiency, because pricing decisions are coordinated in a way that leads to a jointly profit-maximizing transfer price.⁸

The double marginalization model and related models of incentive conflicts in vertical supply chains share the feature that integration shifts authority from separate managers to a single coordinating entity. What it leaves unexplained is why integration does a better job of restoring efficiency than a sophisticated nonintegrated contract (Tirole 1988). Nevertheless, it is a workhorse for applied economists, because of its clear predictions (e.g., the potential inefficiency will be larger and the incentive to integrate greater when there is substantial market power both upstream and downstream). In this sense, the approach taken in recent decision rights models may be a promising framework for empirical research, particularly for studies where it is possible to observe decision processes and outcomes in integrated and nonintegrated situations.

2.4. Incentive Theory Models

A complementary set of vertical integration models focus on how integration decisions shift the financial incentives of workers and managers. As a simple example, we can consider a firm contracting with a sales agent. Suppose for the moment that nonintegration is associated with the agent having high-powered incentives—for instance, a contract under which the agent buys the product at a fixed price and keeps the proceeds from its sales. Conversely, integration means that the agent becomes a salaried employee with low-powered incentives. Whether integration is optimal will depend on how important it is to provide incentives for the sales agent and whether monitoring can substitute for high-powered financial incentives.

This type of agency model has been the dominant paradigm in research on franchising arrangements and related distribution integration decisions. It has several attractive features. First, internal organization often does seem to feature low-powered incentives relative to market-based exchange. Second, the basic logic of incentive theory models is familiar, and the relevant quantities—the sensitivity to incentives, the difficulty of measuring or monitoring behavior, the degree of risk aversion, and so forth—are in principle objects that can be proxied or quantified.

One element that is missing, however, is why integration should be equated with low-powered incentives in the first place. Holmström and Milgrom (1994) provide an answer. Their argument is that financial incentives generally are part of a broader incentive environment. Other elements might include decisions about asset ownership, or the set of tasks that are permitted or excluded. Holmström and Milgrom show that under certain conditions, asset ownership by the agent (e.g., nonintegration) can be complementary to providing high-powered financial incentives. Conversely, taking assets away (integration) makes it desirable to use low-powered incentives. From this perspective, integration is likely to be associated with broader shifts in incentives and other organizational variables, even if asset ownership per se is not the primary driver of incentives (see also Holmström 1999).

8. Related models focus, for instance, on the inability of nonintegrated firms to coordinate investment or marketing decisions, or to price complementary products efficiently. Tirole (1988) and Perry (1989) provide extensive coverage of these types of models.

The incentive system model is particularly useful for thinking through shifts in incentives and organizational design that might accompany integration decisions. For example, privately funded start-up firms in Silicon Valley often compensate their workers and managers with equity or options. The work atmosphere can be intense. These firms attract workers and managers who are drawn to the high-pressure, high-powered incentives of starting a new business. If a large firm acquires the start-up, it may seek to align the start-up's activities and efforts with its own. Measuring alignment can be difficult, so the logic of the model suggests that an acquisition will be followed by a shift to lower-powered incentives and perhaps the subsequent departure of some of the original managers and employees.

The challenge that arises in making the theory operational for empirical work is that its predictions are again very rich. Many outcome variables should move together as a response to underlying shifts in the environment. As a result, most of the research linking agency considerations to integration decisions has tended to focus on simpler, although perhaps less interesting, predictions.

2.5. Capabilities Theories

The theories we have described focus mainly on decisions at the boundary of the firm and often deal with cases where firms integrate to internalize the transfer of some tangible good or service. In contrast, research on business strategy and organization theory frequently emphasizes the idea that firms may seek to expand or acquire other firms to leverage their internal capabilities or exploit superior management capabilities (e.g., Penrose 1959; Cyert and March 1963; Wernerfelt 1984). These theories rest on two premises. The first is that organizations develop certain capabilities or know-how that is embodied by managers and employees or in organizational routines. The second is that capabilities or knowledge cannot easily be traded or shared across firm boundaries.

These ideas have received less attention in economic theory, although there is a range of work that speaks to related issues. In the Lucas (1978) model of firm size, managerial talent is a scarce resource that can be leveraged by creating hierarchical organizations. Lucas uses the model to derive predictions about the size distribution of firms in the economy. Subsequent work has adapted his model to study the optimal organization of hierarchies (e.g., Garicano 2000). Clark (1985) and Bloom and van Reenen (2007) provide evidence that managerial practices can be an important factor in explaining productivity differences across firms.⁹

These theories address the first piece of the capabilities view—that firms differ in managerial know-how, and this difference is important for production—but not the second. That is, they do not address why integration, as opposed to contractual arrangements, is required to leverage managerial talent. One natural hypothesis is that managerial authority tends to coincide with firm boundaries, an idea that is captured in the model of Hart and Holmström (2010) discussed in Section 2.3, and is a common presumption in less formal analyses.

9. These papers look at comparable firms and have an observable definition of “better” managerial capabilities. As Clark (1985) points out, to understand complementarities between different organizations, one needs a definition of managerial capabilities that includes the task to be carried out as well as effectiveness at pursuing that task.

A complementary line of research argues that vertical integration allows information flows that cannot occur across firm boundaries (Malmgren 1961). For instance, Arrow (1975) considers a model in which information can be transmitted within an integrated firm but not between disintegrated firms. Again, the model sidesteps the question of why transmitting information or knowledge across firm boundaries might be difficult. One potential justification is that employees who interact regularly in a firm develop a body of shared knowledge that facilitates further communication.

Another difficulty with sharing knowledge or information across firm boundaries is that once information is shared, it cannot be rescinded, creating an appropriability problem. Indeed, Cohen and Levinthal (1990) argue that the ability to absorb information can itself be an important organizational capability. In Section 4.4 we argue that identifying situations in which firms have an advantage in coordinating the production and dissemination of knowledge is particularly useful for thinking about the organization of innovative industries.

3. Empirical Evidence on Vertical Integration Decisions

Since the 1980s, many empirical studies have attempted to test or apply contractual theories of integration. The studies vary in the details but share common features. The general approach is to predict observed integration decisions using transaction characteristics identified in the theory. The integration decisions lie at the firm boundary—whether to buy certain inputs, to use a contracted sales force, to franchise retail outlets, or instead to bring these services in house. These decisions typically are at the firm level, holding fixed the nature of the goods and services being contracted over, the contracting environment, and the surrounding market structure.

These papers also share common measurement challenges. Testing contractual theories of integration requires empirical measures of concepts, such as the degree of specificity, the importance of noncontractible investment, and the potential for opportunism and hold-up. Testing also requires variation in their incidence. The variation might be across firms or across the transactions of a single firm. But its source needs to be plausibly exogenous to the integration decision itself. It is also necessary to identify the set of possible contracting outcomes. This undertaking is complicated by the possibility, noted above, of a wide range of contractual solutions to a given problem. Most studies try to capture moves closer to or further from integration with some sort of binary classification and avoid fine distinctions among contractual arrangements.

Virtually all studies we discuss report statistically significant correlations between integration decisions and proxies for theoretically relevant transaction characteristics. This correlation has been viewed as quite favorable for contractual theories. A more skeptical perspective, however, is that these analyses often do not provide a very sharp test of the theory. In some cases, the empirical proxies used to capture complexity, specificity, or the potential for opportunism do not have an obvious relationship to the theoretical concepts. In other cases, the source of identifying variation seems to be earlier or concurrent decisions made at the firm or industry level.

Perhaps the main limitation of this work, however, is that very few studies provide any quantitative (and sometimes not even qualitative) sense of the transaction costs or incentive distortions associated with different contractual forms. As a result, it is frequently unclear

whether the difference between integration and nonintegration is really that important in any economic sense. In Section 3.6, we argue that this last concern requires combining evidence on integration decisions with specific ex post measures of transaction costs or performance, and that this approach is a key direction for future research.

3.1. Sourcing Complex and Specific Inputs

Some of the earliest empirical studies look at industrial make-or-buy decisions in search of evidence that firms might seek to integrate the production of complex or specific inputs. Two classic examples are Monteverde and Teece (1982) and Masten (1984).¹⁰ Both studies relate make-or-buy decisions to empirical proxies for hold-up and opportunism and thus are usefully representative of a much larger empirical literature.

Monteverde and Teece (1982) studied how Ford and General Motors source auto components. They used a probit regression to relate sourcing to measures of transaction specificity and complexity. A component is “specific” if the procuring firm is the exclusive purchaser of that component. An engineering cost estimate is used to proxy for complexity, or technical know-how. Because many components consist of parts procured in different ways, Monteverde and Teece defined a component as “made” rather than “bought” if the cost fraction of the component produced internally exceeds a given threshold. Their main finding was that both specificity and complexity are positively correlated with internal sourcing.

Masten (1984) examined a single large aerospace project that required nearly 2,000 inputs. Masten also constructed measures of specificity and complexity, in his case on an input-by-input basis. Here too, an input is specific if the general contractor is the exclusive user. Inputs are classified as complex or not complex, based on a survey of the procurement team. Masten found that both measures are highly correlated with sourcing. In fact, more than 90% of the specific and complex inputs were sourced internally versus less than 1% of the nonspecific and noncomplex inputs.

These pioneering studies highlight some of the challenges in testing contractual theories of integration. One challenge is to find empirical measures of transaction frictions that correspond closely to the conceptual ideas in the theory. For instance, both studies use measures of technical or engineering complexity as proxies to indicate that purchasing a component is complicated. The relationship is clearly imperfect. Computers are very technically complex, and yet most firms readily source computers from external vendors. From a theoretical perspective, it would be better to define complexity in terms of communication or information about a transaction. Are there many possible contingencies? Does performance involve a great many details that are difficult to communicate or incorporate in a contract? Is it difficult to identify the responsible party if problems arise? Is there substantial room for asymmetric information? These notions each require a different approach to make them operational. For example, the idea that complex transactions may involve asymmetric information calls for an empirical treatment recognizing that one party may have superior information at the time of contracting. This idea, so important

10. Related work on industrial or government procurement decisions includes Walker and Weber (1984), Masten et al. (1989, 1991), Crocker and Reynolds (1993), and Levin and Tadelis (2010).

in the rest of the economics literature on asymmetric information, appears essentially nowhere in the empirical literature on vertical integration.¹¹

Defining “specificity” is also problematic. Monteverde and Teece (1982) and Masten (1984) use what is most naturally viewed as an outcome, the demand for an input by only one customer, to proxy for a primitive, namely the specificity of the investments associated with the exchange relationship. The fact that the input has a sole user may reflect some fundamental and fixed attribute of the input (and in a study that focuses narrowly on a single firm, that may be the obvious source of variation on which to focus), but it may also reflect broader market forces. For example, variation in the efficient scale of production relative to demand needs may play a large role in determining whether an input is classified as specific. If the input is efficiently produced at large scale relative to the demand of individual users, we might expect to see several firms using the same input, even if it is produced by only a single supplier, creating the type of bilateral market power emphasized in the theory. If production of the input is flexible, users may adopt customized versions, irrespective of whether the market to supply the input is highly competitive or very concentrated.

Note that the important part of this argument for analytical purposes is not the specific point about scale. It is the movement of the argument from firm to market. In the firm-level theory, an input is made rather than bought because producing it requires specialized equipment, knowledge, or a specialized location, or because the input itself has no alternative use, and moreover because this specialization leaves parties open to opportunism if the input is bought instead of made. In the market-level alternative theory, some inputs are sold to multiple buyers because that is the efficient market organization, and this causes their use to be less specific. This arrangement might be optimal because of scale economies in production, because the market is organized in a way that facilitates the pricing and distribution of standardized products, or because regulatory or legal uncertainty favors standardized transactions.¹²

These problems illustrate the difficulty of distinguishing aspects of a transaction that are primitive from those that follow from design decisions or market equilibrium. Baldwin and Clark (2005) have tried to tackle this problem from an engineering perspective. They argue that within a production process it is possible to identify the engineering interfaces that are more or less amenable to a market transaction. One suspects this approach could prove powerful in certain instances, particularly if it is possible to measure performance along a chain of production (e.g., failure rates or delays).

11. Many of the most successful approaches to asymmetric information are based on datasets in which the econometrician, by gathering data later, can observe an outcome that only one party could observe at the time of contract (e.g., Einav et al. 2010). This approach is beginning to be deployed in the few studies of vertical integration that examine outcomes of this sort. Below, we look at a paper by Arora et al. (2009) that studies pharmaceutical development for licensed (i.e., contracted) versus in-house chemical entities. They interpret the observed lack of difference in success rates between licensed and in-house developed drugs as evidence against any “lemons” theory of asymmetric information in the licensing market.

12. One can also raise issues of causality with reference to a single firm. If the market supplies a small set of input varieties, a producer may be able to tailor its design to use these varieties rather than a specific input. Similarly, Novak and Stern (2009) point out that if there are complementarities in production, manufacturers may internally source clusters of inputs if they anticipate difficulties in coordinating design changes that require large-scale modifications.

We have emphasized the difficulties in measuring transaction frictions, but difficulties in measurement also arise on the left-hand side of transaction cost regressions. In the case of auto manufacturing, U.S. manufacturers traditionally relied on a partial outsourcing model in which suppliers compete for contracts each year. Japanese firms adopted a very different approach involving close relationships with a set of closely coordinated suppliers (Asanuma 1989). The economic and engineering problems faced by firms in this industry in different countries are not all that different, but history and broader institutional issues led these firms to adopt different organizational modes. Depending on the study country, one might arrive at very different views of what it means to buy rather than make a component.

3.2. Specificity, Market Thickness, and Hold-Up

Empirical researchers arguably have had more success in linking integration decisions, or at least the use of more complete vertical contracts, to measures of market structure (e.g., the availability of multiple suppliers in the upstream market). Two emblematic studies are Stuckey (1983) and Joskow (1987). These studies get around many of the problems discussed above by identifying settings where parties make large investments in specific assets—in each case, specialized production facilities—and there appears to be substantial potential for hold-up in subsequent price negotiations stemming from the limited availability of trading partners.¹³

Stuckey (1983) focuses on aluminum manufacturing. The primary input in this process, bauxite, is very costly to transport. Thus, it is efficient to locate aluminum refineries close to bauxite mines, and indeed the largest refineries are mine-mouth plants. Because refineries and mines require substantial sunk investments and have long lifetimes, Stuckey argues that integration is a natural response to the threat of costly breakdowns. He documents that integration of co-located mines and refineries is indeed common. Hennart (1988) provides an interesting comparison: the production of tin. Relative to aluminum, tin production has much lower capital and transport costs, less specialization of refineries, and also much less vertical integration.

Joskow (1987) studies coal-fired electric utilities. He points out that utilities located in the eastern United States have relatively easy access to multiple coal suppliers, while utilities located in the West have fewer options. As a result, western utilities are more exposed to costly hold-ups and are more likely to take contractual precautions. Geographic variation in market structure therefore provides a source of identifying variation. The dependent variable in the study is the duration of supply contracts, as vertical integration is relatively uncommon. Joskow shows that utilities in the East have relatively short contracts, whereas those in the West can last 15 years or more. Over such a long duration, the value of energy can be expected to vary widely. Thus, the costs of long-term contracting might be considerable, especially if the contractual price only poorly tracks the spot prices that would have prevailed (Joskow 1988). Presumably this cost is weighed against the benefit of protecting investments in choosing contract duration.¹⁴

13. Acemoglu et al. (2010) take a less direct approach to assessing the relationship between investments and integration, but one that is motivated by property rights theory, studying the relationship between technological intensity and integration in British manufacturing.

14. A related line of work uses variation across firms within an industry, or across local markets, to test whether integration decisions are related to the number of available suppliers or to upstream concentration. See, for instance, Lieberman (1991), Ohanian (1994), or the additional studies discussed in Section 4.

In the aluminum and coal examples, asset specificity is closely related to market structure. In Stuckey (1983), co-location and high transport costs ensure that refineries have few alternative suppliers. In Joskow, firms in the West cannot rely on a thick spot market and competition to avoid hold-up. In each case, a concentrated market structure (i.e., few ex post options) provides an empirical proxy for potential opportunism.

The availability of alternative suppliers can depend a great deal on the relevant time horizon. A firm may have many options if it plans well in advance, but few on short notice, creating what Masten et al. (1991) refer to as “temporal specificity.” Pirrong (1993) argues that differences in the incidence of temporal specificity can explain organizational arrangements in ocean shipping for different commodities. Grain and fertilizer are at one extreme. They can be carried using general-purpose vessels and have liquid spot markets. The thickness of the market leaves little room for haggling over prices, and both commodities are commonly shipped under spot contracts. In contrast, iron ore requires specialized vessels to ship, and the number of mines and steelmakers is limited. Integration and long-term contracts are the norm. Either steelmakers own their own shipping subsidiaries, or they secure a shipper for a long period of time, with the agreement typically negotiated prior to the construction of the specialized ship.

3.3. Decision Rights and Coordination

One of the central ideas in transaction cost theory and in models of the optimal allocation of decision rights is that integration might help firms adapt to contingencies that are anticipated in a broad sense but not in specific detail. Testing this proposition calls for a setting in which such contingencies arise frequently and with enough similarity to facilitate statistical analysis, but with sufficient variation to prevent easy contracting in advance. Several studies have made progress by looking at integration decisions in transportation industries, where scheduling poses a coordination problem that often has to be solved in real time in a fashion that allows adaptation to changing circumstances and events.¹⁵

Forbes and Lederman (2009) study the relationships between major U.S. airlines and their regional affiliates. Some carriers own their regional affiliates, while others use long-term contracts. The organizational structure is revised infrequently, but numerous issues (e.g., scheduling) must be resolved on an ongoing basis. Forbes and Lederman focus on the possibility that weather disruptions might be a particular source of conflict. They argue that when there is a disruption, a carrier may want to adapt local flights to keep their network running as smoothly as possible. Regional carriers may not internalize broader problems on the network. Forbes and Lederman use cross-route variation in weather patterns to proxy for the incidence of conflict. They find that major carriers are more likely to use wholly owned regional operators on routes with worse weather. Integration is also more common on routes that are more intricately linked to the network, where the need for coordination is arguably larger.¹⁶

15. Gil (2007) provides a related analysis of adaption in the movie industry, where the market for any given movie is initially uncertain but realized over time, leading to a question of how long theatres should continue to exhibit the movie when the box office receipts are being shared with (disintegrated) movie distributors.

16. Forbes and Lederman (2009) do not provide much direct evidence on the costs of integration that encourage carriers to sometimes rely on contracts with nonintegrated affiliates. They hypothesize that arm's-length

In a subsequent paper, Forbes and Lederman (2012a) tighten this story by relating integration decisions to ex post measures of performance, in this case flight delays. They find that integrated regionals experience fewer delays than nonintegrated ones, particularly on airport days with adverse weather conditions. The finding is consistent with the idea that the national airline, not the regional carrier, disproportionately bears the costs of delay and that opportunistic behavior by the regional carrier hinders adaptation in certain contingencies. Although delays do not translate immediately into dollar costs of disintegrated supply, the paper is unusual, and admirable, in completing the link from plausibly exogenous market conditions to integration decisions to ex post performance.¹⁷

Problems of adaptation also feature prominently in studies by Lafontaine and Masten (2002), Nickerson and Silverman (2002), and Baker and Hubbard (2003, 2004) on organizational arrangements in the trucking industry. In trucking, costs are reduced by minimizing driving distance and maximizing the likelihood of full loads. These features mean that efficient matching of trucks and loads can create substantial value, and often the matching needs to be done in real-time, based on the location of trucks and loads. One conjecture is that when load matching is more important, we might expect a greater prevalence of trucking employees driving company-owned trucks rather than independent operators contracting for loads.

Consistent with this broad hypothesis, Nickerson and Silverman (2002) find that employee drivers are more common in “less-than-truckload” (LTL) carriage, where they argue there is more need for coordinated scheduling. Baker and Hubbard (2003, 2004) find a similar relationship between the use of employee drivers and difficulty in finding backhauls, where again the potential for miscoordination and haggling may be greater. In an interesting extension, Baker and Hubbard (2003) look at the adoption of information technology in the form of on-board computers. They point out that on-board computers had ambiguous implications for organization form. On the one hand, by allowing companies to track driver locations, they facilitated load matching and more efficient capacity utilization, favoring an integrated structure. On the other hand, they allowed for improved monitoring of driver activities, facilitating arm’s-length contracting.

The Baker and Hubbard (2003, 2004) papers and Pirrong’s (1993) work on shipping raise the interesting question of whether vertically integrated control structures have a natural advantage in solving complex coordination or matching problems. In transportation, scheduling and load-matching problems are frequently tackled using optimization models that incorporate various constraints on allocation and dispatch. Economists immediately understand that solutions to these types of problems have a market analogue, for instance with multipliers on different constraints corresponding to implied prices for different routes. What is the incentive to shift from market control to operations research control? Pirrong points to the problem of having sufficiently thick markets to generate reliable prices. Another rationale might be the

contracting keeps the employees of the regional firm at a distance from the generally quite powerful unions of the parent carrier.

17. In a further related study, Forbes and Lederman (2012b) analyze an industry shift from revenue sharing contracts with regional carriers to capacity utilization (or “per flight”) payments. They show that this shift was associated with the adoption of flexible regional jets and argue that the change in contract was needed to reduce haggling with the regional carriers over what flights to fly.

difficulty of solving complex scheduling and matching problems in a decentralized fashion, although arguably this type of problem might be addressed with more sophisticated market mechanisms.

3.4. Agency, Incentives, and Monitoring

Empirical researchers have also explored the extent to which incentive contracting theories of integration have predictive power. The large literatures on retail franchising decisions and sales force integration are typical in this regard.¹⁸ Here, researchers have attempted to link organizational decisions by the parent firm—such as whether franchise outlets are to be company owned—to the importance of franchisor and franchisee effort and to difficulties in monitoring this effort. Because direct measures of the marginal returns to effort and the ability to monitor typically are hard to come by, most researchers rely on proxies. For example, studies have found that more remote outlets (e.g., those in rural areas, without neighboring outlets, or farther from headquarters) are more likely to be franchised as opposed to company owned (e.g., Brickley and Dark 1987; Minkler 1990; Kehoe 1996). Other studies report correlations between franchise ownership and such variables as employee-to-sales ratio or the experience required of new franchisees.

A common issue in interpreting these findings is that (once again!) the empirical proxies may not relate very tightly to a particular theory. For example, the cost of monitoring remote outlets may be higher, making it desirable to provide higher powered revenue incentives. Alternatively, remote outlets also may be less integral to the chain's reputation, making it less important for the parent to exercise control. The set of individuals interested in obtaining a remote franchise and the potential customers at remote outlets also may be different from nearby franchises.¹⁹ This ambiguity can lead to multiple explanations for a reported correlation.

Some studies have been able to mitigate the proxy problem by identifying cases where there is compelling cross-franchise or cross-location variation in the nature of tasks. Shepard's (1993) study of gasoline stations in Massachusetts is a good example. Shepard views the choice of organizational form for gasoline stations as resolving a trade-off between resolving double-marginalization problems in pricing and providing incentives for the station operators. She argues that incentives are likely to be more important at stations that offer ancillary services, such as auto repair or full-service gasoline. Consistent with this logic, Shepard finds that the stations offering ancillary services are less likely to be company owned.²⁰

18. On franchising decisions, see, for example, Caves and Murphy (1976), Brickley and Dark (1987), Norton (1988), Minkler (1990), Lafontaine (1992), Lafontaine and Shaw (2005), and Yeap (2006). Studies of sales force integration include Anderson and Schmittlein (1984), John and Weitz (1988), and Regan (1999).

19. Other studies proxy for franchisee effort using such measures as the employee-sales ratio (Norton 1988) or the amount of franchisee experience required (Lafontaine 1992). Related work adopts proxies for the importance of franchisor effort, such as advertising expenditures (Lafontaine and Shaw 2005) or the number of years a chain went before franchising any outlets (e.g., Lafontaine 1992). It is not entirely obvious why the variation in these variables should be unrelated to other factors influencing franchisee ownership.

20. Yeap (2006) takes a similar approach to studying franchising decisions by fast-food chains. Her central finding is that restaurants where food preparation is done on site and table service is supplied are more likely to be franchised. See also Slade (1996).

Studies of retail organization also face difficult problems of selection. For instance, a common hypothesis in research on franchising is that parent companies should tend to own outlets where revenue is highly variable, as a way to shelter franchisees from risk. The evidence, however, is highly inconclusive (Lafontaine and Slade 2007). Of course, finding a convincing proxy for risk is not easy, but even apart from this measurement problem, one may be concerned about selection. For instance, franchise operators may vary substantially in their risk attitudes, and those with greater risk tolerance (or perhaps greater wealth) may be drawn to the more risky outlets and also prefer to have ownership.²¹

A broader issue with the contractual literature on franchising is that it does not provide much evidence on whether outlet ownership has first-order operational effects. After all, a statistical relationship between incentives and ownership structure does not necessarily establish that the incentive problems under one organizational form are large. From an incentive perspective, a company-owned McDonald's might be radically different from a franchisee-owned McDonald's, or it might be pretty much the same. To assess the difference, one needs to know whether there really is substantial variation in effort or behavior across franchises and whether it covaries with organizational form. Absent such information, it is difficult to infer whether agency considerations are really the central issue driving franchising decisions or whether such issues as capital structure and financing are more important. The best way to address these questions would be to incorporate direct measures of outlet performance into the analysis.

3.5. Knowledge and Information Transfers

In contrast to empirical work on transaction specificity and incentives, the literature that tries to link vertical integration decisions to knowledge and information flows is less well developed. One likely reason is that the relevant variables—organizational capabilities or know-how, managerial ability, and internal processes—can be difficult to measure, a prerequisite for empirical work. (Bloom and van Reenen's (2007) survey measures of management practices are an interesting and promising exception.) As discussed earlier, the theory is also less sharply organized in terms of generating specific testable hypotheses.

One area where there has been some progress is the study of organizational structures in the pharmaceutical industry. Knowledge creation in pharmaceuticals happens in the early stages of drug discovery and in subsequent stages of development and clinical trials, and there are further stages of production and distribution. Several studies have found evidence for economies of scope at various stages of the chain, which they attribute to firms developing specialized capabilities.

Henderson and Cockburn (1996) focus on the first stage of drug discovery, using data on development projects gathered from large pharmaceutical firms. Their dataset is unusual in that it contains information on projects that do not succeed as well as those that do. The number of patents provides a measure of success. By this measure, projects taking place in firms with larger overall research programs appear to be more successful, and Henderson and

21. The same concern can be voiced about Shepard's (1993) study to the extent that the operators of auto repair stations are relatively entrepreneurial and may prefer to be owners—although Shepard does try to provide auxiliary evidence that weighs against selection bias.

Cockburn argue that this can be attributed in part to scope economies. Their work suggests that complementarities across research projects may help explain the boundaries of pharmaceutical firms.

Subsequent to their study, the industry underwent a major shift toward early-stage drug discovery taking place outside the large pharmaceutical firms, in academic laboratories or smaller entrepreneurial firms. This shift creates a potential market or contracting friction. Relatively few firms appear able or willing to push drugs through to commercial use, whether because of scale economies or differences in capabilities at the later stages of drug development. As a result, a licensing market has emerged, where drugs invented in one firm are transferred for development or commercialization in another. A natural concern is that the licensing market might suffer from problems of expropriation or asymmetric information.

Arora et al. (2001) investigate whether licensing transactions might be subject to a “lemons” problem of asymmetric information. They gather a dataset that includes ex post outcomes that might not have been forecastable by (all) parties at the time of contract. They look at the later stages of drug trials and commercialization for licensing agreements signed before phase I clinical trials. It appears that, contrary to the lemons hypothesis, success rates do not differ between products that are out-licensed and those retained in-house for further development. Arora et al. also conclude, perhaps less surprisingly, that there are economies of scale and scope at the firm level in the later stages of drug development.

Concerns about organizational capabilities are also the key to Azoulay’s (2004) case study of outsourcing in the pharmaceutical industry, where firms increasingly rely on contract research organizations to perform clinical trials for new drugs. Azoulay looks at how the decision to outsource varies with the nature of the trial. He argues that the incentive systems and capabilities of large pharmaceutical firms and contract research organizations are fundamentally different. Contract research organizations are organized to efficiently gather and analyze large quantities of routine data, whereas pharmaceutical firms are better equipped to manage trials that require the production of new knowledge rather than just new data. The data appears to be consistent with this story. For instance, Azoulay finds that studies that involve more academics, and hence may be more skewed toward knowledge production rather than data production, are much less likely to be outsourced.

These interesting results suggest connections between knowledge transfer and organizational capabilities and integration in one specific industry. Even so, one might argue that these papers are not yet fully testing what is arguably the most interesting hypothesis related to integration in innovative industries. Specifically, smaller, newer firms might have the advantage of flexibility and diversity (particularly with respect to new drug ideas), whereas larger established firms might have superior commercialization and regulatory skills. These differences might be behind the pattern of licenses, alliances, and entry and growth of firms of different types.

3.6. When and How Do Vertical Integration Decisions Matter?

We have already highlighted one of the main limitations of the empirical literature. By and large, it focuses on the decision of whether to vertically integrate, but not on the implications of this decision for economic outcomes or realized transaction costs. This focus leads to questions

about when integration has first-order incentive effects (e.g., in the case of franchising), effects on decisionmaking or adaptation (e.g., in the case of sourcing different types of inputs), or important effects on innovation and productive efficiency.

Quantifying the effects of integration decisions poses some challenges. One difficulty, of course, is the econometric problem of selection. If firms choose to integrate when they think it will lead to productivity benefits, finding the right variation to identify the effect of integration on productive efficiency is going to be difficult. In the case of coal contracts, for example, one might like to measure the costs and benefits of longer contracts holding fixed the market environment. Most of the utilities with short-duration contracts, however, are in the eastern United States, whereas those with longer duration contracts are co-located or are in the western United States.

A second difficulty with measuring the effects of integration is that most empirical studies focus on borderline cases, where integration is a close call. Of course, integration may have both a large efficiency benefit and a large efficiency cost, but this is not guaranteed. Thus, a more promising strategy may be to look at decisions that are complementary to integration. For instance, as emphasized by Holmström and Milgrom (1994), small variations in the environment might lead firms to make large changes to a cluster of policies if there are important complementarities.

These difficulties notwithstanding, there is a variety of evidence that sheds some light on differences across integrated and nonintegrated firms. One example comes from research on manufacturing productivity.²² For instance, Hortaçsu and Syverson (2007) compare integrated and nonintegrated concrete and cement plants. They find that integrated plants are larger and more productive in the cross-section, that plants that become integrated are more productive, and that the event of becoming integrated is associated with an increase in productivity. They argue that the source of these productivity advantages may be tied to better logistics coordination, a benefit that is associated more with size than with vertical integration per se.²³

Further evidence along these lines is provided by Atalay et al. (2012), who use establishment-level data from a broad range of industries. They again show that integration, plant size, capital intensity, and labor productivity are positively correlated. The paper also includes a striking finding about commonly owned plants in vertically related industries. There is relatively little transfer of physical goods from one plant to another. Instead, plants within the same firm in vertically related industries are overwhelmingly involved in merchant operations, in which they transact across the firm's boundary.

22. Less work has been done on behavioral or operating differences between integrated and nonintegrated manufacturers. For instance, Mullainathan and Scharfstein (2001) study the capacity decisions of vinyl chloride monomer manufacturers, some of whom are integrated downstream into the production of waterproof plastic, of which this monomer is an input. They present evidence that nonintegrated vinyl chloride monomer producers react more strongly to market demand for the monomer, whereas integrated producers focus on internal demand needs, and they argue that this might be explained by differences in managerial focus and attention.

23. Related work by Van Biesebroeck (2006) on automobile manufacturing finds that component integration is associated with higher productivity, especially in plants that have adopted flexible manufacturing techniques. His results also are consistent with the view that integration facilitates greater coordination in the production process.

This observation strongly suggests that much common ownership of vertically related plants is driven by the sharing of intangible assets (e.g., managerial skills, know-how, or other information) or is related to the financing of the firm.²⁴ This general story is also consistent with work on large diversified firms, such as that of Schoar (2002), who provides evidence that plants in diversified firms are more productive than those in single-segment firms.²⁵ This sort of evidence pushes us away from a primarily operational or commodity-flow understanding of vertical integration.

Relating these papers to the theory calls for telling where exactly the trade-offs arise in making integration decisions. To what extent can managerial know-how be leveraged, and where do the benefits drop off? Does an increase in scale or scope feed back into productivity? These analyses also do not make much contact with the types of contractual concerns on which theorists have focused. They also differ from those discussed above in that there is little explicit measure of what happens at the firm boundary or at the divisional boundary within a vertically integrated firm. Instead, an inference is drawn from firm scale and scope. Thus, the interpretation in terms of the underlying theory is necessarily indirect, although a natural trend is toward theories that involve spreading a fixed managerial input over a range of production activities (e.g., Lucas 1978).

The productivity and incentive consequences of vertical integration have also received attention in research on healthcare organizations. In the United States, healthcare systems have become significantly more integrated over the past 25 years, through partnerships between general and specialist physicians, physicians and hospitals, and hospitals and specialty care units, among others. Although one explanation for this integration is that physicians and hospitals are attempting to improve their bargaining power vis-à-vis insurers and exercise market power, another line of thought holds that integrated systems are able to successfully resolve contractual inefficiencies and can provide more efficient, coordinated care.

The current literature seems to be broadly inconclusive (Gaynor 2006), but some studies offer interesting specific findings, some of which are consistent with contractual theories. Afendulis and Kessler (2007), for instance, look at the problem of integrating diagnostic services and treatment. They find that in the case of coronary artery disease, patients seen by cardiologists whose practices also provide surgical treatments were more likely to receive angioplasties; these patients received generally more expensive care but did not have better health outcomes. Afendulis and Kessler interpret this result as consistent with moral hazard or incentive contracting theories of integration.

In more recent work, Afendulis and Kessler (2011) look at how changes in Medicare reimbursement policy affected skilled nursing facilities that were and were not integrated with

24. In an effort to make this finding more direct, Hortaçsu and Syverson (2007) also examine the white collar (nonproduction) workers in the plants they study. Their inclusion might tie the inference closer to a theory about management. However, many of the white collar workers in manufacturing plants are not, typically, managers of the manufacturing production process, but rather managers of the market or nonmarket processes by which intermediate inputs flow into the plant and outputs flow out of it.

25. More surprisingly, however, she finds that existing plants become less productive following an increase in firm diversification. She hypothesizes that this result also can be explained by management, to the extent that a new acquisition leads to a shift in managerial focus away from existing lines of business. This interpretation is consistent with another systematic merger fact, which is that many mergers are followed by spin-offs of the acquired business (Ravenscraft and Scherer 1987).

hospitals. They find that a shift to prospective payment (essentially fixed-price reimbursement rather than cost-based reimbursement) led to significantly greater declines in healthcare costs for the integrated facilities. The mechanism that enables integrated hospitals to better respond to changes in external financial incentives is not entirely clear, and indeed, studies have reached mixed conclusions on whether hospitals that are more broadly integrated generally have lower costs (Ciliberto and Dranove 2006; Cuellar and Gertler 2006).

Ciliberto (2006) uses integrated and nonintegrated hospitals to offer a more specific test of hold-up theories, by looking at the decision to invest by offering outpatient and diagnostic services. These services rely on referrals from primary care physicians, so the hypothesis is that hospitals that are integrated with their physicians might be better positioned to internalize referrals, which might support investments in service provision. Ciliberto indeed finds that vertically integrated hospitals added more of these services following integration. The effect is strongest in areas where HMO penetration is higher, which is roughly consistent with the idea that the returns to integration might increase with the prospect of hold-up.

What are the efficiency consequences of this finding? The perspective Ciliberto (2006) takes is that the potential for hold-up leaves nonintegrated hospitals investing too little in outpatient and diagnostic services, and integration resolves the inefficiency. An alternative interpretation, closer to the view in Afendulis and Kessler (2007), is that offering these services provides a mechanism for physicians to capture rents. These rents could arise from failures of the physicians to act as the perfect agents of patients in making referrals or from problems in the setting of prices paid for these services by third-party payers.

The example illustrates the difficulty of moving from even cleanly measured behavioral effects to efficiency or welfare interpretation in a complex market and organizational environment, such as health care. Nevertheless, we expect that this topic will, and should, receive a great deal of attention in coming years.

4. Vertical Integration and Market Structure

A recurring theme in our discussion of the empirical literature on vertical integration is the connection between integration decisions and market structure. This link has not been the focus of contractual theories of vertical integration, but it is a major focus of research in industrial organization. In this section, we distill some of the key ideas and relate them to work in organizational economics.

The theories we examine bring several different sets of ideas to the foreground. One set of ideas relates to the determination of horizontal market structure, typically based in firm-level costs or in strategic interaction among firms. In some circumstances, cost efficiencies or strategy decisions that impact horizontal structure also affect vertical organization. Another set of ideas concerns the creation of institutions supporting market exchange and the importance of these institutions for supporting disintegrated forms of production. The final set of ideas pertains specifically to innovative industries and the efficient organizational and market structure for coordinating and spurring innovative activity.

Apart from their focus on industry-level outcomes, the industrial organization theories we describe differ from the organizational theories in paying far less attention to the foundations of contract theory. They tend to assume, without spelling out exact reasons, that integration

offers more control or a greater ability to coordinate decisionmaking than a market contract does. For this reason, one can think of the two sets of theories as complementary inputs in a full explanation of vertical integration, even if this complementarity has not always been fully recognized.

4.1. Scale Economies and the Extent of the Market

An important line of research in industrial organization relates vertical integration to fixed costs and market size. This approach has its roots in Adam Smith's dictum that the division of labor is limited by the extent of the market (Young 1928; Stigler 1951; Bresnahan and Gambardella 1998). The central idea is that vertical integration decisions are closely connected to the horizontal structure of the constituent industries.

This point can be understood in a simple model that involves the production of two complementary inputs subject to scale economies. Suppose the market for the final product is so small (relative to the scale economies) that it can support only a single firm in each of the two input markets. Because of the horizontal structure in each of the two markets, the vertical relationship between the two producers is bilateral monopoly. If this relationship leads to inefficiencies because of haggling, hold-up, incentive distortions, or any of the other reasons explored above, the efficient vertical relationship calls for integration. The same problem, however, may not arise if the product market expands. Suppose that final demand becomes sufficiently large (relative to scale economies) to support a competitive market structure in both layers. With this horizontal market structure, the bilateral monopoly problem need not arise, and the efficient vertical structure may involve disintegrated specialists.

Note that this argument blends two very different bodies of theory. It requires a theory of horizontal industry structure, drawn from industrial organization, and a theory of bilateral contracting, drawn from organizational economics. Like most theories we discuss in this section, the elements are simple. But they focus attention on the joint determination of firm and industry structure and the interaction between ideas from the two fields.

Stigler (1951) developed this basic idea into a theory of industry evolution. He argued that in the early and innovative phases of an industry, firms have to be vertically integrated, because there are no markets for the relevant inputs—the costs of organizing those markets, he assumes, are higher than the costs of coordinating the production of the inputs within the firm. As the industry becomes larger, what had formerly been internal inputs are supplied by new, vertically disintegrated industries. In addition to the trade-off between efficient horizontal scale and vertical market power, Stigler's theory adds the idea that market institutions to support disintegrated trade are themselves endogenous and have to be developed over time.

Many historical accounts of particular industries resonate with Stigler's theory. One example is Rosenberg's (1994, 1998) account of how design procedures for chemical processing plants evolved over time. Initially, manufacturing firms that operated chemical processing plants undertook plant design themselves. Plant design is complex and represents a plant-level fixed cost, but much of the knowledge needed to design a single plant can be used to design other plants. Thus, the potential existed for a separate disintegrated design industry that could allow the acquisition of this knowledge to be shared across multiple plants.

As Rosenberg (1994, 1998) points out, this potential was not immediately realized, because it required the creation of a new market boundary—identifying exactly what services specialized engineering firms would provide in plant design. Ultimately, however, specialized engineering firms did emerge. Their emergence subsequently changed the degree of scale economies in chemical manufacturing, because firms no longer needed to have many plants to spread the fixed costs of maintaining a plant design capability. The change in scale economies helped facilitate a less concentrated industry structure in a number of distinct chemical processing industries (Arora et al. 2001).

Another example in which one can see evidence for Stigler's (1951) ideas comes from the integrated circuit industry. Integrated circuits must be designed and then manufactured. A few decades ago, the creation of an interface between computer-aided design and computer-aided manufacturing permitted the design and manufacture to be done either by the same firm or by different firms. As the manufacturing facilities are very large, and some products have very short production runs, the creation of the interface led to a great deal of vertical disintegration. Firms that specialize in design but do not manufacture are now able to contract with firms that specialize in manufacturing but not in design.

Scale economies play a role here, because many products with small markets may be produced in the same large manufacturing facility. There are also individual products with very large markets, such as Intel microprocessors. Firms selling the products with the largest markets, such as Intel, are vertically integrated. This permits them to strategically align manufacturing process improvements with product design improvements, presumably with less contractual frictions than might arise in a situation of bilateral monopoly between layers of production. So the variation in the extent of the market across products (rather than over time) generates patterns of integration consistent with the Stigler theory.

In addition to historical case studies of individual industries, some attempts have been made to statistically test relationships between vertical integration and varying measures of scale economies or horizontal concentration. Holmes (1999) takes an interesting approach by asking whether vertical disintegration is more prevalent in geographic areas where manufacturing industries are localized. For each plant, he measures localization as the amount of employment at neighboring plants in the same industry. Roughly, the idea is that in areas where an industry is localized, there is the potential for specialized suppliers to thrive and support a disintegrated vertical production structure. Holmes finds that vertical disintegration (measured by the share of purchased inputs in production) is indeed higher in areas where there is extensive local employment in a given industry, broadly consistent with Stigler's hypothesis.

An alternative cross-sectional approach has been to test whether industries that are more highly concentrated or have larger firms are also more vertically integrated. The Levy (1984) paper is an older but carefully executed study along these lines. Levy looks at the relationship, across three-digit industries between vertical integration (as measured by value added divided by sales) and covariates, such as average firm size, demand growth, and concentration. He reports that industries with larger firms, more demand growth, and more concentration are all more likely to feature vertical integration (see also Elberfeld 2002). Even with careful execution, however, these types of correlations are very difficult to interpret as sharp evidence for or

against any particular theory, because there are so many factors that can influence cross-industry relationships between vertical integration and other industry characteristics.²⁶

One of the elaborations of Stigler's (1951) general approach to thinking about vertical integration occurs when complementary goods are produced with very different levels of scale economies. This can lead to the common industry structure in which one or a few firms supply a general specialty or platform input that is complementary to a potentially large number of products or inputs produced by other firms (Stigler 1951; Bresnahan and Gambardella 1998). A typical trade-off here is that any efficiency benefits that might come from the platform provider integrating into complementary markets must be weighed against the potential for reduced competition.

For instance, consider a setting in which differentiated products rely on the same complementary platform. Standard models of market structure in differentiated products industries give rise to an equilibrium in which firms enjoy some market power to cover the fixed costs of product differentiation, and a trade-off occurs between achieving scale economies in a particular product versus having product variety and competition across products. If the horizontal industry equilibrium has many more firms than scale economies in the complementary layer permit, vertical integration that forecloses the platform to competing products may have the effect of eliminating the benefits of competition and differentiation in the market where they are feasible.

An example considered by Stigler (1951) is the production and transportation of manufactured goods. Efficient industry structure in production is likely to involve many distinct firms, whereas parts of the transportation system are subject to increasing returns and thus are supplied by only a few firms. Both competition and product diversity drive the production layer toward multiple firms. Although some manufactured goods (e.g., iPads) may be produced by only a few firms and others (e.g., lag bolts) by many, in the aggregate we expect a large number of firms producing a wide variety of goods. In contrast, scale economies play a much larger role in determining the equilibrium industry structure for transportation by limiting the number of railroads, canals, or roads that can link any two places as well as the number of ports or airports that can be built at any given city.

Note that there is some tension between the industrial organization theories of market structure in the types of industries we are considering (i.e., those with differentiated products) and the organizational economics theories. The industrial organization theories take certain firm boundaries as given. For instance, they offer no explanation for why a single firm could not control and produce a wide range of differentiated products. Instead, they begin with the assumption that no firm could integrate all manufacturing processes, even if it remains an open question whether each manufacturing firm owns ships or railroad cars. Although this argument can be seen as merely one of common sense, it implicitly relies on some notion of organizational diseconomies of scale or scope.

26. Acemoglu et al. (2009) take a somewhat different approach by asking whether firms in countries that are more financially developed are more or less likely to be vertically integrated. They find no direct relationship between financial development and the prevalence of integrated firms, but they do find a higher prevalence of integration in countries that have both greater financial development and higher contracting costs.

This gap has been met partially by organizational economics theories that explain organizational diseconomies of scale. Williamson's (1985) suggestion that bureaucratic decisionmaking is one disadvantage of large firms, Simon's (1947) idea that larger firms must undertake more communication, and Radner's (1992) idea that more complex and larger teams will make worse decisions have all received some exploration in this regard.²⁷ These questions, which have received only modest attention in organizational economics, become particularly important when we consider the joint determination of firm and industry structure.²⁸

4.2. Role of Strategy in Determining Industry Structure

The simple framework discussed above suggests a relationship between horizontal concentration and vertical integration that is driven by efficiency considerations—the size of scale economies relative to the size of the market. What it neglects is the possibility that firms might make strategic efforts to limit competition. An industry can be very concentrated and feature considerable market power because of scale economies or because business strategy limits the number of active firms (e.g., by affecting the potential for entry).²⁹ Indeed, that organizational economics theories have focused so much on efficiency rationales for vertical integration suggests that we might want to reformulate Coase's crack about monopoly theories: nowadays if an economist finds something—a business practice of one sort or another—that she does not understand, she looks for an efficient contracts explanation!³⁰

Once we allow for the possibility of strategic investments, the relationship described above between market size and concentration can become less clear. Consider the class of industries that feature what Sutton (2007) has called “endogenous sunk costs.” These are industries in which firms can undertake strategic investments (e.g., in technological innovations or brand building) to make their products more attractive. If the investment opportunities in endogenous sunk costs are sufficient (in a sense made precise in the literature), then industry structure remains concentrated, even as demand grows without limit. The link from increased market size to reduced horizontal concentration to vertical disintegration is broken.

A very large literature on industrial organization also has pointed to the potentially important role of vertical integration or vertical contracts themselves in helping to limit competition or more generally influence horizontal market structure. A classic example might be a monopoly supplier of an input that integrates or signs an exclusive contract with the supplier of a complementary input to maintain monopoly power in the first market or create it in the second. The literature has debated two questions about this type of situation. First, is it even possible for

27. See, among others, Simon (1951), Calvo and Wellisz (1978), Williamson (1985), Radner (1992), Anton and Yao (1995), and McAfee and McMillan (1995). Some evidence on the source of scope diseconomies in technology industries can be found in Bresnahan et al. (2012).

28. Another partial solution comes from the industrial organization theories themselves. Models of horizontal disintegration through competitive entry call for separate firms in order to have competitive outcomes. Vertically integrating all firms in a competitive industry with the same complementor would defeat the competitive purpose.

29. See, for example, Berry and Reiss (2007) and Sutton (2007).

30. Coase's (1972: 67) original line was: “If an economist finds something—a business practice of one sort or another—that he does not understand, he looks for a monopoly explanation.”

the monopoly supplier to raise prices by integrating? Second, is it anticompetitive, and as such, should antitrust policy seek to prevent this type of strategic foreclosure?³¹

Whinston (2007) provides a lucid and thorough treatment of these issues, which go well beyond the scope of this chapter. We note, however, that this literature—although potentially highly germane if one wants to understand the joint determination of firm and industry structure—has by and large not connected with organizational economics rationales for integration. Indeed, it often treats vertical integration and restrictive vertical contracts in roughly a parallel fashion. It is true that in formulating antitrust policy, the potential organizational efficiency benefits of allowing a contract or merger to go through are sometimes weighed against the competitive costs, but generally these are treated as distinct phenomena.

We also note that in addition to strategic theories in which firms integrate as a way to gain market power in anticompetitive fashion, there are arguments for why strategic integration might be welfare enhancing. For instance, Teece (1986) has suggested that firms can sometimes integrate to consolidate “good” market power. If a firm has an invention in an area with poor patent protection, for example, it might vertically integrate into a downstream business with entry barriers and avoid losing the return on its innovation through competition.³² Another class of theories, discussed for instance in Perry (1989), consider how vertical integration can facilitate certain forms of price discrimination that might be efficient (e.g., by allowing a supplier to integrate downstream and sell its input at different prices to the integrated downstream producer than it does to the general market).

4.3. Market Institutions and Vertical Integration

The point made by Stigler (1951) that market institutions need to be invented before a wide variety of firms can participate in them remains only partially explored in organizational economics. Distinct literatures have taken up this question, many of which raise interesting issues about vertical integration and market structure.

A textbook benefit of a well-functioning market is that the price mechanism coordinates the needs of many parties and determines an efficient use of resources. If matching is less efficient, a buyer and seller might agree to go around the market. This idea is captured in Carlton’s (1979) model of supply assurance as a rationale for vertical integration. He considers a setting in which market frictions upset the functioning of the spot market for inputs, so that buyers cannot be assured of reliable supply. If the problem is severe, buyers want to integrate upstream, or

31. The Hart and Tirole (1990) paper is a classic reference on the first question, which turns on the question of commitment: after integrating forward, can the supplier really commit to shutting off supply to rival downstream firms? On the second question, the classic argument against government intervention is the “one monopoly rent” story associated with the Chicago School. The basic argument is that, in some circumstances, a monopolist supplier can achieve the same profit regardless of whether it integrates forward and raises the downstream price or simply raises the input price. Whinston (2007) discusses a range of conditions under which this argument does not hold, and vertical integration or exclusive contracts indeed can be anticompetitive.

32. Of course, the same argument applies to any tactic that might generate market power, and the Teece (1986) proposal has become a general management doctrine for creating rents at the firm level. See, for example, the widely cited article by Amit and Schoemaker (1993).

alternatively formulate a nonmarket forward contract to assure supply.³³ So Carlton's theory provides a potential explanation in which vertical integration might be linked to the existence of a well-functioning market interface between layers of production (see also Green 1986).

A related observation can be made in the context of transaction cost analyses of integration. If we consider, for instance, the studies of transportation industries, such as trucking or shipping discussed above, a central problem being solved is logistical—the efficient short-run allocation of heterogeneous suppliers to heterogeneous tasks. The existence of market institutions—standard contractual forms, preexisting agreements on exactly what service will be exchanged, or the availability of comparable reference prices on which to base negotiation—can be crucial to support a disintegrated structure, because they are necessary to support efficient, predictable, and potentially competitive agreements at low cost.

The existence of market institutions to support disintegrated exchange is not a given. In many cases, market institutions tend to co-evolve with industry structure. Financial markets provide an exceptionally rich set of examples. Consider, for instance, a loan from a bank to an individual to allow the individual to purchase a house. Historically in the mortgage market, the same bank extended the loan and then undertook collections and received interest and principal payments from the borrower. In this setting, selling a loan portfolio would have been an idiosyncratic and unusual transaction. Yet over time, the development of relatively standard securitization contracts allowed the initial originators of loans (banks and later also less well-capitalized companies) to sell their loans to investors, creating a vertically disintegrated market structure, albeit one with some potential incentive problems on the part of loan originators.

The securitization example is useful: one can in fact point to a range of institutions required to support a disintegrated market structure. These include not only standardized contracts to facilitate sales of loans but also effective institutions for transferring foreclosure rights in the event of a default, rating agencies to limit the potential for adverse selection in the sale of loans, and functioning markets to allow investors who have bought securities to later sell them. From this perspective, standard transaction cost variables, such as complexity and specificity, look somewhat different. A particular transaction—say, the sale of a loan portfolio—might seem highly complex and specific at one point in time, but much less so once market institutions are developed to support it.³⁴

The more general point here is that transaction costs depend on existing market institutions—institutions that facilitate search and matching, and institutions that facilitate contractual and pricing arrangements. As a result, a disintegrated market structure—particularly the creation of a disintegrated industry with frequent arm's-length exchanges—often requires the creation of market institutions: standards for products and contracts, and mechanisms for matching buyers and sellers, determining prices, disseminating information, and so forth. Although these issues fall outside the traditional theory of the firm, they become hard to avoid

33. Bolton and Whinston (1993) provide an alternative model, based on the property rights theory, that also shows how supply assurance motives can lead firms to vertically integrate.

34. At the same time, the creation of market institutions is facilitated by having a degree of standardization in the underlying products. It may be relatively easy to develop an effective market for loan resale if the loans themselves are relatively standardized in most dimensions.

when one takes the theory to empirical settings, and perhaps they deserve more attention from organizational economists interested in firm boundaries.

4.4. Coordination and Innovation

A wide range of economically important innovations depend on complementary but distinct inventions. Computers would not be particularly valuable without applications software, to take one famous example. New products are more valuable if process innovations allow them to be produced cheaply. The invention of mass production itself would have been much less valuable without transportation technologies that permitted large plants to serve geographically dispersed customers. Research on platform industries, on product and process innovations, and on general-purpose technologies all emphasize the importance of coordinating complementary invention and raise the question of whether this should take place within large organizations or across disparate innovative firms.³⁵ The resulting trade-offs provide an interesting example of how organizational theories of integration intersect with considerations of market structure.

A potential benefit of integrating the invention of complementary technologies is that investments may be better coordinated. A basic price theory intuition is that creators of complementary inventions may end up in a position of bilateral or multilateral monopoly, and they may fail to coordinate their pricing and other *ex post* decisions. This can lead to a form of hold-up where the full returns on *ex ante* investment are not appropriated. Kenneth Arrow (1974) famously pointed out one particular problem with contracting over innovation, which is that firms seeking to reach an agreement may find it difficult to exchange information in a way that protects their ideas. For these reasons, vertical integration, or a similar contract to internalize externalities in complementary invention, can increase the private return from innovative activity.

A second and distinct argument for integration comes from game theory. The multiple invention problem is a coordination game, and it might have failures to coordinate if the different inventors cannot be sure *ex ante* of one another's plans for invention. In addition, separate firms may have an incentive to delay investments in order to assess which technologies or standards will emerge as grounds for coordination. These forces work against decentralized innovation and favor *ex ante* partner selection and contracting.

A countervailing force comes from the economics of invention with uncertain goals or methods. Suppose that, in one or more of the complementary inventions, the highest value direction of technical progress is *ex ante* uncertain. Different potential inventors can have different views about the appropriate direction, based on their private information. In such circumstances, *ex ante* selection among alternative invention projects can be inefficient, even when there is a fixed cost of inventive effort.³⁶ The alternative is to have invention competition and then let the market choose the best alternative. The advantage of *ex post* invention market

35. In the case of truly infrastructural inventions, such as those in transportation, communications, or basic scientific research, government has also played a considerable role in coordinating innovation. In this chapter, however, we focus on the trade-off between markets and integrated firms.

36. See Nelson (1961), Evenson and Kislev (1976), Metcalfe (1986), and Klepper (1996) for models of competition with uncertainty about the direction of technical progress with *ex post* market selection.

selection is that it can choose the best innovative efforts out of a number of initiatives based on their technical success or their success in meeting market needs. As a result, a market form of organization may have considerable value when there is substantial uncertainty about the optimal direction of technical progress or about the source of that progress,

The computer industry, which over time has witnessed both a high degree of vertical integration and considerable disintegration, provides a useful case study of these considerations.³⁷ The first highly valuable segment of the industry, mainframe computers for corporate data processing, was pioneered in the 1950s. IBM, which dominated the market for four decades, was highly vertically integrated in invention and production. Its inventions included not only the computer but also a large number of complementary hardware and software components useful in business data processing.³⁸ As a result, the boundary of the firm coincided with the boundary between general and specific technologies. IBM sought to supply all general-purpose components for its corporate customers, including the tools that would let them invent specific applications.

What factors might have led to all of the general components, each of which needed ongoing invention, being supplied by one firm? The key was the *ex ante* identification of a desired direction of technical progress for the system as a whole. At the time of IBM's entry into computing, the basic technical knowledge associated with the computer itself was largely public.³⁹ IBM was already the leading seller of business data-processing products and subsequently built a research and invention capability in computers.⁴⁰ As a result, IBM had knowledge not only of the technical opportunity but also of demand needs. This information gave a single firm considerable *ex ante* knowledge about the set of feasible directions for improvements in the overall system and the set of products that would be valuable to its customers. IBM picked reasonable innovative goals from the intersection of these two sets, allowing it to coordinate multiple inventions in the general mainframe components—computer, tape drive, programming languages, and operating system—going forward.⁴¹

37. See Bresnahan and Greenstein (1999) and Bresnahan and Malerba (2002). See also Langlois and Robertson (1992) on the value of vertical disintegration at the PC industry segment's founding.

38. These components included data-processing complements (e.g., tape or disk storage devices), input and output devices (e.g., printers), and especially software (e.g., operating systems and database management systems). Throughout IBM's tenure as the leading firm in this segment, customers had a high opinion of the way the complements making up an IBM system worked together but not of the technical level of its computers themselves.

39. It is important to point out that this discussion refers to the creation of computer systems for business use, not to the original invention of the computer itself. Many essential elements of the computer itself were invented before IBM's entry. The view, taken by IBM and others, that these essential elements were in the public domain, was extremely controversial. The controversy was heightened by IBM's late entry into the computer business and appropriation of existing knowledge. See Bresnahan and Malerba (2002) for a discussion. The point here depends on the fact that IBM, already knowledgeable about demand needs, could easily appropriate knowledge associated with the invention of the computer itself, not on the propriety of that appropriation.

40. The earlier business products were mechanical and electromechanical products, such as card sorters.

41. Industry historians will point out that this story misses important nuances. For example, the later emergence of applications software companies, especially semi-custom software developers such as EDS, meant that the distinction between the general and the specific is not such a bright line. Our point that the IBM system was largely one of vertical integration of the general components is robust, however.

The same trade-off worked the other way at the founding of another important computer industry segment, the personal computer. In that instance, *ex ante* knowledge about the overlap of technically feasible inventions and demand needs was much weaker, making coordination difficult. None of the founders of the personal computer industry—the designers of computers, disk drives, programming tools, or operating systems—had a clear view of the appropriate direction of technical change *ex ante*. As a result, the original industry structure was not vertically disintegrated, with considerable independent innovation in each component. Coordination was achieved *ex post* invention through market institutions, such as voluntary compliance with interconnection standards.⁴²

Eventually, the invention of certain key applications, such as the word processor and the spreadsheet, helped clarify the direction of technical change—namely, toward business applications. That increased clarity led to efforts to coordinate supply by contract, notably in the IBM PC.⁴³ Those contracts, however, did not specify the direction of technical change, nor were they exclusive on either side. Innovation in the different components continued to be organized more along market lines than by contract.⁴⁴ Indeed, some of the leading firms involved in IBM PC contracts, including IBM itself, were later replaced by others through market selection. The advantage of vertical disintegration of invention, even of the general-purpose components, was the possibility of component-by-component invention races and the extensive use of *ex post* market selection, also on a component-by-component basis.

This vertical industry structure and component-by-component market selection process continued through a number of rounds of fundamental innovation. Indeed, some dominant firms supplying important PC markets were replaced through competition for the market on a component-by-component basis.⁴⁵ As long as the overlap between technical opportunity and demand needs was hard to see *ex ante* the next round of innovation, the less-coordinated model had considerable advantage.

Another example of the trade-offs in coordinating innovative activity comes from the organization of scientific research. Here the relevant boundary is between firms that undertake research with the express purpose of commercialization, and universities and other organizations that undertake research with potentially broader objectives. The resulting industry structure often locates basic research in noncommercial organizations, with applied research taking place in firms in a vertically disintegrated structure (though the distinction is frequently blurred). In a pioneering article, Dasgupta and David (1997) emphasize two points about this structure: first, that the reward structure for academic scientists is very different than it is for commercial inventors; second, that noncommercial research institutions are organized very differently than are firms.

42. Once again, we skip important nuances. Some firms, most successfully Apple, had a more vertically integrated model. See Langlois and Robertson (1992) for more details, and for the observation that the more vertically integrated efforts failed precisely because of their integration.

43. IBM entered with a computer and sought to contract with the leading firm in each important complementary technology, successfully so in disk drives, spreadsheets, programmer tools, and microprocessors. In operating systems or word processors, the leading firm would not sign and IBM found other partners.

44. Even hardware specifications of the computer itself were set in the market by firms other than IBM. See Bresnahan and Greenstein (1999) for details.

45. See Langlois and Robertson (1992) and Bresnahan and Greenstein (1999) for details.

The structure of incentives facing scientists rewards them less with money and more with freedom, prestige, and status (Stern 2004). These peculiar goals are reflected in a large number of distinctive scientific institutions, including peer review, status based on priority rather than ultimate commercial success, and openness in publication and the permission of replication. Because these institutions were designed by scientists rather than by managers (i.e., individuals interested primarily in the commercialization of science), they lead to a situation in which even commercial scientists' rewards can depend more on other scientists than on the managers in their own organizations. The incentives created by scientific institutions can enhance productivity—openness, for example, lowers the costs of access to existing knowledge by a large group of potential inventors, while competition to be first pushes each discipline toward more rapid technical progress. But it also can have disadvantages, for example, if peer review leads to rewards for work that is highly regarded by one's peers but not particularly useful or interesting to others outside one's narrow field. In contrast, the system of incentives for commercial innovation is more straightforward, as the market provides a primary metric for success.

These differences lead to tensions when basic and applied research take place in a disintegrated fashion. Commercially oriented managers experience difficulty incentivizing scientists to engage in work that is not rewarded by their discipline (e.g., work on specific rather than general problems) or to interact with others outside their field. For scientists who are considering commercializing their inventions or discoveries, there can be a commercial incentive to keep innovations secret rather than to publish, weakening the reward system of academic science (Murray and Stern 2007). And successful structures at the boundary of science and commercialization, such as university licensing programs kicked off by the Bayh-Dole Act permitting university scientists to patent inventions that result from government-funded research, sometimes have been criticized for distorting basic scientific research incentives.

Nevertheless, there are considerable reasons to think that a system whereby basic scientific research was left to commercial firms would be problematic. Perhaps the most obvious are the lack of immediate commercial reward to foundational research and the spillovers that result from many scientific breakthroughs. Even when scientific research produces inventions that are in principle appropriable, they may not be appropriable in their initially planned use. A large and diverse firm might be able to capture some spillovers from scientific research but not all of them. A famous example comes from Bell Laboratories. Bell Labs worked not only on basic engineering projects but also on basic science, discovering (among other things) the transistor effect. Although the Bell System certainly had uses for a wide range of inventions, the breadth of use for the transistor was too wide even for highly diverse Bell, so the firm put that fundamental innovation into the public domain as part of a strategy to avoid government interference.

5. Conclusion

We have discussed a wide range of economic theory and empirical work related to the vertical integration or disintegration of production. Theories from organizational economics have tended to focus on the contractual issues that affect the integration decisions of individual firms, posing an interesting contrast to resource- or capabilities-based theories of integration, and to industrial organization theories that emphasize the relationship between integration decisions and the determination of horizontal market structure. We have argued that the intersection of

these areas—in particular, how transaction cost issues interact with other forces to determine the overall structure of industries and markets—deserves more attention. We also see considerable room for progress in formulating empirical tests of the various theories and in measuring the incidence and importance of transaction costs under alternative contractual or organizational arrangements. As better data on contracts and organizations become available, most notably in emerging areas (e.g., the online world and rapidly industrializing economies), we expect there will be many opportunities along these lines.

Ownership and Organizational Form

Henry Hansmann

1. Introduction

In contemporary market economies, productive enterprise is undertaken predominantly by large numbers of independent firms. Although in theory these firms could be organized in myriad ways, in practice they typically adopt one or another of a small number of standard forms. In this chapter we examine the basic elements of those forms and analyze the economic forces that induce their adoption.

Section 2 begins by exploring the basic legal nature and economic role of the firm. We focus on the firm as a contracting entity, and on the relationship between two different boundaries of the firm: the control boundary and the asset boundary. Sections 3–9—the heart of the chapter—then turn to the ownership of the firm. We examine why it is that a firm is typically owned by one or another class of its patrons—that is, its suppliers and customers—and seek to explain the choice of the ownership class as a trade-off between costs of market contracting and costs of ownership. We focus, in this connection, not just on investor-owned firms but as well on the surprisingly numerous forms of supplier-owned firms, customer-owned firms (including mutual companies), and employee-owned firms (including professional partnerships) that are found in modern economies. We also consider, in the same framework, nonprofit firms and governmental enterprise.

Section 10 briefly explores the patterns of owners' and creditors' rights that constitute the basic standard forms for legal entities and the reasons for evolution in those forms. Section 11 asks why law is important to firm structure and governance. Section 12 concludes.

2. What Is a Firm?

The economics literature has long described a firm as a “nexus of contracts” (Jensen and Meckling 1976). As it has come to be used, this expression is ambiguous. Often it is invoked simply to emphasize that most of the important relationships in a firm (including, in particular, those among the firm's owners, managers, and employees) are essentially contractual in character. This

insight is important, but it does not distinguish firms from other networks of contractual relationships.

2.1. Control: The Firm as a Nexus for Contracts

The more fundamental fact is that a firm is a nexus *for* contracts. More precisely, a firm is a common party to a group of contracts—what might be termed a “contracting entity.” Although authority in a single firm is often exercised through a cascade of relationships, as in the conventional pyramidal organization chart, that is not the way that a firm’s contractual relations are organized. General Motors, for example, is the common party to millions of contracts with the firm’s investors, employees, suppliers, and customers. Employees of the Chevrolet division each have a contract of employment with General Motors, and not with the Chevrolet division, much less with departments or supervisors in the division. The same is true of suppliers of steel to GM or any of its divisions, and of dealers that purchase cars produced by GM.

Figure 1 offers a simple illustration. The nodes numbered 1 through 12 are distinct persons—either natural persons (individuals) or firms. The dark connecting lines indicate contractual relationships. For concreteness, we might assume that persons 1 through 4 are employees, persons 5 and 6 are lenders of capital, persons 7 and 8 are suppliers of other productive inputs, and that persons 9 through 12 are customers. Together, these persons constitute the patrons of the firm—that is, persons who have a contractual relationship with the firm as either a supplier or a customer. Figure 1a shows a single firm, designated A, with each of the 12 persons as patrons. In Figure 1b, in contrast, the same persons are patrons of two distinct firms, designated B and C (which might or might not themselves be connected by contract, as indicated by the dashed line).

A much-studied question, famously raised by Coase (1937), concerns the efficient scope (or boundary) of an individual firm. One interpretation of this boundary question is to ask which persons should be made patrons of a given firm. Under what circumstances, for example, is the one-firm structure in Figure 1a more efficient than the two-firm structure in Figure 1b? The answer to this question concerns, importantly, the appropriate scope of control for the managers of a firm. The owners of a firm, or their designated managers, have authority to exercise the discretion—that is, the residual control rights—afforded by the various contracts to which the firm is a common party. In choosing between the alternative firm structures in Figure 1, for example, it is important to know whether it is more efficient to have discretionary authority over all contractual rights in the hands of a common management, as in Figure 1a, or divided, as in Figure 1b. Moreover, just as a firm can enter into contracts in its own name, it can also own assets in its own name; consequently, the firm’s discretionary powers extend beyond its contractual rights to include the residual control rights that are a concomitant of ownership (Grossman and Hart 1986).

The determinants of the firm’s boundaries in terms of control, and related issues of incentives, are surveyed in Bresnahan and Levin (this volume), Gibbons and Roberts (“Incentives in Organizations,” this volume), Lafontaine and Slade (this volume), and Segal and Whinston (this volume). Considerations beyond the scope of control are involved in choosing a firm’s boundaries, however. In particular, there is the question of how the firm’s contractual commitments are to be bonded.

Figure 1. The firm as a nexus for contracts.

2.2. Bonding: The Firm as Asset Partitioning

As a general default rule of law, the contracts entered into by a firm—or by any legal entity,¹ including a natural person—are bonded by the assets owned by that firm, in the sense that a patron with an unsatisfied claim against the firm can seize the firm's assets to satisfy that claim. An important distinction between the organizational structures shown in Figure 1, then, is that in Figure 1a the contractual claims of both patron 1 and patron 2 are bonded by all the assets (including contractual rights, e.g., accounts receivable) of Firm A, whereas in Figure 1b the same bonding assets are partitioned into two separate pools, with the claims of patron 1 bonded by the assets of Firm B, while the claims of patron 2 are bonded by the assets of Firm C.

This distinction becomes particularly salient when one firm owns another. Suppose, for example, that the two firms in Figure 1b are organized as separate business corporations but

1. The term “legal entity” is used broadly here to comprise all the law’s standard forms for enterprise organization, from marriages, trusts, and partnerships to business corporations, nonprofit corporations, and municipal corporations. Thus, the terms “legal entity” and “contracting entity” are used synonymously. Because the term “legal entity” has various and often vague definitions in the law, however, some legal authorities would not consider all these forms to be legal entities.

that firm C is a wholly owned subsidiary of firm B (a relationship which we can now take to be indicated by the dashed line connecting them). In that situation, there is effectively no difference between the organizational structures in Figures 1a and 1b in terms of control: the managers of B can exercise as much control over the decisions of C as they could if C and B were merged into a single firm, as in Figure 1a. (The most direct means of establishing control is simply to install employees of B as the directors of C.) Yet the structures in Figures 1a and 1b would nonetheless remain very different in terms of creditors' rights. If C becomes insolvent, then a creditor of C—that is, any patron of C with an unsatisfied claim against the firm—can proceed only against the assets of firm C. The patron has no claim on the assets of firm B, even if B is quite solvent, and even though B entirely owns and controls C. This is a consequence, of course, of the limited liability that is granted the owners of business corporations. In this sense, limited liability partitions the assets of Firms B and C between their respective creditors, giving Firm B's creditors exclusive claim on that firm's assets.

But there is another aspect of asset partitioning that, though less often commented on, is more fundamental than limited liability. To see this, suppose that firm B goes bankrupt while firm C remains solvent (i.e., C's assets are more than adequate to pay what is owed to C's own creditors). Then C's creditors will be paid in full out of C's assets before any of those assets become available to satisfy B's creditors. Put differently, firm C's assets—and hence its creditors—are shielded from the creditors of firm B by virtue of the fact that B is a separate corporation. This is an example of the general characteristic of *entity shielding* that is a feature of all legal entities: creditors of the firm have priority of claim, over the creditors of the firm's owners, on all the firm's assets. Entity shielding is, in a sense, the converse of limited liability, which is a form of *owner shielding* that gives the creditors of a firm's owners first (or exclusive) claim—over the creditors of the firm—on assets owned directly by the firm's owners.

It is asset partitioning—entity shielding and limited liability—that make the situations in the two diagrams in Figure 1 fundamentally different, even when Firm B owns Firm C. What is the advantage of the two-firm structure of Figure 1b? Most importantly, it can reduce the organization's overall cost of capital. Suppose, for example, that a firm in the airline business decides that, to realize some valuable synergies, it will also enter the hotel business. Then it is likely to be advantageous to set up the hotel business as a separately incorporated subsidiary, like C in Figure 1b, while the airline is operated by the parent, like B in that figure, or by a separate subsidiary of the parent. The reason is that creditors of the hotel business (lessors of land and buildings, vendors of furnishings, suppliers of linens, etc.) may be quite familiar with the prospects of the hotel industry in general, and with the management (and competitors) of C's hotels in particular, and hence in a good position to estimate the risks of doing business with C. At the same time, they may be quite unfamiliar with the airline industry, and hence poorly positioned to appraise the risks of being a creditor of B. With C separately incorporated, C's creditors can adjust their terms of business according to the risks posed just by C and can largely ignore the likely fortunes of B. Likewise, creditors of B (e.g., lessors of aircraft and vendors of jet fuel) can focus principally on the risks of the airline industry, which they are well positioned to understand, and can largely ignore the likely fortunes of the hotel operations undertaken through the subsidiary C. Thus, the aggregate cost of credit—or, more generally, the aggregate cost of contracting—for the airline and hotel operations may well be reduced by

organizing those operations as separate entities, even though they are under common overall management.

In short, by partitioning an organization's assets so that some are pledged to the patrons of one line of business while others are pledged to the patrons of another line of business, the two-corporation structure can reduce monitoring costs for creditors by allowing them to focus just on the assets and operations with which they have greatest familiarity.² But the same two-corporation structure may also bring added costs, relative to the single corporation structure, by creating the potential for opportunistic behavior on the part of the parent firm B and its owners. Most obviously, B's owners might be tempted to drain assets out of C and into B, to the detriment of C's creditors, if it begins to look as if C will fail.³ Various legal rules and contractual devices are designed to inhibit such opportunism, but they are imperfect. As a consequence, organizing the two commonly controlled businesses as separate corporations, rather than as mere divisions in a single corporation, is efficient—holding other considerations constant—when the reduction in the costs of creditor monitoring exceeds the increased costs of opportunism on the part of the firms' owners.⁴

Although we have focused on a corporate subsidiary to illustrate the role of the legal entity as a device for asset partitioning, the same considerations are involved in partitioning the assets of a firm from the assets of the firm's owners in general. In the conventional business corporation with multiple shareholders, for example, limited liability shields the personal (and other business) assets of the firm's owners from the claims of the firm's creditors, while entity shielding protects the firm's assets from the claims of the shareholders' personal creditors and other business creditors. In firms with multiple owners, both these forms of asset partitioning not only offer the monitoring economies described above but also facilitate the transferability of shares by making the creditworthiness of the firm largely independent of the personal creditworthiness of the firm's owners.

Limited liability has, until recently, been the principal focus of the literature on the economic relationship between organizational forms and creditors' rights (Halpern et al. 1980; Woodward 1985; Easterbrook and Fischel 1991). Yet entity shielding—although until recently largely ignored (and even lacking a name) in the Anglo-American literature in both law and economics—is the more elemental rule (Hansmann and Kraakman 2000a,b; Hansmann et al. 2006). All standard legal forms for enterprise organization today offer entity shielding; that is, they give the creditors of the organization first claim on the organization's assets, ahead of the individual creditors of the firm's owners. Limited liability, in contrast, is not universal. For

2. Thus, legal entities can serve a function long recognized for security interests in specific assets (Jackson and Kronman 1979).

3. Opportunistic behavior of the reverse character, exploiting entity shielding rather than limited liability, is the problem if it is the parent corporation B that might fail. In that situation, B's owners have an incentive to pass more of B's assets down to C, hence shielding them from B's creditors and permitting them to be used as security for further borrowing on the part of C. This tactic was central to the financial debacle at Enron, which created more than a thousand subentities for the purpose of extensive nontransparent leveraging. The bankruptcy doctrine of substantive consolidation is a crude means of dealing with this form of opportunism.

4. Other factors, such as the likelihood of incurring the administrative costs of bankruptcy for one or another entity, must also be entered into the efficiency calculus (Hansmann et al. 2006).

example, the partnership offers entity shielding but not limited liability. And the partnership, not the corporation, was the dominant form for organizing commercial activity in Western society from the Middle Ages until the late nineteenth century.⁵

All this is logical. Limited liability demarcates the assets on which the creditors of the firm do not have a claim. Entity shielding demarcates the assets on which the creditors of the firm do have a (prior) claim—that is, the pool of assets that affirmatively bond the firm’s contractual commitments.

2.3. The Boundaries of the Firm: Control versus Assets

In all the standard legal forms for enterprise organization—such as partnerships, business corporations, nonprofit corporations, and trusts—the organization’s scope of control and its pool of bonding assets are, as a default rule, coterminous, in the sense that the organization’s bonding assets comprise all the contractual and property rights over which the organization has control and, conversely, all the firm’s contracts are (unless otherwise specified) backed by all the organization’s bonding assets. The reason is that legal entities serve, critically, as devices for signaling the assets that back contractual commitments. As illustrated in the discussion of the hypothetical organization that is engaged in both the airline and the hotel businesses, however, the efficient scope of control may be different from the efficient size of a pool of bonding assets. We might say that, in such cases, the efficient boundary of the firm for control purposes (the “control boundary” of the firm) is different from the efficient boundary for bonding purposes (the “asset boundary” of the firm).⁶

In particular, as the airline-hotel example shows, the efficient asset boundary may be smaller than the efficient control boundary. In that case, the different business activities may be organized into two (or more) distinct entities, with one owned entirely by the other or with both owned by a third entity (e.g., a holding company). Subsequent sections focus principally on entities with multiple owners. But, for the reasons discussed above, entities with a single owner—such as a business corporation with a single shareholder—can also be efficient and are extremely common. General Electric, for example, has about 1,500 separately incorporated subsidiaries, most of which it wholly owns.

3. Ownership of the Firm

In principle, the choice of a firm’s owners is largely distinct from the determination of the boundaries of the firm: ownership can be structured in any of a host of different ways for a firm with any given control and asset boundaries. In practice, however, the two questions are related, because the owners of the firm are nearly always a subgroup of the firm’s patrons, that is, of the persons with whom the firm has a contractual relationship as suppliers or customers.

5. The historical evolution is actually somewhat more complex. The partnership, though lacking limited liability, had a weak form of owner shielding throughout most of the past millennium. See Section 10.

6. Iacobucci and Triantis (2007) draw a similar distinction between what they term the “economic” and the “legal” boundaries of firms; they survey some further considerations in dividing activities across two or more separate corporate entities.

3.1. Owned versus Unowned Firms

The “owners” of a firm—as that term is conventionally used and as it is used here—are persons who possess two rights: the right to control the firm and the right to appropriate the firm’s residual earnings. There are obvious incentive reasons for putting these two rights into the same hands: if those who control the firm are not entitled to its residual earnings, they have little incentive to maximize those earnings, and hence may manage the firm inefficiently. Consequently, most firms have owners. There are, however, some firms, such as nonprofit firms, in which the right to control is separated from the right to receive residual earnings, making the firms ownerless (or, viewed differently, self-owned). The discussion that follows focuses first on the assignment of ownership in firms with owners and then examines the reasons some firms do not have owners. The approach overall will echo that followed by Hansmann (1988, 1996).

In speaking of the persons who have the right to control the firm, we mean here the persons who have what might be termed “ultimate,” or “formal,” control rights. In a business corporation, for example, the owners—the firm’s shareholders—may lack the right to manage the firm directly and simply have the right to elect the firm’s board of directors and to approve major transactions, such as mergers or dissolution of the firm. In a publicly traded corporation with dispersed shareholdings, even those rights may in practice be exercised feebly, making the firm’s management effectively self-appointing. For this reason, it is often said that such corporations exhibit a “separation of ownership from control.” In the discussion that follows, however, such a statement is an oxymoron: ownership by definition comprises control. However attenuated the ultimate or formal control rights may be, in their structure or in their exercise, the persons who hold them are, for purposes of the discussion here, the firm’s owners, so long as they also have the right to appropriate the firm’s residual earnings. Consequently, the shareholders of a business corporation are clearly its owners, however modest their effective control over the firm’s managers may be. An important reason for this usage is that, as discussed below, the economic considerations that lie behind the choice of a firm’s owners seem to apply to both strong and weak owners.

3.2. Ownership by Patrons

In theory, anyone could own a firm. In practice, however, the assignment of ownership follows very distinct patterns. In particular, the owners of a firm are nearly always one or another subset of the firm’s patrons—that is, persons who have some transactional relationship with the firm, either as suppliers or customers, apart from their possession of the rights of ownership. Often that transactional relationship is the supply of capital to the firm, in which case we have the conventional investor-owned firm. Not infrequently, however, ownership of the firm is instead placed in the hands of another class of patrons. This is the case, for example, with producer cooperatives, consumer cooperatives, mutual companies, employee-owned firms, and governments (which, when democratic, are essentially a form of consumer cooperative). Indeed, such noninvestor-owned firms play an astonishingly large role in modern economies, from consumer goods wholesaling and agricultural marketing to retail franchising, financial services, and the service professions; we consider a number of representative examples below.

Consequently, in exploring the assignment of ownership, the focus here is on (1) why firms are owned by their patrons, (2) what determines which class of patrons is given ownership, (3) why that class often—but by no means always—is a subset of the suppliers of capital, and (4) why some firms, such as nonprofit firms, have no owners at all.

3.3. The Efficient Assignment of Ownership

The evident reason ownership of firms is typically assigned to one or another class of the firm's patrons is to reduce the costs of contracting between the firm and those patrons. The circumstances surrounding the contractual relationship between a firm and its patrons—such circumstances as market power, asymmetric information, or the need for the patrons to make transaction-specific investments—often place the firm in a position to behave opportunistically toward its patrons if it deals with them on an arm's-length (or “market”) basis. Making the patrons the owners of the firm reduces or eliminates the incentive for the firm to exploit that position.

If this were the only consideration in the assignment of ownership, then efficiency would call for assigning ownership to the class of patrons for whom the costs of market contracting would be highest, or perhaps for simply sharing ownership of the firm among all its various types of patrons. But ownership, too, has its costs, including most obviously (though not necessarily most importantly) the agency costs associated with delegation of authority to the firm's managers. Some patrons are better positioned than others to keep those costs low. Consequently, when choosing which class of a firm's patrons are to be its owners, there can be a trade-off between reducing the costs of contracting and reducing the costs of ownership. Moreover, the costs of market contracting for any given class of patrons may be affected by which group, among the firm's other patrons, is given ownership. Efficiency therefore calls for assigning ownership in a fashion that minimizes the total costs of contracting and of ownership for all the firm's patrons combined. That is, in a firm with n groups of patrons, the efficient assignment of ownership is to the group that satisfies

$$\min_j C_j^o + \sum_{i=1}^n C_{ij}^c,$$

where C_j^o is the cost of ownership when patrons in group j own the firm, and C_{ij}^c is the aggregate cost of contracting for patrons in group i when group j owns the firm.

Of course, the costs of market contracting can commonly be reduced or eliminated not just by having the firm owned collectively by its patrons but conversely by having the firm own its patrons, as when a firm integrates upstream to own its suppliers or downstream to own its customers. Often, however, there are strong incentives (well captured by Grossman and Hart 1986) for keeping each patron under separate ownership, whether the patrons are individuals (where ownership by the firm implies slavery) or small businesses. It is the latter situations, where the firm is owned by a numerous subset of its patrons, that are our focus here.

3.4. Market Selection

If ownership is relatively easy to reassign from one group of patrons to another, and if organizational law, taxation, and regulation do not strongly influence the choice of ownership form,

then—by virtue of market selection and self-conscious choice—the patterns of ownership we observe should generally be efficient. As it is, these conditions are reasonably well satisfied in the United States⁷ and apparently hold to a rough approximation in most other developed market economies as well. Consequently, existing patterns of ownership should offer evidence as to the relative importance of the various costs of contracting and ownership. With this in mind, let us proceed to look first at the costs of contracting and then at costs of ownership, considering examples of industries where these costs seem conspicuous in determining which patrons own the firm.

4. The Costs of Contracting

There are a variety of costs associated with arm's-length contractual transactions that can be reduced by bringing the contracting parties under common ownership. We focus here on four that seem particularly important in explaining the patterns of ownership observed in market economies.

4.1. Simple Market Power

Situations in which a firm occupies a position of monopoly or monopsony vis-à-vis one or another class of its patrons offer conspicuous examples of the assignment of ownership to reduce the costs of contracting. Many types of firms organized as producer or consumer cooperatives fall into this category. Prominent among these are agricultural marketing cooperatives, which handle a large fraction of basic crops—from corn and wheat to oranges and nuts—grown in the United States and other developed economies. These cooperatives clearly arose in response to the economies of scale that gave purchasers of crops substantial market power in comparison to the otherwise highly fragmented farmers who grew them. For example, one or two elevators commonly suffice to collect, store, and transfer to a railroad all the grain grown by farmers in a given locality—a situation that stimulated U.S. farmers to establish cooperative ownership of local grain elevators from the late nineteenth century on (Refsell 1914). The consumer cooperatives that have long distributed electricity to many communities in the American West constitute another clear example, with the cooperatives avoiding both the costs of monopoly and those of public rate regulation.

Stock exchanges have historically provided yet another example. The liquidity offered by the exchanges depends on a high volume of trading, resulting in large economies of scale and consequent market power. In response, exchanges have commonly been organized as cooperatives, collectively owned by their major customers, who are the brokers and dealers with rights to trade on the exchange. The recent trend toward converting major exchanges from broker cooperatives to investor ownership evidently reflects changes in the technology of trading that increase the competition offered by alternative trading forums to the established exchanges, reducing the exchanges' market power (Lee 1998; Pirrong 2000). Whether this reduction in market power is permanent or only temporary remains to be seen.

7. That is not to say they hold perfectly. Most conspicuously, some service professionals have been constrained by law, or by the profession's internal discipline, to practice only in employee-owned firms. This was largely the case for doctors in the United States until 1973, for example, and remains the case for lawyers today.

4.2. Ex Post Market Power ("Lock-in")

Another source of the costs of contracting that create an incentive for assigning ownership to a particular class of patrons is the ex post small numbers situation (Williamson 1985) that results when patrons must make transaction-specific investments after choosing the firm with which they will transact. Franchising offers an illustration. Franchisees commonly must make substantial investments that are specific to the franchisor with which they have a licensing agreement. The familiar result is to provide scope for the franchisor to behave opportunistically toward its franchisees. The problem is aggravated by the need to give the franchisor substantial discretion to alter its mode of operation (e.g., the particular products it offers) and to discipline errant franchisees. The problem can be solved by having the franchisor own the franchisees. But this arrangement eliminates the strong incentives for local efficiency that derive from having each store owned by its local manager (Grossman and Hart 1986). Consequently, the opportunism problem is commonly addressed in the reverse fashion, by making the franchisees, collectively, owners of the franchisor.

Franchisee-owned franchisors are in fact common. At one time most consumer hardware in the United States was marketed through seven national franchise systems (e.g., True Value Hardware or Ace Hardware), each of which was collectively owned by its several thousand franchisees, which were local independently owned hardware stores. Similar franchisee-owned franchisors have been prominent in other industries, including grocery wholesaling, baking supplies, van lines, and news reporting. And the two dominant credit card systems, VISA and MasterCard, have for most of their lives been collectively owned by the thousands of local franchisee banks that issue, and provide the credit behind, their cards.⁸ In each of these cases, simple monopoly power—from the economies of advertising and wholesaling—evidently provided part of the stimulus for franchisee ownership. But that incentive has been strengthened by the investments in brand-specific facilities and goodwill that local franchisees must make and that render it costly to switch to another franchisor or to operate as an independent firm.

Because franchisee ownership mitigates the problem of franchisor opportunism without altering the other advantageous structural features of a franchise relationship, it might seem the natural form of organization for all mature franchise systems. Nonetheless, most franchise systems—most notably, those in the fast-food business—remain investor-owned rather than franchisee-owned. We return to the reasons for this when we examine the costs of ownership.

The lock-in problem also provides an incentive for collective tenant ownership of apartment buildings (as in cooperative and condominium housing) and for collective employee ownership of the firms that employ them (as in partnerships of professionals, which are discussed in Section 6; Roberts and Van den Steen 2001).

4.3. Asymmetric Information

A firm's customers or suppliers may also be vulnerable to costly opportunism because they are unable to observe or verify important aspects of the firm's performance or its contractual com-

8. In 2006, faced with threatened antitrust enforcement based on the overlapping ownership of the VISA and MasterCard systems that had evolved, MasterCard converted to investor ownership via a public offering of stock, though the franchisee banks retained voting control over the firm.

mitments. Again, patron ownership reduces the firm's incentive to exploit this informational advantage and hence may reduce the costs of contracting. Simple but clear examples are provided by fertilizer and hybrid seed grain when these products were first commercially marketed to farmers early in the twentieth century. It was difficult for farmers to evaluate the content of the fertilizers or seed grain offered for sale, and investor-owned producers exploited this vulnerability. In response, manufacture and sale of these products was undertaken by farmer-owned supply cooperatives. Investor-owned firms regained dominance in these industries only when, partly as a result of federal disclosure regulation, quality became observable and verifiable.

Life insurance offers another example. A whole-life insurance contract requires the insured to make payments to the insurer throughout her lifetime, in return for the insurer's promise to pay a large sum to a third-party beneficiary on the insured's death. This arrangement creates a natural incentive for the insurer to invest the premiums in highly risky ventures, or simply pay them out as dividends to the owners, because if the firm's reserves ultimately prove inadequate to cover its liabilities and it goes bankrupt, the losses will be borne largely by the policyholders. As a consequence, only mutual firms (policyholder cooperatives) were able to sell whole-life insurance policies in the United States before states began regulating insurance company financial reserves in the middle of the nineteenth century.

The most conspicuous example of ownership as a response to the costs of asymmetric information, however, is the conventional investor-owned business corporation. If a firm borrows most or all of its capital from nonowners via conventional debt contracts, the contracts must generally be long term; otherwise, the firm may face repeated liquidity crises or hold-up by the lenders. But if the loans are long term, the borrowing firm, like the early life insurance companies just discussed, has an incentive to behave opportunistically, investing the borrowed funds in excessively risky ventures or simply distributing them as dividends and leaving the resulting risk of bankruptcy to be borne largely by the lenders. In contrast to the situation with life insurance, moreover, this problem cannot easily be solved by public regulation of firms' investments. That approach works in life insurance, because the firm's capital is held almost entirely in the form of financial investments whose risk profile is relatively easy to observe, and because the amount of capital that an insurance company must maintain to pay its future obligations to its policyholders is relatively easy to calculate. For other types of firms, however, regulation of investments for the sake of protecting creditors has proven largely impossible, as indicated by the progressive historical abandonment of both legal and contractual obligations for firms to maintain stated levels of legal capital.

The more workable solution, instead, has generally been to make the lenders of capital, or a major subset of them, owners of the firm, hence removing the incentive for the firm to behave opportunistically toward them (Klein et al. 1978; Williamson 1985: 298–325; Tirole 2001).

4.4. The Risks of Long-Term Contracting

Contracts between a firm and its patrons do not just allocate risk but sometimes create risk as well, particularly when the contracts have very long terms. Life insurance again offers a clear example. A whole-life insurance contract may have an expected term of several decades. Consequently, if both premiums and death benefits are fixed in nominal dollars, the ultimate value of the contract to both the insured and the insurer will depend heavily on inflation rates,

productivity growth rates, and mortality rates over the intervening period, all of which are difficult to predict and were particularly unpredictable when the life insurance industry first began to develop in the early nineteenth century. The result is that life insurance contracts are essentially a gamble between insurer and insured on these macroeconomic factors, creating private risk that far exceeds social risk and raising the cost of the contract to both parties. This risk can be substantially eliminated by giving collective ownership of the life insurance company to its policyholders, in the form of mutual companies, so that what policyholders lose on the gamble as insureds they gain as owners of the insurer, and vice versa. This incentive for mutual life insurance companies arguably helps explain their continued dominance of the industry long after public regulation of reserves largely removed the risk of default by the insurers.

5. The Costs of Ownership

The efficient assignment of ownership, as noted, must consider not just the costs of contracting but also the costs of ownership. Ownership, in turn, has two elements: receipt of residual earnings and exercise of control. Some costs of ownership, such as risk bearing, are associated with the former, whereas others, such as agency costs and those of collective decisionmaking, are associated with the latter.

5.1. Risk Bearing

For any given firm, some types of patrons are better situated than others to bear the risks of ownership. For large firms with publicly tradable shares, investor ownership has this strong and familiar advantage. However, most firms are insufficiently large to have freely tradable shares. Rather, if they are investor owned, they must be closely held. As a consequence, customer ownership may offer comparable risk-spreading benefits.

More importantly, the risks of ownership are sometimes inversely correlated with other risks facing the firm's customers. Apartment buildings offer an example. It is common for retirees to sell their single-family homes and move into an apartment building, perhaps located in a climatically mild region, such as Florida or Arizona. But if the retiree has an income that is fixed in nominal terms, as with a defined benefit pension plan, renting an apartment exposes the retiree to the risk of inflation or other factors that might raise nominal rents. Ownership of an apartment building by its tenants, as in a cooperative or condominium, financed by a mortgage with payments fixed in nominal terms involves a large undiversified investment with risks that offset those imposed by the pension contract. In consequence, the apartment tenants may have low costs of risk bearing relative to other potential owners.

But in general, allocation of risk may not be a first-order consideration in the ownership of enterprise. Here as elsewhere, incentives seem to dominate risk bearing. A conspicuous illustration is offered by the millions of family-owned farms that dominate the production of staple grain crops in the United States. These farms are extremely capital intensive, sell their products in highly volatile markets, and are quite undiversified (often depending heavily on a single crop). In addition, competition is rigorous, and the rate of technological progress is rapid, with the result that individual producers are constantly being squeezed out of business. Yet large-scale corporate farming under investor ownership has never made noticeable inroads on the

sector despite the enormous advantages such a change would offer in risk bearing. The reason, evidently, is that seasonality of crops frustrates specialization of labor and hence economies of scale,⁹ and family ownership—in effect, employee ownership—provides strong incentives for high productivity. And, importantly, families are willing to bear the extraordinary risks involved.

5.2. Agency Costs of Controlling Managers

Some classes of patrons are also in a better position than others to minimize the agency costs of controlling a firm's managers. In particular, some agents make better monitors than do others. Franchisees, for example, are good monitors of their common franchisor: franchisees necessarily know their franchisor's business well. They are in constant contact with the franchisor and are aware of its performance. Moreover, good management of the franchisor has a large impact on the franchisee's own success. For similar reasons, farmers are good monitors of the marketing and supply cooperatives of which they are members.

By the same logic, employees should be good monitors of the management of the firm where they work. (One should have in mind here not just blue-collar assembly line workers, but key personnel, such as plant supervisors, division chiefs, and managers in engineering, finance, and marketing.) Yet employees rarely have ownership of large firms, which instead (at least in the United States and the United Kingdom) are often owned by dispersed small shareholders who are relatively poor monitors.¹⁰ Consequently, monitoring capacity is evidently not decisive in the allocation of ownership.

5.3. Collective Decisionmaking

In firms with multiple owners, some means—typically involving voting—must be used to aggregate the preferences of the owners for purposes of exercising control. Whatever the means chosen, it will bring costs of two types. First, there are the costs of the decisionmaking process itself. These include the time and effort needed to inform the various owners of the issues, to discuss the matters among the owners, and to make and break coalitions among subsets of the owners. Second, there are the costs of the substantive decisions taken, which may be inefficient as a consequence of problems in the process. For example, if majority voting is the method of decisionmaking employed, the result may be to take the decision representing the median rather than the mean of the owners (modeled in Hart and Moore 1996). Or the decision may be skewed toward the interests of those owners who are better informed about their own interests or who are strategically positioned to control the agenda. The more heterogeneous the interests of a firm's co-owners, the higher the costs of both types are likely to be.

9. The tasks done on a farm (e.g., plowing, planting, weeding, fertilizing, and reaping) change with the seasons, with most efforts concentrated on one task at any given time. Consequently, farm workers cannot specialize in one of these tasks but must be generalists, capable of handling some aspect of each task. Increasing the size of a farm consequently provides only modest opportunity for increasing the specialization of labor (Smith 1776: Book I, Chapter 1).

10. Of course, shareholders of publicly traded corporations have the great advantage of information provided by market institutions, though this information does not necessarily tell them where problems lie in the firm's management.

The patterns of ownership that we observe suggest that these costs of collective decisionmaking weigh heavily. In firms with only two or three owners, heterogeneity of interests is common. The prototypical example is the classic partnership, in which ownership is shared between one partner who provides the firm's financing and another who manages the business. Evidently, with these small numbers, differences of interest can be resolved through negotiation. With larger numbers of owners, however, homogeneity of stakes is the overwhelming rule.¹¹ Ownership is virtually always confined to a single class of patrons, such as investors of capital, employees, suppliers of other inputs, or customers. In the class of patrons who serve as owners, moreover, ownership interests are, or are structured to be, highly homogeneous. Thus, in business corporations with more than a handful of owners, the interests of the owners are typically homogenized by giving them all shares of a single class of common stock with uniform rights. Agricultural marketing cooperatives generally handle only a single type of crop, such as wheat or corn or cranberries, passing up economies of scope and risk diversification for the sake of having owner-members with essentially identical interests in all the firm's decisions. Employee-owned firms are generally owned by a single homogeneous class of workers—whether the drivers in a bus company or the senior lawyers in a law firm—who perform similar jobs and exhibit little vertical hierarchy among themselves.

There are, to be sure, many otherwise investor-owned firms in which employees have substantial shareholdings. In general, however, the employee-held shares in these firms are either too few to provide any voice in management or are held via a vehicle (e.g., an employee stock ownership plan) that effectively strips them of control (e.g., by denying the employee-held shares a vote for the firm's directors).¹² This suggests strongly that, even though there may be net efficiency gains from sharing profits between employees and investors in a firm, shared control brings costs of collective decisionmaking that generally exceed any additional reduction in the costs of employee contracting that might result.

Additional evidence of the costs of collective decisionmaking can be found in other devices frequently employed to avoid conflicts of interest among the owners of a firm. A conspicuous example is the use of crude focal points, such as a simple norm of equality, to simplify decisionmaking. Thus, equality of compensation, or compensation according to a simple objective formula, is typical among the members of employee-owned firms. A striking instance is the once-common practice of allocating shares of earnings to partners in leading law firms strictly according to age, hence eliminating any financial incentive for productivity—all for the sake, apparently, of avoiding the internal conflicts that would accompany any effort to establish a more individuated compensation scheme.¹³

11. Although casual observation suggests that the number of firms with ownership shared among heterogeneous patrons falls off very rapidly when more than two owners are involved, we seem to lack systematic empirical evidence on the point. There may be a huge drop between the number of firms with two owners and those with three, or the number of firms may instead fall more continuously as the number of owners increases to as many as five or six. At stake is how much traction the Coase Theorem has in multi-actor settings.

12. The most conspicuous experiment in true shared control between capital and labor—United Air Lines as it was reorganized in 1994—ended a decade later in conspicuous failure. The apparent reason was irreconcilable conflict among the three ownership groups: public investors, pilots, and members of the mechanics' union. Conflict between the two groups of employee-owners (pilots and mechanics) was a major part of the problem.

13. Another explanation offered for lock-step compensation in law firms—that it is a form of risk sharing (Gilson and Mnookin 1985)—not only seems inconsistent with observed behavior toward risk in other industries,

Franchise operations arguably also offer evidence of the difficulty of creating institutions that discriminate among owners of a firm. As noted above, collective ownership of franchisors by their franchisees, though common in the sale of such goods as hardware and groceries, is rare among franchises for services, such as fast food. One plausible reason is that service franchises require that the quality of performance by franchisees be rigorously policed to avoid negative reputational externalities. This policing requires in turn that the franchisor be prepared to impose severe sanctions on errant franchisees, including, in particular, termination. The difficulty in deviating from a strong norm of simple equality of treatment among co-owners evidently renders franchisee-owned firms incapable of deploying such sanctions rigorously.¹⁴

Although it seems apparent from casual empiricism that the costs of collective decisionmaking play a decisive role in determining which allocations of ownership are efficient, the precise source of these costs is less clear. In particular, it is not obvious whether the principal source of these costs lies in the processes of decisionmaking or in the nature of the substantive decisions reached. One might expect important insight into the nature and magnitude of these costs to come from the literature on political processes, but that is not the case. In fact, it may be easier to study the costs of political-type collective decisionmaking mechanisms in firms than in governments. This is in part because firms are so numerous and operate under strong market conditions, and in part because, via the allocation of ownership, firms offer a clear choice between markets and politics as a means of aggregating the interests of the members of different classes of patrons.

6. Employee-Owned Firms

Employee ownership has attracted particular attention in the industrial organization literature and is a helpful focus for testing the relative importance of the various costs and benefits of alternative ownership structures. Employee-owned firms have long been particularly conspicuous in the service professions, including law, accounting, engineering, investment banking, advertising, and medicine, though in recent decades there has been a decided switch toward investor ownership in many of these industries, including the last three among those just mentioned. Various theories have been offered to explain these unusual and shifting patterns of ownership. Despite the prominence of professional service firms in modern economies, however, there is no consensus on these theories.

One theory is that employee ownership serves to increase work incentives for hard-to-monitor employees (Alchian and Demsetz 1972). A sophisticated variant on this theory is offered by Morrison and Wilhelm (2004, 2005, 2007), who seek to explain employee ownership in investment banking, and its recent decline, in terms of incentives for senior employees to commit credibly to train their juniors under circumstances in which customers cannot directly evaluate the quality of the services that the employees are capable of providing. But this theory faces several obstacles. The most obvious and familiar of these obstacles—and one that faces

such as farming, but is also inconsistent with the patterns of specialization observed in law firms (Garicano and Hubbard 2009).

14. Other factors also help explain the absence of franchisee-owned franchisors in particular industries. For example, the high capital requirements of oil production and refining are presumably an obstacle to putting major oil companies under the collective ownership of their gas station franchisees.

any such effort to explain patron ownership as a means of dealing with moral hazard on the part of the patrons themselves rather than the firm—is the $1/N$ problem. In a firm with N worker-owners, a worker on average gets only $1/N$ of the returns to her increased effort. Although incentives for mutual monitoring might overcome this problem (Kandel and Lazear 1992), the evidence is that it does not in professional partnerships (Gaynor and Gertler 1995; Prendergast 1999; Von Nordenflycht 2007).¹⁵ Another difficulty with the worker incentive theory is that service professionals, relative to other employees, appear relatively easy to monitor. Corporate lawyers, for example, commonly work alone or in small teams and document the use of their time (and the client to be billed for it) at 6-minute intervals. This contrasts markedly with, say, an assistant manager in the finance department of a large industrial firm, whose marginal contribution to the firm's annual revenues would be extremely difficult to measure. This is not to say, of course, that employee ownership has no positive effect on incentives, but only that it does not seem to explain why employee ownership arises in the service professions and not elsewhere.

A rather different theory is offered by Levin and Tadelis (2005), who explain employee ownership of professional service firms not as a means of reducing the costs of contracting between the firm and its employees, but rather as a means of reducing the costs of contracting between the firm and its customers. They focus on employee-owned professional service firms that have equal profit sharing or some other form of cross-subsidy from more productive to less productive worker-owners. They argue that the clients of professional service firms have particular difficulty observing the quality of the services rendered them, creating a risk that law firms will increase their quantity of service provision by employing low-quality lawyers. That incentive, they suggest, can be offset by the otherwise inefficient incentive (Ward 1958) for profit-sharing employee-owned firms to hire workers whose marginal productivity is (otherwise) inefficiently high, making those firms more trustworthy for their customers than are investor-owned firms. A concern with this theory, however, is that it seemingly requires strong assumptions about customers' understanding of the firms' internal incentive structure.

A simpler theory than the two just mentioned—and one that is more consistent with the role of noninvestor-owned firms in other sectors—is that employee ownership in professional service firms serves not to prevent the employees from behaving opportunistically toward the firm or its customers, but to prevent the firm from behaving opportunistically toward its employees. One potential source of opportunism is the employees' investment in firm-specific skills, such as knowledge of the firm's particular personnel, procedures, and clients. Another is the inability of employees, after the passage of years, to signal to other prospective employers their abilities. (Because their current employer, to whom the employees' abilities are presumably well known, has little incentive to communicate those abilities truthfully to competitors in the labor market, the firm has the ability to pay the employees less than their marginal product.)¹⁶ Both these

15. Indeed, it is hard to find evidence in general that employee profit sharing or ownership significantly improves productivity (Weitzman and Kruse 1990).

16. Another incentive for employee ownership may come from the market power that established professional service firms arguably often have over their customers—market power that derives from the customers' inability to judge the value or cost of services, and from the customers' perceived costs of switching suppliers (i.e., customers' supplier-specific investments; Morrison and Wilhelm 2007). If it is relatively easy for the employees to establish

problems, to be sure, may be much less serious among service professionals than among the employees of, for example, large manufacturing firms. But for professional service firms, the costs of employee ownership appear especially low because of the unusual homogeneity of interests among the employees who share ownership—a homogeneity that derives from their similarity in jobs and talent and from the absence of internal hierarchy. Moreover, the relatively low requirements for firm-specific capital in professional service firms permit the employees themselves to provide the necessary capital and avoid the costs of raising it on the market from nonowners. In short, under this theory, costs of ownership (in particular, the costs of collective decisionmaking) are far more important than costs of contracting in determining the presence or absence of employee ownership in any given industry.

If this is the correct explanation for employee ownership in professional service industries, then why has there been a recent trend toward investor ownership in some, but not all, of those industries? One possibility is that the quality of professional services, and of individual professionals, is becoming easier for customers to value, hence reducing firms' ability to avoid paying employees a competitive wage (and reducing their market power as well).¹⁷ Another is that the capital requirements for some of these industries are growing. There is evidence of both phenomena, for example, in the investment banking industry (Morrison and Wilhelm 2005, 2007).

7. Nonprofit Firms

For some goods and services, the costs of contracting between firms and one or another class of their patrons is potentially extremely high, but at the same time the class of patrons in question cannot be organized to serve as effective owners at any feasible cost. In these cases, the efficient solution may be to create a nonprofit firm, that is, a firm without owners. In these firms, control is separated from the claim to residual earnings by imposing a bar (the “nondistribution constraint”) on distributions of the firm's net earnings or assets to persons who control the firm. The consequence is that all the firm's revenues must be devoted to providing services. By removing strong incentives for the firm's managers to earn profits, the incentive to exploit the firm's patrons is reduced.

Asymmetric information between a firm and its customers is typically the source of the contracting costs involved. More particularly, the problem is often that the firm's customers cannot observe the quantity of product or service that the firm provides in return for the price they pay. Such a situation arises commonly when an individual, out of philanthropic motives, seeks to purchase services to be delivered to needy third parties in distant places. Payments to an organization like Oxfam to deliver food to famine victims in Africa are an example. The contributors are in no position to determine how their individual contributions are used. If such a firm were owned by someone other than its customers, the firm would have an incentive to provide few or no services in return for the payments it receives. Prospective customers, expecting this behavior, would refuse to patronize the firm. At the same time, however, the

ownership of the firm (i.e., the costs of ownership are low), then the employees can capture these monopoly rents for themselves.

17. See the previous note.

firm's customers (referred to as "donors") are too transient and dispersed to be organized, at any acceptable cost, as owners capable of monitoring effectively the firm's managers. Consequently, customer ownership is not a viable solution. A similar problem faces firms producing public goods, such as cancer research or commercial-free broadcasting: a contributor may be able to observe both the quantity and quality of services that the firm is producing but cannot determine whether, at the margin, her own contribution induced an increase in quantity or quality.

Of course, once those who control the firm are deprived of the profit motive, one must ask what incentive they have to put any effort whatsoever into managing the firm, much less into producing a level of quantity and quality acceptable to customers. The best explanation is that, in the absence of competing "high-powered" profit incentives, the managers' actions are guided by "low-powered" nonpecuniary incentives, including pride, professionalism, and identification with the goals of the organization (Glaeser and Shleifer 2001).

The nonprofit form seems most commonly to be a response to the problems of contracting when quantity is (at the margin) unobservable. In particular, this problem generally occurs in organizations supported by donations, from the Salvation Army to the performing arts to universities. But there are also situations in which the nonprofit form is evidently a response to unobservable or unverifiable quality.¹⁸ In such situations, one can find nonprofit firms that derive all their revenue from prices charged to their customers. Nursing homes for the elderly—where, for example, sedating patients into inexpensive tractability is a tempting strategy for the producers—are evidently an example.

However, the observed distribution of nonprofit firms across industries cannot be assumed to be a strong reflection of their comparative efficiency vis-à-vis other ownership types. In comparison with firms with owners, transactions in control (and particularly conversions out of the nonprofit form) may not occur when they would be efficient. In principle, a nonprofit corporation can sell its business as a going concern to a proprietary firm and either donate the proceeds to another nonprofit organization and liquidate, or invest the proceeds in another activity that the nonprofit can manage more efficiently. By virtue of the nondistribution constraint, however, the managers who control a nonprofit cannot gain financially from such a transaction; they may in fact suffer from it both in financial (salary) and in nonpecuniary (interest and status of employment) terms. In this regard, it is particularly significant that the managers of a nonprofit firm do not bear the opportunity cost of the capital that the firm has accumulated. Moreover, a nonprofit firm can survive indefinitely, even if it earns only a zero net rate of return on its (self-owned) capital, and can in fact grow if it earns any positive rate of return, no matter how small. Consequently, survivorship cannot be taken as an indication of the efficiency of the nonprofit form as confidently as it can with proprietary forms of ownership.

This problem is compounded by the evolution of industries over time. The nonprofit form is sometimes the best or only way to organize production in the early stages of developing a new service, before effective mechanisms to monitor and pay for the service have been developed. When those mechanisms subsequently come into place, proprietary firms can take over production, and the nonprofit form becomes anachronistic. Yet, because market mechanisms are weak in inducing exit by nonprofit firms, they may long continue to account for a large share of the in-

18. Glaeser and Shleifer (2001) interpret their model, which is the best we have, in terms of unverifiable quality, though it can as easily be interpreted in terms of unobservable quantity.

dustry's production. A conspicuous example is offered by nonprofit savings banks, which arose in the United States (and elsewhere) in the early nineteenth century, because (as with life insurance), in the absence of public regulation, depositors could not trust that their savings would still be intact for withdrawal after many years in a proprietary bank's possession. Although regulation and deposit insurance long ago removed this reason for the nonprofit form, it continued to have a large presence in the industry until recent times (Rasmusen 1988; Hansmann 1996: 246–264). Similarly, there is evidence that nonprofit hospitals—originally institutions supported by donations that provided services to the poor—retain a large market share today, not because they are more efficient than proprietary hospitals but because of weak mechanisms to induce exit (Hansmann et al. 2003).

The distinction between formally nonprofit firms and firms that simply have extremely weak owners is vanishingly small at the margins. Mutual life insurance companies, for example, are in formal terms collectively owned by their policyholders (i.e., they are consumer cooperatives) and hence are in principle proprietary firms. Yet the firms' highly fragmented policyholders have little incentive or ability to exercise effective control over the firms' managers. As a consequence, most U.S. life insurance companies, from the time of their initial formation, have effectively been nonprofit firms, controlled by self-perpetuating boards of directors and holding a growing pool of assets whose value the policyholders do not entirely appropriate. Similarly, there is today little meaningful difference in the United States between mutual savings and loan associations, which are formally depositors' cooperatives, and mutual savings banks, which (despite the term "mutual") are formally nonprofit entities.

Large business corporations with highly dispersed shareholdings that are largely free from the market for corporate control, as some U.S. firms arguably have been over substantial periods, may likewise be little different from nonprofit entities with respect to the costs of ownership—which, for nonprofit firms, consist principally of managerial agency costs. There are, in fact, some industrial firms that are formally organized as nonprofit corporations or very close to it. The most conspicuous examples are the "industrial foundations" that are common in northern Europe (though effectively proscribed by tax law in the United States). These are business firms that are either organized as a nonprofit firm or are entirely controlled by one. The available empirical evidence fails to show that these industrial foundations are less efficient than their investor-owned counterparts (Thomsen and Rose 2004), lending some support to the judgment that, even at the extreme, the agency costs of delegated management are relatively modest in comparison with other costs of ownership and with the costs of market contracting.¹⁹ Even with no owners at all—or, as we might say, even with a true "separation of ownership from control"—firms can be managed with fair efficiency.

19. Even if these results prove robust and are not idiosyncratic to the Danish environment, it is possible that the particular dual-level structure of these firms is an important factor. The industrial firms in the sample are themselves organized as business corporations, with a controlling majority of their shares held by a separate nonprofit foundation. Thus, in a sense, the industrial firms are proprietary firms with an owner—namely, the foundation. And though the foundation is nonprofit, its management may think of the operating company principally as a source of revenue for the foundation and hence seek to assure that the company is managed with substantial efficiency. In a sense, this structure is an extreme form of a company with a dual board system—an outside supervisory board that chooses an inside managerial board—which is itself a formal extension of the idea of having a single board with a majority of outside directors. For analogous results involving nonprofit hospitals in the United States, see Hansmann et al. (2003).

8. Governments

Governments fit comfortably into the analytic framework described here. In effect, governments are territorial consumer cooperatives. This is most obvious at the local level, where (in the United States) geographically contiguous residents are relatively free to form themselves into a municipal corporation. Municipalities commonly provide a package of collective-consumption services to their residents for a price collected as taxation. As Tiebout (1956) long ago suggested, these packages of services might instead be offered by proprietary firms for an annual fee. But if the consumers purchase real estate within the territory served by the firm, they become locked in to the service provider and hence subject to exploitation. And if the service provider itself owns all the real estate and rents it to residents, there will be poor incentives for the residential and commercial occupants of the property. The simple solution is to have the residents own their own homes and businesses and then collectively own the local service provider. (Municipalities are, of course, not fully owned by their residents, but rather are on the previously discussed borderline between cooperative and nonprofit entities.)

9. Resulting Patterns of Organization and Ownership

We have relatively little rigorous empiricism on the trade-offs among the costs of ownership and the costs of contracting just surveyed. The general patterns of ownership that we observe do, however, permit some broad inferences about the relative magnitudes of these costs.

9.1. The Firm as a Political Institution

Perhaps most strikingly, the costs of collective decisionmaking through nonmarket mechanisms are evidently high and play a strong and even decisive role in determining which forms of ownership are viable. It is rare to see ownership in the hands of a heterogeneous class of patrons regardless of the costs of contracting that those owners face. Conversely, noncapitalist firms, such as employee-owned firms, are evidently quite viable when the class of patron-owners is highly homogeneous, even if the costs of contracting that those patrons would face if they were not the firm's owners appear relatively small. This observation supports the conclusion that investor-owned firms are dominant in the economy largely because, relative to other classes of patrons, the interests of capital suppliers can easily be made highly homogeneous (Jensen and Meckling 1979).

9.2. Weak versus Strong Owners

The patterns of ownership that we observe also support the inference that, among the factors that determine those patterns, the agency costs of delegated management are distinctly secondary.

To be more precise, let us imagine a firm with two classes of patrons. For class A, the costs of contracting are high, and so are the agency costs of delegated management; for class B, in contrast, both types of costs are low. For example, class A might be purchasers of whole-life insurance, or savings bank depositors, in the early nineteenth century, while class B might be a small group of investors who can provide financing for the insurance company or the bank. Or class A might be a group of widely dispersed small investors, and class B might be a

reasonably homogeneous group of senior employees at the firm. In such a situation, the observed distribution of ownership suggests that it is generally more efficient to give ownership to class A: the costs of contracting avoided are greater than the agency costs of delegated management that are incurred. The reason, apparently, is that the difference in costs between tightly controlling owners and owners who are no more than nominal is modest compared to the potential costs of market contracting. Put differently, it is clearly important, in terms of overall efficiency, that vulnerable patrons not face a firm that is owned by persons who will exploit their vulnerability. It appears much less important that the patrons themselves, when made the firm's owners, be able to exercise much control over the firm. This is not to say, of course, that managerial agency costs are entirely unimportant; too much of modern scholarship on corporate governance says otherwise. Rather, it is just to say that managerial agency costs do not seem to be of first-order importance in determining the class of patrons to which ownership is most efficiently assigned.

9.3. Regulation and Capitalism

The literature on corporate governance appropriately emphasizes the importance of capital market regulation for facilitating efficient investor ownership of enterprise. But regulation of other markets in which firms operate is also important in this regard. By reducing the costs of contracting for patrons other than investors, regulation of product and supply markets makes investor ownership feasible for industries that might otherwise be heavily populated with cooperative, nonprofit, or governmental firms. Conspicuous examples are life insurance and savings banking, discussed above, and consumer goods in Sweden, where the absence of antitrust law long fostered a large cooperative sector.

10. Further Structural Attributes of the Firm

Earlier it was observed that, as a consequence of the protean character of the standard legal forms for enterprise organization (the business corporation, the partnership, the limited liability company, the cooperative corporation, the nonprofit corporation, etc.), there is only a modest correspondence between those forms and the choice of the class of patrons to whom ownership is assigned.²⁰ There are, however, some strong regularities across legal entity forms in the patterns of relationships that owners and other patrons have to the firm. This is most conspicuous with respect to claims on firm assets.

Asset partitioning in organizations exhibits a greater variety of forms than just those described in Section 2. Owner shielding, for example, has exhibited a variety of different forms over time, of which three have been (and remain) particularly common:²¹

Complete owner shielding ("limited liability"). The personal assets of a firm's owner are completely shielded from the claims of the firm's creditors, as in a modern business corporation.

20. As a further indication of this vagueness, the nonprofit form is sometimes even stretched to be used for fully owned organizations, such as cooperative housing and stock exchanges.

21. We deal here only with liability toward voluntary (contractual) creditors, not involuntary (tort) creditors. The two types need not be treated the same, and it is arguable that limited liability for tort claimants is in general an inefficient rule that survives because of severe collective action problems affecting potential tort victims (Hansmann and Kraakman 1990).

Weak owner shielding. Firm creditors have a claim on the personal assets of the firm's owners, but only a claim that is subordinated to the claims of the owners' personal creditors. This rule is traditional for partnerships.

No owner shielding. Firm creditors can proceed against the personal assets of the firm's owners on equal terms with the owners' personal creditors. This has been the rule for U.S. partnerships since 1978.

Likewise, for commercial firms there are two principal forms of entity shielding:²²

Weak entity shielding. The personal creditors of a firm's owners have a claim on the assets of the firm, but that claim is subordinated to the claims of the firm's own creditors. This rule is characteristic for partnerships.

Strong entity shielding. This form is like weak entity shielding, except that personal creditors cannot force liquidation of the firm but rather must wait until it voluntarily dissolves to assert their (subordinated) claim to its assets. This rule is characteristic for corporations.

Closely tied to asset partitioning is the question of whether the owners of the firm have individual withdrawal rights. Passing over complexities, there are two principal possibilities:

Free withdrawal. An individual owner of the firm can, at will, terminate his membership in the firm and withdraw his share of firm assets. This rule is the default in a general partnership.

No withdrawal. An individual owner cannot withdraw his share of firm assets until the firm itself is dissolved by its owners acting as a group (though the owner may be able to transfer his ownership share to another person). This rule is typical in a business corporation.

Though there are variations, these rights tend to come in particular combinations, of which two have historically been the most common. The first, the general partnership, combines weak (or no) owner shielding, weak entity shielding, and free withdrawal. The second, the corporation, combines complete owner shielding (limited liability), strong entity shielding, and no withdrawal. The elements of each of these two packages are complementary, largely based on avoidance of owner opportunism toward personal or business creditors. In the partnership, personal liability compensates firm creditors for the instability in the firm created by the right of the owners and their personal creditors to force liquidation of firm assets. In the corporation, strong entity shielding and the absence of withdrawal rights provide creditors with a reliable base of assets to compensate for the lack of a claim on owners' personal assets.

Although the corporate form was employed in ancient Rome (Malmendier 2005) and medieval Genoa (Ferrarini 2005), it did not supplant the partnership for most commercial activities until the twentieth century. This was not just a demand-side evolution, driven by the need to accumulate larger amounts of firm-specific capital, because even small service firms—of the type once commonly formed as partnerships—are now organized as corporations. Rather, it is arguably in part a consequence (though the issue remains a bit clouded) of (1) better creditor

22. Nonprofit corporations exhibit yet a third form, complete entity shielding, in which creditors of the firm's (beneficial) owners have no claim at all on firm assets.

protection, both through bankruptcy law and through financial contracting and monitoring, and (2) better owner protection, through greater judicial sophistication in guarding minority shareholders. Better owner protection renders it less costly for those shareholders to give up their withdrawal rights, which offer valuable protection against expropriation by controlling owners (Blair 2003; Hansmann et al. 2006; Lamoreaux and Rosenthal 2006).

11. The Role of Law

The mushrooming “law and finance” literature, seeded by the eponymous article of La Porta et al. (1998), explores the empirical relationship between legal systems and the development of corporate capitalism. That literature has focused heavily on the importance of particular substantive provisions of the law, such as rules that govern shareholders’ ability to control corporate managers (antidirector rights). By and large, however, that literature does not ask closely what makes rules of law important. To be sure, the law and finance literature examines the degree to which the law is effectively enforced. But that is a characteristic of the legal system in general, not of organizational law in particular. The harder question—one that arises at the intersection of Coase’s two most famous articles (Coase 1937, 1960)—is why specific rules of organizational law should be important, given the possibility of contracting around those rules.²³

As noted above, rules of law are necessary to define the control and asset boundaries of the firm, because these boundaries provide the background social conventions necessary for contracting to take place. Nearly all other aspects of entity structure, however, can in theory be determined by contract among the organizers of the entity and placed in the firm’s charter (articles of association) or in shareholder agreements. In particular, this includes the designation of the firm’s owners and the allocation of earnings and control among them, as well as all details of the firm’s internal governance structure. Thus, in principle, the modern statutory business trust offers all that is really necessary in a legal form for enterprise organization: it provides for contracting authority and strong entity shielding but lacks even default rules for most other aspects of entity structure, which are left to be specified in the firm’s governing instrument. Yet the business trust is used almost exclusively for just two specialized purposes: asset securitization and mutual funds. Other types of organizations instead choose to form under much more heavily articulated statutes—such as a general business corporation statute, a limited liability company statute, or a cooperative corporation statute—that offers specific rules governing nearly all aspects of organizational structure. Moreover, although closely held firms often adopt specially crafted charter terms, publicly traded business corporations rarely take advantage of the broad freedom given them to deviate from the default terms of the corporation statutes, no matter how controversial those terms are, adopting instead all the standard statutory provisions.

Just why firms do not more commonly use individually tailored governance structures is not entirely clear. Nor is it clear why, if firms adopt standard-form structures, the standard forms they adopt are publicly provided via statute rather than (like many other standard form

23. Acemoglu and Johnson (2005) offer evidence that, in the long run, such rules of law are not in fact important.

contracts) privately drafted. Network externalities in marketing shares or in obtaining legal advice is one potential explanation (Kahan and Klausner 1997). Another is that state-provided organizational law may be a solution to a severe problem of incomplete contracting. Firms with long expected lifetimes, such as publicly traded business corporations, need to revise their governance structure as surrounding circumstances (e.g., the character of financial markets, or the nature of applicable tax and bankruptcy and labor law) change over time. But recontracting among the firm's participants—majority shareholders, minority shareholders, managers, and creditors—to amend the firm's own charter is a highly imperfect means to such adaptations. The available mechanisms for charter amendment are unlikely to lead to efficient results; one group or another will have either too much veto power over changes or too much leeway to force changes on the other participants. By deferring to the legally provided default terms, firms delegate this process of continual charter revision to the state, which—at least if it is a small and economically marginal state, such as Delaware—is a reasonably neutral party that is likely to avoid strong capture by any of the interests involved in corporations, including controlling shareholders, public shareholders, managers, creditors, and employees (Hansmann 2006; Listokin 2009).

12. Conclusion

Viewed as contracting entities, firms are assemblages of owners' rights and creditors' (more generally, patrons') rights. A classical firm has a simple structure in this regard. Ownership of the firm is in the hands of a single and highly homogeneous subset of the firm's patrons. All the firm's other patrons have contractual claims on the firm that are backed by a single undivided pool of bonding assets, which consists of all productive assets and contractual claims of the firm. Historically, there have been two principal variants of this classical form: the general partnership and the business corporation.

The historical tendency, for at least the past century, has been to complicate this simple structure with respect to creditors' rights by providing for subdivision of the firm's assets into smaller pools that can be separately pledged to particular subsets of the firm's patrons. One route to this end has been increasing flexibility in the formation of subsidiary entities. Another has been increasing flexibility in the mechanisms for giving security interests in particular assets to selected creditors. The trade-off here is between the costs of monitoring the assets that back a given contractual claim and the costs of giving notice of the various claims on firm assets—the first of which generally decrease, and the second of which generally increase, as asset partitioning becomes more refined. That trade-off has gradually shifted in favor of greater subpartitioning as information costs of giving notice have decreased. The result has been increasing dissociation between the control boundaries and the asset boundaries of firms.

Even though better access to information has thus led to more articulated contracting between firms and their nonowner patrons, it has not permitted similar refinements in the political-type collective choice mechanisms employed to aggregate the preferences of a firm's owners, which seem difficult to improve on. Although there has been experimentation with more articulated approaches to sharing or apportioning ownership rights among patrons with heterogeneous interests in a firm, they have fared poorly. Efforts that have been made in this

direction include, conspicuously, German-style codetermination, employee stock ownership plans, and tracking stock.²⁴ None has taken hold in the absence of legal compulsion or substantial subsidies. Perhaps more complex ownership structures will someday become feasible. For the present, however, ownership of the firm must evidently remain in the hands of patrons with highly homogeneous interests. Therefore, because it is particularly easy to homogenize the interests of contributors of financial capital, free enterprise economies are likely to remain largely (though not exclusively) capitalist economies for the foreseeable future.

Contracts between Legal Persons

Lewis A. Kornhauser and W. Bentley MacLeod

The duty to keep a contract at common law means a prediction that you must pay damages if you do not keep it—and nothing else.

Oliver Wendell Holmes,
“The Path of the Law,” *Harvard Law Review*, 1897

1. Introduction

Contract law and the economics of contract have, for the most part, developed independently of each other. While contract law has existed for centuries, if not millennia, the economic analysis of contract is both very recent and largely divorced from the content and structure of contract law.¹ Current reviews of contract theory, such as Laffont and Martimort (2002) and Bolton and Dewatripont (2005), do not discuss either the substantive law of contract or the role that courts play in enforcement. In this chapter, we begin to bridge this gap.

We briefly review the notion of a contract from the perspective of a lawyer and then use this framework to organize the economic literature on contract. The review thus provides an overview of the literature for economists who are interested in exploring the economic implications of contract law. The title, “Contracts between Legal Persons,” limits the review to that part of contract law that is generic to any legal person. A legal person is any individual, firm, or government agency with the right to enter into a binding agreement. Our goal is to discuss the role of the law in enforcing these agreements under the hypothesis that legal persons have well defined goals and objectives.²

The possession of well-defined preferences does not imply that legal persons never make mistakes. In fact, a key ingredient to understanding the observed form of contract law requires the introduction of some imperfections in decisionmaking. Since the seminal work of Herbert Simon (1982), there has been little disagreement that a complete understanding of human

We thank Elliott Ash, Kevin Davis, Robert Gibbons, Avery Katz, John Roberts, and participants at the fourth annual Research Triangle Conference on Law and Economics for comments on earlier drafts of this chapter. We also thank Elliott Ash, Wilfredo Lim, and Teck Yong Tan for research assistance.

1. The introduction of Laffont and Martimort (2002) provides a nice historical overview of the development of incentives contracts.

2. For example, the field of corporate governance (see Hermalin (“Corporate Governance”), this volume) is concerned with the design of legal institutions that ensure that firms have preferences corresponding to maximizing firm value.

institutions requires the incorporation of errors in decisionmaking. However, there is little agreement regarding the best way to achieve this goal. In this review, we follow the widely accepted hypothesis that imperfect and asymmetric information are key ingredients of any theory of contract form. We show that these elements are sufficient to tie together the various strands of the literature. We then outline a plan for future research.

The review is divided into three substantive parts. Section 2 focuses on the primary legal concepts on which contract law rests—including the notion of a legal person and what is meant by an enforceable agreement. We focus on the substantive remedial regime that determines how contracts are enforced and on two features of the process of adjudication—fact-finding and interpretation—that determine what obligations the parties have and when they have been breached.

Section 3 examines how the implicit assumptions underlying the economic literature on contract compares to the substantive law of remedy. Economic models of contract make stylized assumptions regarding how the law enforces contracts. In many cases, these assumptions are consistent with existing law. In some cases, particularly when the contract requires a person to act in a particular way, the implicit assumptions are inconsistent with existing law in such jurisdictions as the United States. This inconsistency is manifested in some recent work that builds on results in mechanism design. The same inconsistency may help explain, as Tirole (1999) observes, the gap between the predictions of these models and observed contract forms. In addition, Section 3 discusses the literature on economic analysis of law that begins to bridge the gap between the sparse assumptions on remedial regime in the economic literature and the complexity of the law.

Section 4 discusses the sparse literature on fact finding and interpretation. This literature asks two questions:

1. When parties write an incomplete contract, how should a court determine the obligations that the parties have?
2. How do courts find facts? In terms of the economic literature, what is the technology of verification?

Section 5 concludes the chapter.

We deploy the conceptual scheme of contract law summarized in Section 2.2 to organize a summary of the literature on the economics of contract. Our characterizations of some of the underlying economics literature may thus seem a bit askew, but we hope that the legal perspective will open additional avenues of research.

2. Contract Law

In this section, we set out the legal view of contract. We begin with the legal view of agency for two reasons. First, it provides a sharp contrast with the economic view. Second, as most contracts are between firms, we require a conception of a firm and of when a transaction is between firms rather than within a firm. Our conception of a firm relies on some basic legal concepts that have consequences for the legal treatment of different types of transactions. We proceed in Section 2.2 to a characterization of contract law.

2.1. Legal Personality

The economic agent is characterized by her preferences; the legal agent is characterized by her legal capacities to hold and convey property, to make contracts, and to sue and be sued. These capacities are central to each of the different legal forms that a firm might take: sole proprietorship, partnership, business corporation, trust, or not-for-profit corporation.³ Natural persons (who have reached the age of majority and are mentally competent) also have these properties. Hansmann (this volume) discusses the importance of asset ownership (and, implicitly, some aspects of exposure to suit). As Hansmann notes, legal personality segregates a set of assets owned by the entity. Consider, for example, a corporation C . C owns some set of assets A that are subject to claims from other persons. Liability of C is limited (to the asset pool A), because the corporate form protects the assets of other legal persons, in particular, the owners of C , from valid legal claims against C .⁴

We focus on the legal person's right to make contracts and to sue and be sued. Legal persons act through natural persons. When the legal person is simply a natural person, both action and identification of which acts are attributable to her is relatively straightforward. Many legal persons, however, are complex; they are constituted by and encompass large numbers of other legal persons, both natural and artificial. For example, law firms 30 years ago were typically organized as partnerships. Each partner was a natural person as were all employees of the partnership (but not all its clients, many of whom were corporations). Some actions of the partners and their employees were attributable to the partnerships, and others were not. Similarly, a business corporation has shareholders, managers, directors, employees, and customers; some members of each of these classes may be natural persons, but others may be corporations. It may also own, wholly or in part, other corporations. Corporations, of course, act only through individuals, some but not all of whose acts are attributable to the corporation.

Two bodies of law solve these problems of attribution: organizational law and agency law. Organizational law addresses problems of the internal organization of the firm or legal person. Often, in conjunction with constitutional documents of the firm—in business corporations the articles of incorporation and the by-laws—organizational law identifies a decision procedure for the firm. In business corporations, this decision procedure is complex, with final authority for most decisions given to the board of directors, though some decisions require shareholder approval and many decisions are delegated to management.⁵ The law of agency determines which actions may bind the legal persons. Under what circumstances is the fictitious person responsible for the acts of its agents (e.g., employees)? Even a natural

3. The attributes of legal personality of the different forms of business organization vary somewhat. So, for example, partnerships are not treated as "persons" for tax purposes, whereas corporations are. More importantly, a partnership can be terminated at will by any partner at any time, whereas corporate death (or dissolution) is more complex. For a brief introduction to the concept of legal personality, see Clark (1986: 15–21).

4. The protection of assets of other legal persons is not complete. In some circumstances, a claimant T on C 's assets may either "pierce the corporate veil" and make claims against the assets of the owner of C when A is insufficient to satisfy T 's claim or claim assets that have been transferred to third parties.

5. On corporate law generally, see Clark (1986).

person might benefit from having an agent, someone who can enter contracts for her and make other decisions. The law of agency governs which actions of the agent belong to the agent and which to the principal.⁶ We ignore here actions that lead to harm to third parties and focus on exchange.⁷ If the agent has actual or apparent authority⁸ to act on behalf of the principal (here the legal person), then the principal is bound by the agent's actions, while generally, the agent has no liability to the contracting party. The principal grants authority either expressly or implicitly; in some instances, it may appear that the agent has authority even when she does not. Agency law places the risk of error on the principal. In what follows, we shall generally assume that the legal person acts through agents with actual authority.

Legal persons may also sue or be sued. We might differentiate contracts between firms from contracts between the firm and its employees and from contracts between parts of the firm in terms of the remedies available to resolve disputes. In essence, the law treats this last class of transactions—transactions internal to the firm (but not employment contracts)—differently from market transactions.⁹ Several distinct questions arise here. Consider some actor X. We may ask first: what rights does X have? Second, what forum is available to adjudicate these rights? More specifically, are state courts available to adjudicate these rights? Third, and finally, if state courts are available, is X able to assert these rights in this forum? In any given dispute, the law provides complex answers to these questions. We provide a brief sketch of the legal terrain (in the United States) with respect to disputes arising from exchange.

In economics, a legal person C is usually a business corporation, though in some contexts, C might be a natural person or a governmental entity. Suppose C is a business corporation. Hence, C has relations with its employees and its subsidiaries, both sets of which are sets of legal persons, with outside firms and outside consumers. Disputes may thus arise from interactions among

6. Clark (1986: 113–117) offers a brief introduction to agency principles. See also American Law Institute (2006).

7. When an individual acts as an agent on behalf of someone else, two questions arise. We emphasize the question raised in the text: under what circumstances is the principal responsible for the acts of its agents? This question might arise in at least two contexts: contract and tort. In the first case, agency law generally determines when the acts of the agent bind the principal to contracts that the agent makes on her behalf. When an agent harms a third party, tort liability arises, and the doctrine of vicarious liability determines when the tort victim also has a claim against the principal. For economic analysis of vicarious liability see Sykes (1981), Kornhauser (1982), and Arlen and MacLeod (2005).

The second question asks under what circumstances is the agent relieved of responsibility for her actions. Again, the analysis of contract and tort differs. Usually, agents are not responsible to the promisee for the contracts that they enter on behalf of their principals. They might, however, be liable to the principal if they acted outside the scope of their authority. See American Law Institute (2006: §§ 6.01, 6.04, 6.10, 6.11). In tort, agents generally are responsible for actions that harm third parties, though public officials in the United States benefit from a qualified immunity from tort liability for actions taken in furtherance of their official duties. See generally American Law Institute (2006: § 7.01).

8. On apparent authority see American Law Institute (2006: § 3.03).

9. Contracts between the firm and its employees are generally governed by contract law, employment law, or labor law.

employees, subsidiaries, or groups of employees, or between agents of the firm and outside suppliers or consumers.

The first question concerns the substantive rights the disputants have. The legal person to a large extent makes its own law to govern its internal disputes; Williamson (1991) makes this point. Thus, our corporation C has the power to determine, within limits,¹⁰ the substantive rights that employees and subsidiaries have against it and the substantive rights that employees and subsidiaries have against one another. C's power to make its own law, however, may be limited by state law, or state law may create a set of default rules to govern without explicit internal law. Employment law provides a good example. Internal rules may not violate employment discrimination rules, and the doctrine of at-will employment serves as a default rule in most jurisdictions in the United States. Of course, C and the outside firms with which it contracts also have the power, subject to the same caveats, to make their own law to govern their exchange; this power is granted by contract law.

Turn now to the second question of forum. Suppose two persons A and B, employees or subsidiaries of C, have a dispute arising under C's internal rules. As the employment contract usually delegates authority to the firm, the state courts will not resolve this dispute (unless the dispute implicates some statutory right of the employee). Nor would the parent corporation usually allow its subsidiaries to resort to the courts to resolve an internal dispute.

Now consider two unincorporated divisions D and D' of C. Neither D nor D' is a legal person for purposes of state law. However, even if they have engaged in an exchange with an "outsider" that constitutes a contract, neither D nor D' has the power to sue or be sued with respect to such a claim. To be concrete, suppose Chevrolet and Pontiac, both unincorporated subdivisions of General Motors, jointly hire an advertising firm; the agreement between Chevrolet and Pontiac provides a formula for allocating the costs incurred by the advertising firm. Any dispute between Chevrolet and Pontiac must be resolved within General Motors. (If these subdivisions were corporate subsidiaries of General Motors, each with a distinct legal identity, then each would have the right to sue or be sued. General Motors, however, might prohibit its subsidiaries from exercising this right.) One may view many of the contributions to this handbook (e.g., Hansmann, this volume) as reviews of the internal procedures and policies that firms use to govern internal disputes.

2.2. The Law of Contract

2.2.1. *Defining the Basic Concepts*

A contract, in the legal literature, is "an agreement between two or more parties creating obligations that are enforceable or otherwise recognizable at law" (*Black's Law Dictionary*; Garner and Black 2005).¹¹ The economics literature, in contrast, provides no definition of a

10. Contract law provides the parties with great latitude in structuring their relationship, but other parts of state law do constrain the substantive rights. The Thirteenth Amendment to the Constitution of the United States bans slavery, for instance. More relevantly, U.S. law includes statutes that require equal treatment by race, gender, age, and disability as well as restrictions on minimum wages and various terms and conditions of employment.

11. The *Restatement Second of Contracts* (American Law Institute 1981: § 1) offers a similar definition: "a promise or set of promises for the breach of which the law gives a remedy or the performance of which the

contract.¹² To the economist, “contract” refers to an incentive structure, often an optimal or constrained optimal incentive structure.¹³

Fruitful interchange between the two literatures thus requires that we specify at the outset a common vocabulary that permits the introduction of a legal framework into the economic analysis of contract. We introduce four concepts: *an exchange environment*, *a contractual instrument*, *contract law*, and *contractual behavior*. We then offer a definition of a contract.

An exchange environment is specified by the preferences of the agents, the information structure among the agents and any third-party enforcer, and the production technology that determines the effects of various investments by the parties on the costs and benefits of exchange. The exchange environment identifies the constraints under which the agents act.

A contractual instrument contains the terms the parties bargained for, while contract law may imply terms that the parties have neglected to make explicit; interpret terms that, in the light of performance, are ambiguous; or, more rarely, impose a term contrary to the one negotiated by the parties. Further, the remedial rules of contract law largely determines the structure of any renegotiation. Contractual behavior refers to the actions of parties to the contract in light of the contractual instrument and the prevailing law of contract. We reserve the term “contract” for the set of obligations that result from the application of contract law to the contractual instrument.

We may think of a contractual instrument as a (partial) list of events and associated obligations for each party. Though the law usually enforces oral agreements, we assume that the agreement has a written form. Thus, a contractual instrument is embodied in a fixed text that is publicly available, so that the parties and any third-party enforcer know the contents of this text. The contractual instrument in conjunction with contract law determines the contractual obligations the parties have. We might say, that is, that the contractual instrument, as understood against the background law of contract, determines the contract between the parties. This contract is, in the sense of Arrow and Debreu (1954), a complete contingent claims contract; it specifies what each party must do in every possible state of the world, though, of course, the specified actions may not be optimal ones.

law in some way recognizes as a duty.” On this issue specifically, and on contract law generally, see Farnsworth (2004).

Different legal systems have different criteria for determining the set of agreements that the law will enforce. In common law jurisdictions, such as the United States and Britain, these constraints are few. The agreement must be sufficiently detailed for the court to determine the content of the bargain; in most cases an agreement that required the transfer of goods at some future date without specifying the quality or quantity of the goods or the price at transfer would be unenforceable. In addition, for a promise to perform a future action to constitute an agreement, the promisee must give “consideration,” but almost any return promise or action is now understood as consideration. See generally Farnsworth (2004: 47–53). Note also that some agreements must be in writing to be enforceable.

12. The index to Bolton and Dewatripont (2005) has no entry for contract law, and the text provides no formal definition. The index to Salanie (1997) does have an entry “contract, definition of,” but the designated page does not provide a clear definition.

13. Salanie’s (1997) discussion in his introduction is consistent with this interpretation. Ayres and Gertner (1992) characterize the economic literature in a similar fashion.

This chapter begins to disentangle the role of the contractual instrument from the role of contract law in the structure of mechanisms. We also specify the constraints that contract law imposes on mechanism design by articulating some of the real features of contract law.

2.2.2. *What Does Contract Law Do?*

One ambiguity remains in our vocabulary. Contract law refers both to the substantive rules governing contracting behavior and to the institutions that interpret and enforce them. Substantive contract law identifies what private parties must do to create a legally binding agreement and guides the courts in the interpretation and enforcement of contractual instruments. In this chapter, we focus on two institutional aspects of contract law that characterize the tasks of courts and on a subset of the substantive law of contract. In effect, the court performs three distinct tasks when it adjudicates a contract dispute. First, it finds the facts. It determines what actions the parties took and what state of the world or nature was realized. Second, it interprets the contractual instrument. Interpretation requires the court to determine what obligations the contractual instrument imposed in the realized state of the world.¹⁴ If the contractual instrument was complete, coherent, and uncontradictory, some term specified these obligations. If the contractual instrument was incomplete, then it will not have specified any obligations in the realized state of the world. In this case, the court must nonetheless determine the obligations of the parties. In other instances, the contractual instrument may be poorly drafted and impose conflicting or ambiguous obligations in some state of the world.¹⁵ Again, the court must determine what obligations the parties actually have. Third, if the court determines that one party (or more) has failed to meet its obligations under the contractual instrument, as interpreted by the court, it must enforce the contract; the court imposes the remedy dictated by the substantive law.¹⁶ Remedies may take many forms. The substantive rules of contract law determine the form of the remedy.

This discussion of the functions of courts suggests that we assess regimes of contract law along three different axes—the process of fact determination, the interpretative practice, and the substantive remedial regime.

2.2.3. *Fact Finding*

A contractual instrument specifies, against the legal backdrop, the obligations of each party. Often the obligations of the parties are state-contingent; what each party must do varies with the state of the world. Resolution of every contract dispute thus requires determination of the actions that each party took and of the realized event.

14. Of course, the content of the contractual instrument and the substance of contract law determine in part what facts the court must find.

15. A poorly drafted contractual instrument might, in one or more contingencies, also specify an inefficient or otherwise inappropriate obligation. Some poorly drafted contracts impose in some events inconsistent obligations on a party (i.e., it requires the party both to do and not to do some act).

16. “Impose a remedy” here means to announce a judgment for the plaintiff (promisee) that specifies an amount of damages to be paid or an action to be taken by the defendant (promisor). If the defendant does not satisfy the judgment, the plaintiff must return to court for an order to direct the sheriff to seize assets sufficient to satisfy the damage award or to seize the defendant as in contempt of court. Thus, strictly speaking, the sheriff, not the court, enforces remedies.

Fact-finding procedures apply across a wide of range of types of disputes, and they are governed by distinct bodies of law (that generally go under the names of civil or criminal procedure and evidence). We may assess these procedures along two dimensions: their accuracy and their cost. In an ideal world, fact finding would be perfectly accurate and costless. In the real world, the invocation of courts is costly, and courts themselves sometimes err in their fact finding.¹⁷

As we discuss below, the economic theory of contract generally distinguishes observable actions from verifiable actions. Courts costlessly observe verifiable actions with perfect accuracy; courts cannot observe unverifiable actions at any cost.¹⁸ Most actions and events, in contrast, are only verifiable at some cost and to some degree of accuracy.

2.2.4. *Interpretive Practices*

Contract disputes often entail more than a dispute over facts. They often include disputes over the content of the contractual obligations the parties faced. A party's obligations may be unclear for several reasons: the contractual instrument may have been ambiguous, so that it is unclear whether an action *a* satisfies the contractually specified obligation; the contractual instrument may have been inconsistent and required that the party undertake an action that was not feasible in the realized state of the world or that the party undertake inconsistent actions; or the contractual instrument may not have contemplated the realized state of the world and so specified no obligation at all. Finally, contract law itself may have been unclear or ambiguous.

Contract interpretation is the legal practice that determines the obligations of the parties. These practices are complex and difficult to specify. To begin, we consider a procedural aspect of interpretive practices: the information on which the court relies in deciding what obligations the parties have under the contractual instrument.¹⁹ The practice may be more or less inclusive in its informational base. It might refer only to the fixed text of the contractual instrument, or it might rely on additional information. It might, for instance, rely on statements during the precontractual negotiations of the parties. It might rely on the precontractual practice (if any) of the parties (i.e., it might look to prior behavior of the parties under contractual instruments dealing with the same or similar subject matter). The court might look to the course of dealing of the parties under the contractual instrument in dispute. Alternatively, the court might look to general trade practice; that is, it might consider how individuals who regularly engage in exchanges of the type governed by the disputed contractual instrument behaved under similar circumstances. We distinguish textualist practices of interpretation (in which the court refers only to the written text of the contractual instrument) from contextualist practices of interpretation (in which the court refers to some information external to the contractual instrument as well as to the text). This simple distinction is sufficient to classify the existing literature, discussed in Section 4.2; this literature has been inattentive to the problem of interpretation.

Of course, even courts that adopt identical informational bases might have different interpretive practices. After all, an interpretive practice is a map from the space defined by the

17. We note in passing that the parties may, in the contractual instrument, alter the usual default fact-finding procedures.

18. The economic literature treats unverifiable actions as a constraint on the contractual instrument.

19. Katz (2004) discusses this issue.

informational base into the set of obligations. Court C might impute one obligation to a given set of facts, while court C' imputes a different obligation to the same set of facts.

We may better understand these imputation practices by considering the different objectives a court might pursue in interpreting the relevant informational base. The court might pursue at least three different objectives. First, it might seek to determine what the parties agreed to (or, if they did not contemplate the realized event, would have agreed to). To accomplish this aim, a court must recover both the interests of the parties and their relative bargaining power.²⁰ Second, the court might seek to determine what "normal" or "average" parties to exchanges of this type would agree to. To accomplish this aim, the court must determine the preferences of the normal contracting parties. Third, the court might seek to determine an efficient contract. Efficiency here might refer to ex ante incentives to invest, or it might refer to efficient risk sharing. Again, the court needs to recover or to impute the preferences of the parties.

In the stylized world of the economics of contract literature, the parties are rational; they would themselves thus write an efficient contract. It might thus appear that the third interpretive aim simply recapitulates either of the prior two aims. This appearance, however, is deceptive for two reasons. First, though rational parties would seek to maximize their surplus, they might divide that surplus in many different ways. Hence, the first two aims require the court to infer the nature of a specific bargain.

Second, the contractual instruments of rational parties are clear and well specified. In the commercial world, however, parties are not fully rational; they may make mistakes. Consequently, contract terms may be vague, unclear, or contradictory (in the sense of requiring a party to take inconsistent actions in some state of the world). The court, in interpreting the contractual instrument, must confront these imperfections and determine what obligations the parties in fact had under the contract.

2.2.5. Remedial Regimes

After the court determines what happened and what obligations the parties had under the contractual instrument, it determines whether each party met its obligations under the instrument (as interpreted under the prevailing contract law). If the court finds that some party did not perform as required, it offers a remedy. Again, contract law has a rich set of remedial rules. We might understand a remedial regime as giving the promisor an option: to perform or not to perform but to make a damage payment. Remedial regimes differ in the option price, or the level of damages that the promisor must pay in the event of nonperformance. We contrast two remedial regimes: (expectation) damages and no damages (against a backdrop of secure property rights).²¹

The standard remedy²² for breach of contract in common law jurisdictions is expectation damages.²³ The principle of expectation damages awards the promisee her (subjective) value

20. In fact, the court needs a complete theory of how the parties would bargain.

21. Hermalin, Katz, and Craswell (2006) surveys the economic literature on contractual remedies.

22. Two types of deviations may occur. In some cases, lesser damages may be imposed, and in some cases, specific performance (see the next note) may be imposed. In addition, the remedial rules of contract law are, to a certain extent, default rules. The parties may specify a level of damages in the contractual instrument that would substitute for the court measurement.

23. In civil law countries, there is a large group of contracts for which the default remedy is specific performance, a requirement that the nonperforming party meet her obligation. This requirement might be enforced by

of performance. Of course, the court generally cannot observe this subjective valuation; the common law has developed some clever rules to implement the principle that, in many cases, contrive to deliver to the promisee her subjective value of performance without actually measuring it.²⁴ In many cases, however, the actual measure of the promisee's expectation leads to undercompensation. This undercompensation results in part from the procedural rule in the United States that each party bears her own costs of litigation. This practice contrasts with the practice in Britain, where the losing party bears the winner's costs of litigation as well as paying substantive damages.

Expectation damages nevertheless applies to most agreements. It differs dramatically from the common assumption in the economics of contract literature that the obligation specified in the contractual instrument will be enforced. The rule of expectation damages will lead to radically different consequences than does the rule of perfect enforcement assumed in the economics of contract literature.²⁵

Finally, the law may simply protect the property rights of the parties and not enforce any agreements at all. In this regime, the parties have no access to the fact-finding or interpretive capacities of courts. Courts do, however, protect persons against bodily harm and property from appropriation by other individuals (and the government). When a promisor fails to perform, the promisee can enforce the contract only through reputational devices or refusals to deal. This regime corresponds to a regime of pure "relational" contracts.

2.3. Discussion

These brief comments suggest a rich panoply of regimes of contract law against which exchange might occur. We consider a few ideal types, all against a backdrop of security of property rights. At the extremes are anarchy and utopia, the two regimes commonly assumed in the economics of contract. Under anarchy, there is no third-party fact finding, interpretation, or enforcement, though each party remains secure in her property holdings. Under utopia, fact-finding is perfectly accurate and costless, interpretation is clear and costless, and enforcement is costless and perfect (in the sense that each party performs her stated obligation). In the world of anarchy, contracts must be self-enforcing; in utopia, the parties can costlessly bind themselves to any obligation they choose.

charging the breaching party with civil contempt, which in common law countries might lead to jail time or to large fines.

24. Consider, for example, the rule of "cover," which permits an aggrieved buyer to purchase the contracted-for goods on the spot market and to receive as damages the difference between the market price at which she covered and the contract price. This rule delivers the promisee her expectation by delivering her the goods at the contract price (on the assumption that the contracted-for goods were standardized goods available in a sufficiently thick spot market).

Notice that, generally, the law may offer a number of different remedial options from which the aggrieved party may choose. Section 7 of Article 2 of the Uniform Commercial Code illustrates well both the panoply of options and the elective nature. In addition, an aggrieved party might rely on either restitution or promissory estoppel rather than pure contract remedies.

25. As noted above, courts applied the remedy of specific performance to contracts for "unique" goods. One might, however, understand the rule of specific performance as an instance (or implementation) of the expectation principle: by delivering the contracted-for performance, the promisor delivers the promisee her expectation. At-will employment, in contrast, does not deliver the value of the performance to the agent.

Courts, however, decide cases in neither an anarchic nor an utopian world but in a world in which fact finding, interpretation, and enforcement are both costly and error-ridden. Contracts here need not be self-enforcing, but they will not be perfectly enforced. Observed contracts reflect this middle ground (as well as the oddities that result from the efforts of boundedly rational or irrational agents).²⁶

3. Enforcement and Remedy in Economic Models of Contract

In this section, we examine the enforcement assumptions implicit in the economic literature on contract. Economic analyses of contract usually make one of three assumptions. The literature on relational contracts assumes that the parties have no remedies available to them other than the enforcement of unconditional monetary transfers. The agency literature assumes, consistent with the substantive legal regime, that an aggrieved party will receive compensation equal to her expectation from the contract. The incomplete contracts literature, in contrast, assumes that an aggrieved party will receive specific performance (i.e., that the courts will enforce all terms in the contract as written). As we discuss in more detail below, specific performance is not the general remedial rule in Anglo-American common law systems, and hence several of the contract forms that have been suggested as efficient solutions to the hold-up problems could not be implemented in the United States.

It is worth pointing out that in economics, the only role that damages play is to ensure that individuals choose to perform their obligations. Kornhauser (1983) observes that contract damages can play a second role, namely, to encourage careful planning by parties. However, this point requires a theory of endogenously incomplete contracts, a relatively new literature. This issue is discussed further in Section 4.

26. We have ignored some complications that arise when parties are insolvent. Our discussion thus far has assumed that the promisor is fully solvent; it can meet all claims on it. Under this assumption, the promisee understands that the promisor will either perform or pay damages as measured by the contract rule. In many actual transactions, however, and in some models, the promisor is potentially insolvent. Insolvency triggers a shift in the set of legal rules that govern disputes over contracts. Fried (1996) sets out the rules governing contracts in bankruptcy. He argues that the rules provide the trustee in bankruptcy with incentives to reject some contracts with expected gains from trade.

Consider a contract at time t_0 between a Seller S and a Buyer B for the delivery of one widget at a price p at time t_2 . Suppose S files for bankruptcy at time t_1 ; S is insolvent. If the contract was performed by both parties prior to t_1 , there is no problem. Suppose therefore that S has not performed by t_1 . There are two possibilities: (1) B has fully performed prior to t_1 , or (2) B has not fully performed by t_1 (in which case the contract is executory). In situation (1), B is an unsecured creditor with no priority over any other unsecured creditors. Of course, B may have taken a security interest in some asset of S 's; then B would have a prior claim on that asset. In principle, an economic analysis of contracting must now ask: under what circumstances would we expect to see either party take a security interest in some asset? Turn now to situation (2). S faces a choice. She may either assume the contract or reject it. If she rejects the contract, then B is once again treated as an unsecured creditor of S . If S , however, assumes the contract, there are again two possibilities. S might perform the assumed contract, in which case there is no problem; or S might later breach the contract. (At the time t_1 of the bankruptcy, the market price for widgets might be $p - 2$; S therefore makes a profit by assuming the contract. At t_2 , though, the market price may have risen to $p + 2$, and S might do better if she breaches.) If S breaches subsequent to assumption of the contract, then B is an unsecured creditor of S , but she now has priority over unsecured creditors whose debts were incurred prior to bankruptcy.

In Section 3.1 we consider relational contracts. Section 3.2 discusses the general question of remedy. Section 3.3 considers expectation damages. These are damages that require the harmed party to pay the plaintiff an amount equal in value to the loss suffered by the breach. Section 3.4 examines liquidated damages. In these clauses, the contracting parties specify their own remedial regimes. Section 3.5 discusses the remedy of specific performance. Section 3.6 compares expectation damages and specific performance. Section 3.7 provides a brief summary.

3.1. Relational Contracts and the Absence of a Remedial Regime

Relational contracts use the threat to terminate a relationship as a contract enforcement device.²⁷ The literature here has antecedents in both the legal and the economic literature. In a classic study on the sociology of law, Macaulay (1963) observed that many business relationships appear to work well, even though they have no formal contract, or the contractual instrument they have is extremely unclear or inconsistent.²⁸ The evidence in Macaulay (1963) suggests that parties performed because of the expectation of future business rather than because of the threat of legal remedies.²⁹

Simon's (1951) classic paper on employment contracts initiated the economic literature on relational contracts. Simon was not concerned with the enforceability of the contract but with how complexity can lead to one or the other contract form. Malcomson (1981: 852) begins his analysis of the employment contract with the observation that the complexity of performance requirements makes it impossible to enforce performance standards. This impossibility creates a problem of *ex post* hold-up (MacLeod 2002). Malcomson (1981) points out that legal enforcement of employment contracts is limited; the firm must pay an employee who arrives at work, but the court will not generally assess the quality of the employee's labor. Hence, dismissal is the sole sanction available to the employer. This characterization is consistent with the common law rule of employment at will.³⁰

These ideas have resulted in a large literature on relational contracts that builds on the hypothesis that courts cannot be relied on to enforce sanctions conditional on the performance of complex tasks. Employment at will is the common-law default rule in the United States but not generally in other jurisdictions. Moreover, even in the United States the law has evolved a number of exceptions to at-will employment that allow employees to seek damages from employers (Miles 2000). Though some recent literature explores the role of employment protection in labor market performance (MacLeod 2011), for the most part, the economics literature equates employment law with a turnover tax.³¹ As we observed above, one of the important roles of

27. See MacLeod (2007) and Malcomson (this volume) for detailed reviews of the literature on relational contracts.

28. This confusion can occur when buyer uses her own purchase order and the seller uses his own invoice, each of which includes boilerplate terms. This practice leads to the famous "battle of the forms" problem in contract law. See Farnsworth (2004: 161–170).

29. See also Posner (1997) for a discussion of the role of norms and how they may shape behavior in contractual relationships.

30. See Feinman (1978) for a history of evolution of the doctrine of employment at will.

31. Blanchard and Tirole (2008) provide a nice analysis of employment policy for the purposes of informing French public policy. They explicitly explore the role of employment insurance and view employment protection as mainly a turnover cost. The fact-finding role of the courts is not discussed at all.

the courts is its fact-finding function; hence, equating employment law with a turnover tax is a rather crude representation of the legal system.

The formal analysis of relational contracts begins with Telser (1980), who introduced the idea that a relational contract can be modeled as a repeated game. He shows that if both parties have sufficient gains from trade, then they will both perform when the consequence of nonperformance is a cessation of trade. His model assumes that both parties might breach the contract, and that this event is observable by both parties. Though Telser does not use all the formalism of repeated game theory, his analysis is consistent with the characterizations of the equilibria of repeated games in Abreu (1988).

Abreu (1988) shows that one can characterize all equilibria in a repeated game with a two-step procedure. First, parties agree on the equilibrium action in each period. In the context of a contract, this stage can be viewed as specifying the performance obligations. Next, Abreu shows that this agreement can be the outcome of playing a subgame perfect equilibrium if, in every period, parties cannot gain by not performing, and then playing the worst subgame perfect equilibrium for the cheater. In other words, when breach occurs, the nonperforming party faces the worst equilibrium possible under the rules of the game.

In this framework, the efficiency of an agreement is constrained by the size of the possible punishment. The Folk Theorem formalizes the idea that, as the frequency of interaction increases, eventually the gain from cheating is less than the cost, and hence an efficient agreement can be reached. In this theory, the discount rate between periods represents the frequency of interaction. In this class of models, increasing the discount rate is equivalent to holding the volume of trade constant per period and having more transactions of smaller value within a single period. In that case, the cost of cheating does not change, but because the value of each individual transaction is smaller, the gain from breach falls.

A crucial assumption is that breach can be perfectly observed. One might wonder whether the set of feasible allocations depends on the allocation of the cost of cheating between the two parties. MacLeod and Malcomson (1989) showed that only the total gains from future trade affect the set of feasible allocations. By carefully designing the breach obligation, combined with a bonus payment by the buyer to the seller at the end of each period, parties can choose any allocation of the surplus.

When performance is not perfectly observable, the problem is much more complex. It may no longer be optimal for one party always to perform. Consequently, it is no longer optimal for the breaching party to face the maximal penalty. The modern theory of relational contracts explores the interplay between uncertainty regarding the breach obligation and the possible punishments available in a relationship. In summary, the main technical difference between the theory of damages under relational contracts and damages under contractual instruments in the shadow of the law is that the maximal punishment under a relational contract is limited by the potential gains from future trade. The insights of the contract design and damages literature also apply to relational contracts when the gains from trade are sufficiently large.

Before proceeding to our discussion of damages, it is worthwhile discussing two papers that are often cited as examples of relational contracting, namely, Klein and Leffler (1981) and Shapiro and Stiglitz (1984). These papers do not explicitly address the question of what is an optimal contract. Rather, they begin with an observed contract form and then ask what the market implications are if parties restrict themselves to this contractual instrument. In the case

of Klein and Leffer (1981), they consider the simple sales contract: the seller sells a good at a fixed price. They then suppose that product quality is potentially imperfect and that the market can observe product quality in the past. They explore the consequences for a competitive market when buyers shun sellers who have produced low-quality goods in the past. They show that this shunning strategy implies that high-quality sellers will have brand names with positive rents associated with them. Sellers will choose not to supply low-quality goods for fear of losing the return on their brand name.

Shapiro and Stiglitz (1984) assume that firms offer fixed-wage contracts but have the ability to dismiss workers at will. When there is uncertainty regarding worker performance or a delay in observing performance, then under such a contract, employed workers must earn higher utility than do newly unemployed workers (and hence there is involuntary unemployment). As MacLeod and Malcomson (1989) show, involuntary unemployment follows from the assumption about contract form and not from the assumption of costly monitoring (for an excellent discussion of the issues see Carmichael 1989). These papers illustrate an important branch of the literature that explores the properties of observed contractual instruments and how features of the contractual instrument (mainly the price) vary with characteristics of the environment (see also Lafontaine and Slade, this volume). For the most part, it is still an open empirical question why some contract forms are chosen rather than others.

3.2. Remedy Generally

Courts do not automatically enforce contracts; rather, the party harmed by nonperformance invokes the court. As such, legal enforcement is more properly viewed as providing parties with a set of decision rights. This idea has its origin in Aghion and Bolton (1992). They observe that bankruptcy can be viewed as a situation in which the control rights to a firm moves from the owners to the debt holders. Similarly, MacLeod (2007) observes that contract breach can be viewed as providing the harmed party the right to seek damages in a court of law.

Contract law determines the remedy available to an aggrieved party; the parties, through the contract design, assign the right to invoke the court for nonperformance. We can illustrate the problem with a version of the simple buyer-seller example. We also use this example to discuss remedies for contract breach.

Consider a buyer-seller relationship where the seller chooses a level of effort or quality $q > 0$ that determines the probability $\lambda(q, E)$ that there has been performance as a function of q and possibly of other events E that occur after q is chosen. Let B_P be the ex ante benefit from performance, B_B the ex ante benefit if there is breach, and $c(q)$ the cost to the seller of performing ($c(0) = 0$, $c'(q)$, $c''(q) > 0$, $\forall q$). Given a price p , the payoffs to the buyer and seller are

$$U_B(q) = B_P \lambda(q, E) + B_B (1 - \lambda(q, E)) - r_B - p,$$

$$U_S(q) = p - c(q) - r_S.$$

The terms r_S , $r_B \geq 0$ are the reliance expenditures made by the buyer and seller, respectively, after the contractual instrument has been signed, but before trade and production. These investments provide a motivation for writing a contract, as formally modeled by Groult (1984) and Hart and Moore (1988).

In addition to protecting investments, the contract must also provide appropriate incentives for the seller to choose the efficient level of effort or output, q^* , given by

$$(B_P - B_B)\lambda'(q^*, E) = c'(q^*). \quad (1)$$

Suppose that the buyer cannot directly observe effort q , in which case we have a model that is technically identical to a principal-agent model with risk-neutral agents, and hence, from a contract theory perspective, is trivial. We suppose that it is efficient to trade, and hence any state-contingent price is of the form

$$p_s = B_s - R, \quad s \in \{P, B\},$$

which effectively shifts all risk to the seller, and thus it induces the seller to choose the efficient level of effort. The term R is the rent that the buyer obtains from the relationship. It would be set as a function of the relative ex ante bargaining power of the two parties.³²

This contractual instrument is not a legal document—it merely specifies the transfers as a function of the seller's decision to perform. It supposes either a costless legal system or a world where individuals do not breach their obligations. In practice, this agreement could be implemented in a number of ways. Consider, for example, two contractual instruments that could govern a simple exchange. The first instrument is denoted by p^A . It defines the price that a buyer pays in advance in exchange for a promise by the seller to deliver a good that conforms to the contract specifications. The second contractual instrument, p^P , is the price that the buyer promises to pay the seller on delivery of a conforming good. Notice that neither contractual instrument is complete, in the sense that neither specifies what will happen in the event of breach. Nevertheless, these contractual instruments are very common in practice, and courts are expected to be able to adjudicate the disputes that arise in these cases.

Notice that, though these are very simple contractual instruments, they have quite different properties when viewed as contractual instruments. In the case of instrument p^A , the buyer has paid, and hence the performance obligation rests in the hands of the seller. If she does not perform, then the buyer must sue and must take care to collect evidence regarding the seller's performance. Thus, it is the buyer who must make the investment to sue. If the seller can be shown not to perform, then the courts must determine the appropriate damages.

In the case of instrument p^P the situation is reversed. In this case, once the seller has performed, the buyer must perform her promise to pay. If not, then the seller would have to sue the buyer to collect the amount due. Note that, in the second case, once performance has been verified, then the question of damages is straightforward—the buyer is obliged to pay the amount agreed on, plus possibly any expenses arising from the delay in payment. We use these two generic contractual instruments to discuss the various remedies for breach of contract that have been proposed by the literature.

32. Under this contract, we have: $U_B = R - r_B$ and $U_S = B_P\lambda(q, E) + B_B(1 - \lambda(q, E)) - R - r_S - c(q)$.

3.3. Expectation Damages

The rule of expectation damages attempts to measure the loss arising from breach of contract. In the case of contractual instrument p^P , if the buyer does not pay, the loss to the seller is p^P , and hence, expectation damages provides the same remedy as specific performance. In the case of contract p^A , if the seller performs, the buyer obtains a return B_P and a return of B_B if there is breach. The loss due to breach would be $D = B_P - B_B$. As we can see from (1), this rule ensures that the seller has an incentive to choose effort efficiently. Crocker and Masten (1988) provide some evidence that in the case of long-term gas contracts, parties prefer expectation damages as a way of ensuring efficient ex post adaptation to changing conditions.

The rule also provides an incentive for efficient matching. For example, suppose that the seller has another buyer of a good for whom the value is $B' > B_P$. If the seller breaches, she would have to pay the buyer B_P , but she could sell the good for B' for a gain of $B' - B_P$. Thus, she would breach when it is efficient to do so.³³ However, as Schwartz (1979) observes, this well-known argument does not necessarily imply that specific performance is inefficient. In the absence of transaction costs, the seller could always renegotiate the contract to share some of the gains from breach with the buyer.³⁴ In practice, this argument is problematic, because parties are unlikely to be truthful regarding their valuations; hence, such renegotiation is not likely to be efficient. Myerson and Satterthwaite (1983) have shown that even in the context of a simple exchange for a single good, if parties have private information regarding their valuations and are fully rational, then it is impossible to obtain efficient trade in all cases. Ayres and Talley (1995) build on this result to show how liability rules should be chosen to enhance the efficiency of contract renegotiation.

The early literature on legal-damage rules (Shavell 1980; Rogerson 1984) observes that even though expectation damages result in efficient breach, it may not provide appropriate incentives for relationship-specific investments. These papers are the beginning of a significant economics literature that compares the impact of remedies on the efficiency of a contractual instrument. This literature used the categorization of remedies by Fuller and Perdue (1936). That classic work reviews existing law and suggests that observed remedies can be categorized into three types:

1. Value that the harmed party expected to obtain from the contract or expectation damages in both the legal and economic literatures.
2. The harmed party's reliance on the contract, generally measured by the specific investment r . The economics literature terms these losses "reliance damages."
3. Specific performance, according to which the promisor is ordered to perform the obligation.

The economics literature has accepted these three categories as the prototype representation of U.S. contract law. There are a series of papers, including Chung (1991), Spier and Whinston

33. See Hermlin, Katz, and Craswell (2006: 102–114) for a discussion of this well-known result as well as a more comprehensive review of the literature on expectation damages and related measures of damages.

34. Alternatively, the second buyer could purchase from the original buyer.

(1995), Edlin (1996), Edlin and Reichelstein (1996), Che and Chung (1999), and Schweizer (2006), that explore the relative efficiency of these three rules. This approach is convenient, because it allows one to carefully compare these rules under a variety of conditions. Depending on the environment, each of the damage rules may be efficient, but in general the rule of specific performance is typically found to be the most efficient, consistent with prescriptions of legal scholars, such as Schwartz (1979) and Ulen (1984). This observation raises the obvious question of why the courts do not use specific performance.

To begin with, Craswell (2000) observes that the damage rules used in economic models are rather crude representations of the law. In the case of expectation damages, the parties could have avoided court costs by specifying in advance the monetary damages for breach, a practice called “liquidation damages.” Moreover, a court cannot force the exchange of a good; we need to ask exactly how to implement the doctrine of specific performance. Given that the best the court can do is impose monetary penalties, why don’t the parties avoid court costs by specifying such payments for all possible contingencies—in other words, why do they leave gaps in a contract? Finally, advance specification of the performance obligation is not the only choice available to parties. The parties might instead delegate *ex post* authority for certain decisions to one of the parties. How are such contracts enforced? In the next three subsections we address each of these concerns in turn.

3.4. Liquidated Damages

Under contractual instrument p^A the seller promises to perform, otherwise there is a breach of contract. If there is nonperformance, the buyer would sue the seller, and under the rule of expectation damages parties should expect a judgment equal to $B_P - B_B$. Equation (1) shows that this remedy provides first-best effort incentives. Going to court to recover $B_P - B_B$ is an expensive exercise. If parties knew the outcome of a court case with certainty, then the costs of litigation could be avoided with an out-of-court settlement, the typical outcome in practice (see Spier 2006).

If the value of performance is private information, then from the Myerson and Satterthwaite (1983) theorem, it may not be possible to avoid conflict and a court case. The parties might adopt a number of solutions to this problem. First, the parties might specify liquidated damages—the amount that the seller should pay in the event of nonperformance. These damages, specified in advance, provide a way for the buyer to signal to the seller her private valuation. In principle, liquidated damages reduces the uncertainty associated with a court case, and hence they increase the prospects for settlement.

In economics, liquidated damages is equivalent to a form of performance pay—the explicit linking of performance to compensation. However, these are two different contractual instruments. A liquidated damages clause substitutes the parties’ measure of damages for the default judicial remedy of expectation damages. The clause directs the courts on the measure of damages if breach occurs—if the seller supplies either no goods or nonconforming goods—and the buyer decides to litigate. In principle, the liquidated damages clause should govern but a clause must satisfy several conditions to be enforceable; consequently, the court has substantial discretion

in the application of the clause. Indeed, the court will not enforce a penalty clause (a liquidated damages clause that sets the amount of compensation too high).³⁵

In contrast, performance pay is a contractual obligation that leaves the court little discretion. If the seller supplies nonperforming goods, that would not be a breach of contract as long as the seller also makes the agreed-upon compensation to the buyer. In this case, breach of contract only occurs over promised transfers, a task for which the courts are generally competent. In economics, the principal-agent models rely exclusively on contracts of this type. This class of models covers a large part of the economics of contract, and so it is worthwhile to discuss their enforceability.

Historically, principal-agent models build on the theory of optimal risk bearing. Risk-averse individuals who face diversifiable risks are expected to purchase insurance. An insurance contract specifies payments to be made when certain events occur.³⁶

Agency contracts are particularly applicable to the procurement of services. A physical good is one that can be delivered and inspected before the buyer accepts the good. However, for services, production and delivery are simultaneous, and hence, third parties can never directly observe performance. Rather, one has signals of performance, which might include the amount of apples harvested, monthly sales, number of customer complaints, the amount by which students improve their test scores, and so on. In each of these cases, the principal can link compensation to a measure of performance. Such contracts are also very common in employment. (MacLeod and Parent (1999) find that more than 25% of U.S. workers are on some form of performance pay.)

Holmström (1979) has shown that the optimal contract in a prototypical principal-agent model entails making compensation vary with any useful measure of performance. The question then is whether such a contract is enforceable. In the case of commissions paid to a sales person there has been some litigation regarding the question of whether firms can dismiss employees and then not be required to pay commissions on sales that were completed while the individuals were employees.³⁷ Many states in the United States have applied the doctrine of good faith and fair dealing to such cases to rule that the firm did indeed have an obligation to make good on such promised payments. More generally, because agency contracts typically require the principal to make monetary payments as a function of well-defined events that are observable by the courts,

35. To be enforceable, a liquidated damages clause must be set at a level that approximates actual damage suffered, and the amount of damages must be, at the time of formation of the contract, uncertain and hence difficult to anticipate. On liquidated damages generally, see American Law Institute (1981: § 375). Goetz and Scott (1977) also provide an introduction to the law.

36. The genesis of the principal-agent model is Arrow's (1963) observation that, in the case of health care, the government is in the best position to insure individuals against the costs of medical care in the event of an accident. However, Pauly (1968) observed that this policy recommendation overlooks an important market incompleteness—namely, these contracts do not control the level of care that individuals use to avoid risks. He argued that insurance contracts create moral hazard: insured individuals have less incentive to take precautions than uninsured persons have. This observation spawned a large literature that today is called either “agency theory” or the “principal-agent problem.” See Bolton and Dewatripont (2005: 129–169).

37. See Miles (2000) for a discussion of these doctrines and the extent to which performance contracts are enforceable.

then we would conclude that these contracts are consistent with existing legal regime. We are sure that this conclusion is a great relief for our dear reader (as it was for us), given the importance of agency theory in modern economics.

3.5. Specific Performance

The economics literature generally assumes that contracts are enforceable in the sense that, if a party has an obligation a , then the party will in fact do a . In legal terms, the economics literature assumes that the default legal remedy is “specific performance.” The discussion in the last section has indicated that this assumption is generally false. The standard common law remedy for breach of contract is expectation damages.

Consider first specific performance in the context of the sales contract given by p^P in which the buyer promises to pay p^P on delivery of the good. If Seller delivers and Buyer fails to pay, specific performance merely requires the payment of a sum of money, a task that the courts are competent to do. Notice that the first-best outcome can be achieved with a price $p^P = B_P$ when $\lambda(q^*, E)B_P \geq c(q^*)$. Also notice that the remedy of expectation damages would provide the same outcome.

Now consider the contractual instrument p^A , where the seller promises to deliver a good after payment has been made. Suppose Seller fails to deliver or delivers a good that is not of the appropriate quality. What does specific performance mean in this case? If the contract merely called for the transfer of physical or real property, then the courts could competently enforce the transfer. In the case of real property they would simply order that a transfer has occurred and have this put into public record. At that point the new owner would simply rely on the sheriff’s office to enforce her ownership rights. In such cases the courts often use specific performance as a remedy.³⁸

What does specific performance mean when the courts cannot directly control the actions of the seller? In these cases, the mechanism design literature, such as Aghion, Dewatripont, and Rey (1994) and Edlin and Reichelstein (1996), observes that the enforcement of specific performance entails the (judicial) threat of penalties that are sufficiently large that the parties choose to perform as promised.³⁹ If it is the case that, at the effort q^* , one has $\lambda(q^*, E) = 1$, then any penalty greater than $U_S(q^*) - U_S(0) = c(q^*)$ would ensure performance. Notice that this is equivalent to a performance pay contract of the form:

$$P(q) = \begin{cases} p^* & \text{if } q \geq q^* \\ -C & \text{if } q < q^*. \end{cases} \quad (2)$$

Under this contract, the seller pays a penalty $-C$ if performance is inadequate. Given that rewards are deterministic, the seller can always elect to avoid the penalty by choosing q^* . Such

38. See Farnsworth (1999). If the prior owner does not vacate the premises, the sheriff will, on an appropriate order of the court, evict. Similarly, if a losing defendant in a contract action fails to pay the ordered expectation damages, the sheriff, on an appropriate court order, will levy and execute on the defendant’s assets to satisfy the judgment.

39. See Edlin and Reichelstein (1996: 482).

a contract might make sense if the buyer wished to ensure performance for a wide variety of costs to the seller. In the absence of a penalty, the seller might choose to default. Such contracts are implicitly used in economic models where the goal is to implement a price-quantity pairing where there is possibly some asymmetric information (e.g., Maskin and Riley 1984; Laffont and Tirole 1986).

As Edlin and Reichelstein (1996) observe, this rule is easy to implement in practice—the courts need only verify whether performance occurred and then impose a sufficiently large penalty if not. They then provide conditions under which specific performance can ensure efficient investment and trade, significantly extending the earlier results of Rogerson (1984) and Shavell (1984). The benefit of the rule is that it provides a method for enforcing effort revelation when the courts cannot observe relevant information or when one party is credit constrained.

However, the *penalty doctrine* (see Farnsworth 1999) directs courts not to enforce liquidated damage clauses that require payments (e.g., C in the contractual instrument given in (2)) that are out of proportion to actual damages. This doctrine allows courts to reduce or waive liquidated damages.⁴⁰ This rule can be used to explain some features of observed contractual instruments. As an example, consider long-term contracts for inputs to a manufacturing process. Joskow (1988) describes in some detail the market for the supply of coal to electric utilities. If parties are risk neutral, then in principle they could agree to terms that might allow the contract price for coal to vary significantly from the spot price. An interesting feature of observed contract prices is that they closely follow the spot price for coal. This raises the question of why parties engage in costly contract design, rather than use the spot price. MacLeod and Malcomson (1993) provide a solution to this problem: if each party needs to make a relationship-specific investment that affects their own payoffs, but not the other's (the so-called "self-investment" case), then it is efficient to have a fixed-price contract. However, over time the price of coal can fluctuate a great deal. Parties could put into place large penalties to enforce trade at the contract price, but these may not be enforceable under the penalty doctrine. MacLeod and Malcomson (1993) show that if parties can index the contractual instruments so that it follows the market price, then it is unnecessary to put in place penalties for breach of contract. Moreover, parties would still have the incentive to make efficient investments into relationship-specific capital, because their investments do not affect the price paid or received in the future. Edlin (1996) has another solution that may work in some circumstances. He shows that Cadillac contracts that call for very high performance can ensure efficient investment under the rule of expectation damages.

These results do not resolve the issue of why courts are reluctant to enforce penalty clauses. Thus, there is an unresolved tension between the results of Aghion, Dewatripont, and Rey (1994) and Edlin and Reichelstein (1996) showing that the doctrine of specific performance allows for the implementation of efficient arrangements, while in practice courts are reluctant to enforce such contracts. One possible reason for this reluctance is that courts must adjudicate all disputes, including disputes involving poorly drafted and incomplete contracts. We now turn to this issue.

40. See Posner and Rosenfield (1977) for an early analysis of these issues.

3.6. Specific Performance and Expectation Damages Compared

Both Schwartz (1979) and Ulen (1984), distinguished legal scholars, have argued that the courts should use specific performance rather than expectation damages as the default remedial rule. In an important paper on mechanism design, Aghion, Dewatripont, and Rey (1994) show in a model with hold-up that the rule of specific performance can ensure efficient investment and exchange. Schwartz and Scott (2003) reiterate this point in a law review. Indeed, the economics literature suggests that specific performance has superior efficiency properties compared to expectation damages.

This conclusion, however, may underestimate judicial and party ingenuity. Consider the case of construction contracts. The complexity of construction presents a particularly challenging environment to achieve first-best outcomes even with specific performance. Bajari and Tadelis (2001) introduce a simple and elegant way to formally introduce unforeseen events into a model of construction contracts. The idea is that the time and money spent drafting a contract can be viewed as relationship-specific investment in the quality of the contractual instrument. Let I be the investment in planning, and let $\rho(I)$ be the probability that only foreseen events occur. It is assumed that $\rho' > 0$, and hence the quality of planning increases with I . With probability $1 - \rho(I)$ an unforeseen event occurs. They then compare two contract forms—fixed price and cost plus. Under a fixed-price contract the seller is responsible for delivering an acceptable product at the agreed-on price. Thus, the seller receives all the returns from any cost-saving actions.

In contrast, under a cost-plus contract, the buyer pays all costs of production, thereby reducing the incentives to the seller of making unobserved cost-reducing investments. If all events are foreseeable, then the fixed-price contract implements the first-best, whereas if events are unforeseeable, then the cost-plus contract is more efficient. Thus, if the costs of planning are sufficiently low that unforeseen events occur with low probability, then a fixed-price contract is optimal; the opposite holds with respect to cost-plus contracts. The model delivers a theory of contract form as a function of the complexity of the environment, as measured by the cost of planning.

Bajari and Tadelis (2001) assume, following the literature, that courts enforce agreement with specific performance as given. Chakravarty and MacLeod (2009) build on their model and explore how such contracts are enforced. They begin with the structure of the American Institute of Architects (AIA) form of construction contracts.

This class of contractual instruments is interesting, because they are widely used in the U.S. construction industry and have evolved over 100 years in response to both experience in the field and the outcome of litigation involving construction disputes. Hence, these contractual instruments are likely to satisfy the economists' assumption that the form of observed contractual instruments can be explained as an efficient solution to the problem of implementing trade, given transaction costs and the characteristics of the contracting parties. Chakravarty and MacLeod (2009) show that these contracts can indeed be viewed as efficient under the following conditions:

1. The buyer's design is costly in the sense of Bajari and Tadelis (2001).
2. The seller's investment in cost reduction is not observable, though realized costs are observable.

3. Buyer's preferences are private information, and they can change between the time of contract and project implementation.
4. Courts use expectation damages but may excuse performance.

In practice construction must occur in the shadow of the law, and it is natural to ask whether efficient trade is possible within existing law. The literature on mechanism design reviewed above suggests that specific performance may be a necessary ingredient for efficient trade. Chakravarty and MacLeod (2009) find that this is not the case—these contractual instruments are able to implement the efficient allocation with a generalized version of expectation damages:

$$\text{Damages} = \text{Foreseeability} \times \text{Expectation},$$

where Foreseeability is a number between 0 (unforeseen) and 1 (perfectly foreseen) representing the extent to which a loss is anticipated. If an event is unforeseeable, and/or impractical to remedy, then the law excuses the breaching party from performance. In contrast, if the event is foreseen, then the rule of expectation damages applies. Both these extremes are consistent with current law. The rule is more general because, when an event is only partially foreseeable, then damages should be reduced. This rule is implemented in the AIA forms by leaving the damages in some cases to be determined by mutual consent.

Thus, even within the economics of contract literature, the superiority of specific performance as a remedy remains an open question. The resolution of the debate over the appropriate default remedy will likely entail a better understanding of the interplay between the fact-finding function of the courts and the contractual environment. Notice, for example, that the rule of specific performance can lead to opportunistic behavior on the part of the seller. If the seller learns that the buyer has had an unfortunate event (say, her plant burns down), then she can take advantage of the buyer's low valuation b to threaten delivery under the contract in order to extract a larger damage payment. If one can anticipate such behavior, then the contract can be design to mitigate its costs. If benefits and costs are private information, then as Myerson and Satterthwaite (1983) have shown, it is not possible to implement the ex post efficient allocation.

One of the messages of the literature on asymmetric information is that there are inevitably costs to revealing information. There is a growing literature that uses models of asymmetric information to understand the process of litigation.⁴¹ This literature is not yet integrated into the literature on contract design. Hence, we conclude that contracts that vary with well-defined performance measures are in general enforceable. However, contracts that entail large penalty payments or rely on specific performance are in general not enforceable.

3.7. Summary

The basic message of this section is that the economic theory of contract does not rely on the complex institution that is contract law. For the standard principal-agent problem this does not entail great loss of generality. Performance pay contracts are in general enforced. However, more recent models that rely on strong forms of specific investment are not in general consistent with existing law.

41. See Cooter and Rubinfeld (1989) and Spier (2006) for excellent reviews of the literature.

This observation may help explain the tension that exists between the property rights approach to the theory of the firm (Grossman and Hart 1986; Rajan and Zingales 1998; and Hart and Moore 1999) and the mechanism design approach to contract (Moore 1992; Maskin and Tirole 1999; Tirole 1999). The former implicitly recognizes that contracts may be limited in their ability to allocate bargaining power, something that can be better achieved with ownership rights.

Parties to a contract are concerned with ensuring that they are able to rely on the contract and thus make appropriate relationship-specific investments. In addition, there is always an element of asymmetric information between parties and the courts that may also lead to transaction costs that may be reduced with the appropriate allocation of bargaining power. Rogerson (1992) has made some progress on integrating asymmetric information and hold-up, but much work remains. In particular, the contract literature has not incorporated the fact-finding activity of a court case into contract design. In the next section we discuss the literature that explores these activities in more detail.

4. Adjudication

Section 3 examined the shadow cast by the substantive remedial rules of contract law.⁴² This section examines the judicial role in dispute resolution. Resolution of a contract dispute requires a court to determine what obligations the parties have and whether any obligation has been breached. The first task requires the court to interpret the contractual instrument. The second task requires the court to determine what in fact happened. Phrased differently, contract disputes may arise for two distinct reasons. The parties may disagree about what happened; in economic terms, they disagree about the realized state of the world (including the actions undertaken by each party). Or the parties may disagree about the content of their obligations.

Disagreement about the state of the world may arise even when contractual instruments are complete. Disagreement about the obligations of the parties, in contrast, assumes either that the contractual instrument is incomplete or otherwise defective (perhaps ambiguous or inconsistent).

We organize our discussion into two parts. Section 4.1 examines the literature on fact finding. As virtually nothing has been written about the role of the court as a finder of facts in

42. We ignore here a substantial literature on the shadow cast by rules of bankruptcy. The law of bankruptcy looms when one party cannot afford to make a transfer required by a contract. In the case of agency theory, given that the state provides a complete description of the environment, this constraint is anticipated and incorporated into the design of the contractual instrument. See Sappington (1983) and Innes (1990) for two early important contributions and Lewis and Sappington (1999) for a more recent contribution and discussion of this literature. The contract design ensures that, even in this case, there is no real role for the courts, because the transfers are always feasible. The contract design must reflect this constraint. There is a vast literature in corporate finance that explores the consequence for contract design when parties face limited liability. See Gale and Hellwig (1985), Bolton and Dewatripont (2005) and Doornik (2010) for a comprehensive review of this vast literature. These papers can be viewed as contributing to our understanding of contracting in the shadow of the law, where the shadow is cast by the rule that limits penalties to the financial wealth of defendants. This limitation was not always the case. In the past debtors might be sent to prison or face other physical penalties. It is an open question why there has been a historical evolution toward limiting liability to one's assets. See Hansmann (this volume) for further discussion on the historical evolution of limits to financial liability.

contract disputes, we review a related literature on fact finding generally. Section 4.2 addresses interpretation.

4.1. Fact Finding

4.1.1. *Fact Finding in the Economics of Incomplete Contracts*

The economic literature on contract classifies facts into four classes: verifiable, jointly observable, observable by one party but not the other, and neither verifiable nor observable.⁴³ A verifiable fact is one that is known (or knowable) publicly, that is, to both parties and to any third-party adjudicator. A jointly observable fact is known to both parties to the contract but is not publicly available. Obviously, a fact that is observable by one party but not the other occurs in contractual environments with asymmetric information. Some facts (e.g., the precise state of the world) may be not observable. The existence of observable but nonverifiable facts constrains parties in the drafting of contractual instruments (and courts in the imposition of contractual obligations). An obligation cannot be conditioned on a fact that is not verifiable.

This classification is very extreme. Either a fact is verifiable (generally at 0 cost), or it is not verifiable (at any cost). The situation in actual exchange environments is more nuanced. A fact may be more or less verifiable at greater or lesser cost. One might say that a “more verifiable” fact is one for which the court or other third party receives a more accurate signal. Moreover, courts can use burdens of proof and burdens of persuasion to influence the quality of signals that parties provide as well as distributing the consequences of erroneous signals.

Before considering the structure of judicial fact finding, we note that much of the economic literature investigates the consequences of nonverifiability for the form of a contractual instrument. One might, for example, understand the entire principal-agent literature this way. Agent effort is not verifiable (nor observable to the principal); consequently, the parties require a contract that conditions the agent’s wage on other verifiable facts.

4.1.2. *Judicial Fact Finding*

A contractual instrument specifies, against the legal backdrop, the obligations of each party. Often the obligations of the parties are state contingent: what each party must do varies with the state of the world. Resolution of every contract dispute thus requires determination of the actions that each party took and of the realized event.

Fact-finding procedures apply across a wide of range of types of disputes, and they are governed by distinct bodies of law (that generally go under the names of “civil” or “criminal” procedure and evidence).⁴⁴ We may assess these procedures along two dimensions: their accuracy and their cost. In an ideal world, fact finding would be perfectly accurate and costless. In the real world, the invocation of courts is costly, and courts themselves sometimes err in their fact finding.⁴⁵

As we discuss below, the economic theory of contract generally distinguishes observable actions from verifiable ones. Courts costlessly observe verifiable actions with perfect accuracy;

43. A more complete account would include dates: when a fact is known by whom.

44. We ignore some evidentiary rules that are specific to contract law, such as the statute of frauds, which requires writing to enforce certain classes of contracts. On the statute of frauds, see Farnsworth (2004: 353–410).

45. We note in passing that the parties may, in the contractual instrument, alter the usual default fact-finding procedures.

courts cannot observe unverifiable actions at any cost.⁴⁶ Most actions and events, in contrast, are only verifiable at some cost and to some degree of accuracy.

A few models—Milgrom and Roberts (1986), Shin (1998), and Dewatripont and Tirole (1999)—examine how accuracy varies with the fact-finding procedure. These models contrast adversarial procedures (in which each party presents evidence favorable to itself) with inquisitorial procedures (in which a nonpartisan agent gathers evidence). These models identify conditions under which adversarial procedures dominate inquisitorial ones.

These models require further elaboration to yield insights for an economic theory of contract. In Milgrom and Roberts (1986), the parties are fully informed about the state of the world. In the legal context, in contrast, each party generally has only partial and asymmetric information about the state.

All three papers address questions of imperfect and asymmetric information. Moreover, Shin's (1998) model addresses adjudication directly. From a legal perspective, however, these models are in a reduced form. Each assumes that the agents and the principal acquire information about the correct final decision that in Shin is dichotomous, whereas in Dewatripont and Tirole (1999) it is trichotomous. The decision in Shin thus corresponds to the disposition of an adjudication (i.e., the judgment that the plaintiff prevails or fails). The disposition in a contract dispute depends both on the state of the world and on the obligations imposed by the contract. These obligations, however, result from the process of interpretation, discussed in Section 4.2.

Common law adjudicatory institutions reflect this structure. Facts in contract disputes in the United States are typically found by juries. Judges determine the law; that is, judges interpret the contractual instrument and determine the contractual obligations of the parties.

4.2. Contract Interpretation

Virtually all models in both the economics of contract and the economic analysis of contract law make two critical assumptions about contractual behavior. First, the models assume that contractual instruments are perfectly drafted: contractual instruments are clear and consistent on their face. Second, the models assume that parties to the contract have foresight and correctly anticipate the consequences of their actions, including those of the court. Neither assumption is warranted: contractual instruments are inevitably incomplete, unclear, and often inconsistent. They require interpretation. Moreover, the practice of interpretation is not completely transparent. As Goetz and Scott (1980) observe, courts have a complex set of rules that often entail changing clearly specified performance obligations.

The economic theory of incomplete contracts does admit one important role for interpretation. When an uncontracted-for event occurs, a court must fill the gap in the incomplete contractual instrument. The court must specify the obligations of the parties to determine whether breach has occurred. The gap-filling ruling is often called a "default rule."

The literature on incomplete contracts and that on the economic analysis of contract law have studied default rules from two complementary perspectives. In the incomplete contracts literature, this study has been implicit rather than explicit; it occurs in the analysis of the causes of the incompleteness of contractual instruments. The economic analysis of contract law, in

46. The economics literature treats unverifiable actions as a constraint on the contractual instrument.

contrast, has generally asked which default rules provide the optimal background against which parties should draft their incomplete contractual instruments. We discuss the choice of optimal default rules in Section 4.2.2 and the role of interpretation in contractual incompleteness in Section 4.2.4.

Gap filling, however, is not the sole purpose of interpretation. In Section 4.2.4, we discuss the sparse literature that adopts a more general approach to interpretation. As noted in Section 2.2, we can understand interpretation as a mapping from some set of interpretative materials that include the contractual instrument (but may include other texts and actions) into a set of contractual obligations for each possible event.

In economics, the dividing line between contract theory and other areas of the theory of organization (e.g., corporate governance or human resource management) typically turns on the notion that courts merely enforce the terms of a written agreement. In contrast, corporate governance focuses on the design of decision rights for officers of the corporation. In fact, a legally binding contractual instrument must explicitly deal with the allocation of decision rights over the relationship. That is, parties to a legally binding agreement provide each other the right to take the other party to a court of law for the adjudication of the contractual instrument in the event of a breach. In the absence of courts, parties would have to rely on other instruments to enforce an agreement, such as reputation effects; threats to reduce trade in the future; or even possibly threats of violence, as discussed in MacLeod (2007).

4.2.1. *What Is Interpretation?*

In the most basic sense, a contract is a complete list of terms k_θ that specify, for each state θ of the world, the obligation a_θ of each party: in state θ , the seller must undertake action s_θ and the buyer must undertake action b_θ . A contractual instrument, in contrast, is a partial list of terms. The list of terms in a contractual instrument is partial in at least two senses. Most obviously, the instrument may not specify an obligation for every state of the world. In addition, a contractual instrument may not fully specify the obligations of each party even when it covers a state of the world. Interpretation is the process through which the court completes the contractual instrument to yield a contract.

The contractual instrument and its partial list of terms may present several different interpretive problems:

1. Missing terms. The realized state θ may not be on the partial list of states included in the contractual instrument.
2. Ambiguous terms. A contractual instrument may specify an agent's obligation ambiguously, or it may specify the event ambiguously.
3. Inconsistent terms. There is an event E for which are two clauses k_i, k_j that specify conflicting obligations. If event E occurs, it is not clear which action, b_i or b_j , should be carried out.
4. Impossible terms. A term imposes an obligation that is impossible to perform in the realized event, even though that event is contemplated in the terms.
5. Unwanted terms. The contractual instrument may, for state θ , specify obligations that, when θ is realized, the parties do not prefer to some other obligations.

Each of these defects present an interpretive problem for the court. As economic models typically assume, suppose that the model parties use an accurate representation of their relationship. Then these defects cannot occur. As a consequence, though there is a substantial amount of law arising from these five contractual defects, there is little economic analysis of these problems. We discuss each of these interpretive tasks in turn.

When the contractual instrument is missing a term, it is, in the most basic sense, incomplete. The statement that “the *contract* is incomplete” is, in contrast, a rather crude and not particularly helpful statement. After all, a simple rule of interpretation ensures that every contractual instrument is complete. Given any contractual instrument K , let E^c be the set of states for which there is no specified obligation. If an event $E \subset E^c$ occurs, then we can complete the contractual instrument by supposing that neither party has an obligation in this event. As one can always do this, one can always suppose, following Ayres and Gertner (1992), that contracts are obligatorily complete. Hence, for each contractual instrument, either parties perform as specified in the agreement, or one party believes there is breach of contract, in which case she has the right to an adjudication.

Notice that, when $E \subset E^c$, a court could adopt a different rule to complete the contractual instrument. The court might, for instance, require each party to perform the obligations that are specified in some other term k . Whatever specification the court implies is called a “default rule.” We discuss default rules in Section 4.2.2.

A term may be ambiguous in two different ways. Typically, a term k in a contractual instrument does not address a single state θ . Rather, it groups states into events E . Given ordinary language, however, it may be unclear whether some state θ is in E . Alternatively, the contractual instrument may have described the obligation of one of the parties ambiguously. The parties may describe a party’s obligation in at least two different ways. Ideally, each term would specify a single obligation of the party, but often, a contractual instrument gives the party discretion. The term might provide a list of tasks that the agent may perform. Or the parties may describe a performance that the agent must accomplish. Suppose a contractual instrument simply states “deliver the fresh fish by 3 p.m. today to 230 Mercer Street, New York City.” This instrument uses a performance to describe the action set; it does not list the multitude of ways that the agent might actually deliver the fish by 3 p.m.—by cart at 2:59, by bicycle at 2:58, etc.⁴⁷ The manner of specification may affect the interpretive task for the court. It may be unclear whether the action undertaken by the party falls within the description of the obligation.

A contractual instrument may also include inconsistent terms. For example, the contractual instrument may specify that the seller supply 100 units when the price of wheat is less than \$5 per bushel and 50 units when the price of corn is greater than \$4 per bushel. If the price of each is \$4.50 per bushel, is the seller in compliance when she supplies 50 units? A court must resolve these inconsistencies.

Impossible terms are a particularly egregious example of an inconsistent term. This is a very common case for simple contractual instruments, such as an agreement to supply q at a price p . Events may make it impossible to supply q . In the well-known English case *Caldwell v. Taylor*, for example, the plaintiff had rented the defendant’s opera house for a performance on a given

47. Notice that these descriptions are incomplete. A complete description of the tasks would identify the route the deliveryman took and the type of cart or bicycle he might use.

date; shortly before that date, the opera house burned down, rendering performance of the defendant's contractual obligation impossible.

When economists speak of incomplete contracts, they often mean contracts with unwanted terms: the parties have, for some state θ , specified obligations that are inefficient. There are some actions available to each party that would yield a higher total surplus to be divided among them.⁴⁸ The court must now decide whether to reform the contractual instrument and require the parties to undertake the efficient actions rather than those specified in the contractual instrument.

4.2.2. *Default Rules*

A default rule determines the obligations of the parties when an event occurs about which the contractual instrument is silent. To reach this conclusion, of course, the court must first interpret the contractual instrument as not having addressed the realized event. Two questions arise: Why is the contractual instrument silent? How should the court specify the missing term?

At first thought, the silence of a contractual instrument is perplexing. Consider, for example, a paradigm supply example. Suppose a caterer contracts for the delivery of fresh fish to a location for an event in the afternoon, at an agreed-on price p . The contractual instrument is very simple: it requires the supplier to deliver by 3 p.m. and emphasizes the importance of timely delivery, because the fish is for an important event. Now suppose the normally reliable supplier is involved in a traffic accident and fails to deliver the fish, which results in irreparable harm to the caterer's reputation for reliability.

The court must determine what damages, if any, should be assessed against the supplier for breaching the promise to deliver the fish. Our example presents a classic problem of an incomplete contractual instrument. To an economist, the prevalence of these disputes is puzzling, because the parties surely understand that accidents sometimes happen. The dispute does not arise from asymmetric information. As the accident was foreseen, why haven't the parties included terms in the agreement that cover such cases? A complete contractual instrument would have clauses that specify payments that would be made when there is nonperformance. In this section we review the various models that have been introduced to explain why contractual instruments are incomplete. In Section 4.2.4 we discuss the role of the law in completing such incomplete contractual instruments.

Four reasons have been offered for the silence of contractual instruments. First, Goetz and Scott (1980) suggest that if breach is a very low probability event, then parties may find that the ex ante cost of negotiating breach terms is greater than the benefit. In this case, they choose to delegate the damage decision to the court (for a formalization of this argument see Shavell 1984). In these cases, they would like the court to set damages equal to the amount they would have agreed on ex ante. As we shall see in Section 4.2.4, costs of drafting provide a general answer to the first question of silence and unwanted terms.

Second, contractual instruments may be strategically incomplete. Ayres and Gertner (1989), Aghion and Hermalin (1990), and Spier (1992) show that a buyer with asymmetric information

48. This inefficiency might arise in two ways. The parties may simply have made a mistake and specified the wrong acts. Or the contract term may be overbroad; it specifies a uniform action for all states in some event E when efficiency requires that the actions differ.

about her own valuation may not include a term that specifies liquidated damages, fearing that it will reveal how much she values the good. The seller could use this information to increase the price. Hermalin and Katz (1993) suggest that courts should allow parties to use fill-in-the-blank contractual instruments to enhance performance.

Third, and related, Bernheim and Whinston (1998) show that parties may choose to leave contractual instruments incomplete because doing so will increase future gains from trade and thus increase the set of outcomes that can be supported by a subgame perfect equilibria. The parties can then place more reliance on the value of a future relationship for enforcement and thereby avoid costly enforcement via a court. Scott (2003) provides some evidence from case law that is consistent with the results of Bernheim and Whinston (1998); namely, parties do seem to use contract incompleteness to enhance the set of feasible allocations. Baker, Gibbons, and Murphy (1994) have what can be viewed as a countervailing result. Namely, they show that if one adds a legally binding agency instrument, then it can increase the set of self-enforcing agreements. Using this idea, Schmidt and Schnitzer (1995) show that when one party breaches a relational contract, then, rather than separate, the parties might choose to use a contractual instrument that is enforceable in court. This option would reduce the cost of breaching and thereby reduce the set of agreements enforceable with a relational contract.

Finally, Bolton and Faure-Grimaud (2005) introduce an explicit planning model and work out how these costs give rise to the incompleteness of contractual instruments. Tirole (2009) interprets the cost of planning as a form of limited cognition and then explores the consequence of planning costs or limited cognition on contract design. He shows that, if one can hide one's information, then the introduction of limited cognition can lead to adverse selection, as in the model of Spier (1992).

The answer to the second question of the judicial response to the silence of the contractual instrument is equally complex but less developed. The complexity arises because contractual parties will bargain in the shadow of the law. The content of the default rules will determine whether parties contract over specified events or leave the instrument silent. Change the default rule, and one changes the content of a contractual instrument. Shavell (1984) shows that, in principle, courts can choose default rules that allow short contractual instruments to induce optimal contractual behavior.

In practice, the actual design of specific default rules is controversial. A prominent view is that courts should fill in gaps using so-called "majoritarian defaults." Under a majoritarian default rule, the court supplies the term that the majority of individuals would prefer. Economic analysts of contract law justify this choice on the grounds that it minimizes drafting costs (Goetz and Scott 1983). Given that the majority of contracts are not litigated, it is not at all obvious that such a notion is well defined or knowable to contracting parties.

Even if knowable, the determination of the optimal default rule *ex post* is challenging. Mechanism design theory reveals the inherent tension between *ex post* and *ex ante* efficiency. The implementation of *ex ante* efficient contracts often entails the use of actions that are sometimes *ex post* inefficient. If an event occurs that is not addressed in the contractual instrument, how does one tell if it is a foreseen event that parties have delegated to the courts to fill or one that is unforeseen? If the event is unforeseen, then as Hart (1990) observes, the consequences of reaching that state can have no effect on *ex ante* decisions. In that case, the efficient rule is always to

choose an ex post efficient allocation. As we have discussed above, a defining feature of expectation damages is that it is an attempt to achieve ex post efficiency. Hence, though the rule of expectation damages does not necessarily achieve ex ante efficiency, the fact that it approximates an ex post efficient allocation makes it an appropriate rule for unforeseen gaps in a contractual instrument.

Ayres and Gertner (1989, 1992) and Bebchuk and Shavell (1991) argued that, in contractual environments with asymmetric information, courts should adopt a penalty default that induces the informed party to reveal her private information. These papers consider models with two types of buyers and assume that the optimal level of seller's investment is a function of the buyer's type. The buyer's type is assumed to be private information. The authors show that a default rule that penalized buyers with a high type would, under the appropriate circumstances, induce low-type buyers to reveal their type. This model, however, failed to clearly distinguish penalty from majoritarian defaults. If low-type buyers constituted a majority of the buyer population, then they would be indifferent between the two rules considered by the court.

4.2.3. *Unwanted Terms*

The economic literature on incomplete contracts has offered an explanation of the presence of unwanted terms. They may arise simply because of the complexity of the contractual environment. This complexity requires that the parties invest time and resources into the creation of a contractual instrument.

Defining exactly what one means by "complex" remains an open question, or more precisely, there are many definitions of complexity that depend on context. The formal model of contract we describe above supposes that a contractual instrument is a collection of event-obligation pairs. Events are subsets of the state space, which even for very simple problems becomes astronomically large (see Williamson (1975: 21); MacLeod 2002). Thus, even with small costs of adding clauses, contractual instruments are likely to be very incomplete. This idea is formalized in the work of Townsend (1979) and Dye (1985) in the context of a simple risk-sharing contract. They show that the fixed costs of adding terms implies that there can be only a finite number of events specified in any contractual instrument. This finite number of terms partitions an infinite state space into a finite number of events. Consequently, it lumps together a number of states. An ideal contract would require distinct acts for some of these states; the contractual instrument has produced an overbroad term that may require the inappropriate actions in some realization, and thus the first-best outcome cannot be achieved.

Rather than exogenously fixing the cost of adding an event, Anderlini and Felli (1994, 1999) endogenize these costs with a model of computational complexity. They also show that the optimal contractual instrument trades off the cost of planning against contractual completeness. Battigalli and Maggi (2002) extend this work and discuss how contract complexity affects the choice between rigid and flexible contract terms. In their model, the parties may be unable to specify the optimal action.

This literature derives results on contractual form by assuming an interpretive practice of the courts. Specifically, the literature assumes that a court will enforce the contractual instrument as written: it will not reform the instrument and substitute ex post the term that the parties would in fact want. Of course, courts may not adopt this interpretive practice. Section 4.2.4 suggests that this interpretive practice is in fact not optimal.

4.2.4. *Interpretation Generally*

The focus on default rules arises naturally in a world in which contracting parties are fully rational and have perfect foresight. Interpretation will play a larger role in worlds where agents err and draft defective contractual instruments.

Even within the limits of perfectly foresighted parties, optimal interpretation requires more than simply filling gaps. Shavell (2007) formalizes interpretation as a function from the set of contractual instruments into itself. An interpretive method takes the contractual instrument—a list of pairs of events and obligations—into another list of event-obligation pairs.⁴⁹

To understand the role of interpretation, we must consider the drafting options available to the parties. Consider some state θ . The parties may draft a specific term that specifies obligations for θ only; they may draft a general term that specifies obligations for some event E with $\theta \in E$, or the parties may ignore θ and leave a gap in the contractual instrument. Both gaps and general terms arise because it is costly to draft a term.

It follows immediately that the optimal method of interpretation has several properties: (1) specific terms are enforced literally; (2) gaps are filled with majoritarian defaults; and (3) general terms are, in some cases, overridden—the majoritarian default rule may be applied to some $\theta \in E$. These results hold for a wide class of exchange environments. There are, however, several caveats. First, there is no renegotiation. Second, there is perfect contract enforcement. Finally, it is not obvious how to link the formal language in this model to observed phenomena. What is a majoritarian default, and how can it be measured? In fact, if these concepts were well defined, a contract could simply be prefaced by directions to the court that they should fill gaps with majoritarian defaults. The difficulty is that the real work of the courts is to figure out what is a majoritarian default, something about which the theory is currently silent.

4.2.5. *Delegation, Renegotiation, and Interpretation*

Interpretation determines the obligations of the parties to a contract *ex post*. There are two other mechanisms for the *ex post* specification of obligations that serve as partial substitutes for judicial interpretation of contractual instruments. Unlike judicial interpretation, these two *ex post* methods—delegation and renegotiation—have received extensive treatment in the economic literature.

Each of these three methods permits the parties to impose or to alter an obligation *ex post*. They differ in the identification of the agent that determines the content of the *ex post* obligation. Delegation gives one of the parties the exclusive right to determine the obligation, perhaps within limits specified in the contractual instrument. Renegotiation permits the parties jointly to determine the content of the obligation *ex post*. Under interpretation, a third party, the court, has the sole power to specify *ex post* the content of the obligation.⁵⁰

Despite this common attribute, interpretation differs in one important respect: interpretation is always available. Delegation (and the decisions of the delegate) and renegotiation occur

49. As Shavell observes and we noted in Section 2.2, an interpretive method might take more than the text of the contractual instrument as its domain: the court might refer to additional texts and actions to determine the obligations of the parties.

50. A contractual instrument might identify a third party other than the court. Many contractual instruments provide for arbitration, a third-party mechanism.

in the shadow of the law. It is important to understand how legal institutions shape the operation of delegation and renegotiation. The extent and operation of delegation in a contractual instrument only has the range and force permitted by a court after interpretation. Similarly, the outcome of a renegotiation depends on the point of disagreement, and that point is determined by the interpretive practice of the court and the remedial rules of contract law.

We focus on delegation of authority. As Lafontaine and Slade (this volume) observe, contractual instruments commonly include an allocation of control rights or authority. We shall see that the reasons for such delegation mirror the reasons that provoke interpretation. This literature may thus shed light on how best to model interpretive questions.

There are essentially three reasons for the allocation of authority to one party or another: unforeseen or costly-to-foresee contingencies, asymmetric information, and the allocation of ex post bargaining power.

The first formal model of authority, indeed the first modern contract model, is due to Simon (1951).⁵¹ He considered a model in which parties sign a contractual instrument, the buyer learns the state of nature, and then the level of output that the seller is to provide the buyer is determined. Formally, the optimal allocation $\{q(x), p\}$ solves

$$\max_{\{q(x), p\}} E\{B(x, q(x))\} - p,$$

subject to

$$p - E\{C(q(x))\} \geq u^0,$$

where x is a random variable, $C(q)$ is the cost of producing q , $B(x, q)$ the benefit of q in state x , p is the price, and u^0 is the seller's outside option. Simon (1951) supposes that x is not contractible and is known only to the buyer. Hence, the buyer is constrained to choose between two contractual instruments. The first is a sales contract, where price p and quantity q are set in advance. The second is an employment contract, a contractual instrument in which the seller (employee) agrees to supply any amount in a set Q at a price p . The benefit of this contractual instrument is that the buyer can adjust q as a function of information received after the contractual instrument is signed.⁵²

In terms of enforcement, notice that the employment contract has two elements. First, the buyer, after observing x , creates a performance obligation $q(x)$ for the seller. If the seller does not perform, then the seller has breached. In employment relationships, such breach does not typically lead to damages but to the dismissal of the employee. Thus, the employment contract is enforceable only to the extent that dismissal is a sufficiently large penalty. A second element to the contractual instrument (i.e., the requirement that $q(x) \in Q$) might be enforced by requiring that the seller can only be dismissed with just cause. If the employer asks for an action outside of the set Q , then the seller has a right to refuse to carry out such actions.

51. Notions of authority and control are also central to the theory of the firm (see Gibbons 2005).

52. Simon has in mind an elemental theory of bounded rationality that is captured by the hypothesis that x cannot be explicitly contracted on—a theme that the profession would not explore again until the 1980s. The main result is that when uncertainty is sufficiently important (variance of x is sufficiently large), then the employment contract is most efficient; otherwise, parties will use a sales contract.

An obvious application of the model is to the theory of the firm—a theory that predicts when contracts are within the firm and when they are between firms. Alchian and Demsetz (1972) argued that Simon's employment contract could not be construed as an explanation for why we have firms. They observe that the buyer and seller are free to reach any agreement they wish, and should circumstances change, the contract terms can be renegotiated. Thus, as MacLeod (2002) shows formally, the introduction of renegotiation ensures that Simon's sales contract can always achieve the first-best outcome. This result suggests that, for a complete model of authority, one needs to add additional ingredients. One such ingredient is asymmetric information.

There are two ways in which asymmetric information may lead to an allocation of authority rights. The first of these has its roots in Williamson's (1975) idea that contractual relations are plagued by *ex post* opportunistic behavior that leads to costly contract renegotiation. These costs are formally captured in the Myerson and Satterthwaite (1983) model. If there is two-sided asymmetric information, and one is not sure if it is efficient to trade, then it is not possible to implement the efficient allocation. Ayres and Talley (1995) and McKelvey and Page (2002) show that one way to enhance the efficiency of bargaining with two-sided asymmetric information is to modify the status quo point in the event of a disagreement.

Asymmetric information is often invoked to explain why there may be costly contract negotiation. A less emphasized implication is that investing in more information can reduce negotiation costs. In particular, if there is one-sided asymmetric information, then it is possible to achieve an efficient allocation by allocating all bargaining power to the informed party. Chakravarty and MacLeod (2009) note that this observation is consistent with the standard clauses in AIA form contracts that allocate authority for design changes to the buyer, while requiring the buyer to compensate the seller for any measured out-of-pocket costs arising from the change. This rule makes sense, because although in principle one can measure construction costs with careful bookkeeping, the subjective valuation a buyer assigns to design is difficult, if not impossible, to measure.

This difficulty is reflected in the common law enforcement of sales contracts that place an obligation on sellers to respond to changes in delivery terms requested by the buyers, and it provides an explanation of why specific performance is not used in these cases. It is efficient to grant authority to the buyer to modify her requirements, while protecting the seller with expectation damages that ensure her profits are not reduced by the buyer's actions.

The United States Uniform Commercial Code is quite explicit regarding damages when the buyer refuses to accept delivery of goods:

§ 2-708. Seller's Damages for Nonacceptance or Repudiation.

(1) Subject to subsection (2) and to Section 2-723:

(a) the measure of damages for nonacceptance by the buyer is the difference between the contract price and the market price at the time and place for tender together with any incidental or consequential damages provided in Section 2-710, but less expenses saved in consequence of the buyer's breach; and

(b) the measure of damages for repudiation by the buyer is the difference between the contract price and the market price at the place for tender at the expiration of a commercially reasonable time after the seller learned of the repudiation, but no later than the time stated in paragraph (a), together with any incidental or consequential damages provided in Section 2-710, less expenses saved in consequence of the buyer's breach.

(2) If the measure of damages provided in subsection (1) is inadequate to put the seller in as good a position as performance would have done then the measure of damages is the profit (including reasonable overhead) which the seller would have made from full performance by the buyer, together with any incidental damages provided in this Article (Section 2-710), due allowance for costs reasonably incurred and due credit for payments or proceeds of resale.

Notice that section 1(b) states that damages should be reduced by the amount saved by the buyer's breach. More generally, under the common law, the seller has an obligation to mitigate the loss. This would include stopping production at the time the buyer sends a letter repudiating the contract. Under the rule of specific performance, the seller would have the right to continue production and then demand the seller to pay for the goods (which might be optimal if the market price were less than the agreed-on price for the goods).

Aghion and Tirole (1997) introduce an innovative model of the authority relationship that extends this theme. Their idea is that authority arises from the access to information necessary to act. In their model, the principal with formal authority will delegate authority to an agent who has better information. However, the principal will reserve the right to overrule an agent when he is better informed. This model can be viewed as another way of explaining employment contracts. The law gives the employer broad discretion when allocating tasks to the employee, and the employer always has the formal right to change an employee's task as long as it is within the scope of work.

Finally, the allocation of authority also affects the allocation of bargaining during contract renegotiation that can occur when contractual instruments are incomplete and there is the potential for hold-up. The property rights literature of Grossman and Hart (1986) and Hart and Moore (1990) implicitly builds on the idea that courts do not generally enforce contract breach through specific performance. Rather than regulate the relationship by contract, they observe that the bargaining power of parties can be allocated by ownership rights over assets. Rajan and Zingales (1998) extend this idea to relationships within the firm, where an organization can choose how much power agents have to grant access to firm resources.

5. Conclusion

A theory of contracts studies the relation among four theoretical objects: exchange environments, contractual instruments, contract law, and contractual behavior. The relation among these concepts is complex. In the short term, the exchange environment and contract law are exogenous; we thus seek to explain both contractual instruments and the resulting contractual behavior in terms of the exogenously given contractual environment and contract law. From a wider perspective, however, both contract law and, to a lesser extent, the exchange environment are endogenous. To a large extent, we choose the legal rules that govern contractual instruments. Similarly, agents choose the environment in which they contract; moreover, they might act to alter the exchange environment in which they find themselves.

Each aspect of the literature on contract focuses on a different explanatory question. The mechanism design literature asks: for a given contractual environment, does a mechanism exist that induces efficient contractual behavior? In this literature, a mechanism conflates contractual instruments and contract law; it examines contracts, the set of obligations that result from the

operation of contract law on contractual instruments. Nevertheless, the literature assumes a legal system that is basically utopian.

The incomplete contracts literature, in contrast, seeks to explain the structure of observed contractual instruments. It often begins with some observed contractual instrument and then asks: in what exchange environment is a specified contractual instrument optimal for the parties? Once again, the structure and competence of the legal system is largely idealized. The incomplete contracts literature explains the oddities of contractual instruments largely without reference to any features of contract law.

The literature on the economic analysis of contract law, finally, abandons the assumption of an ideal legal system. Rather, it often asks: given a contractual instrument in a specific exchange environment, how does the legal rule influence contractual behavior? Here the legal system is not ideal, though the literature has primarily relaxed only the assumption of perfect enforcement.

Each of these literatures has provided significant insight into contractual behavior and the structure of contractual instruments. The mechanism design literature, for instance, has provided clear, formal accounts of specific transaction costs, such as asymmetric information, and analyzed the extent to which these features of the contractual environment impede efficient exchange. The assumption of an ideal legal system, however, limits the practical insights available from these models. An assumption of perfect enforcement, for example, implies that contractual behavior always conforms to the obligations embodied in the contractual instrument. Indeed, rational parties need never invoke an ideal legal system; the shadow of the law is sufficient to regulate behavior. Similarly, the assumption that interpretation is unambiguous, clear, and foreseeable implies that parties can always implement perfectly their intentions.

The economic analysis of contract law adopts complementary simplifying assumptions. It generally studies very simple exchange environments; we have little idea how the ideal legal rule would vary across exchange environments. Similarly, it generally focuses on the effects of legal rules on contractual behavior but ignores the effects of legal rules on contractual instruments. It has provided few explanations for variation in available remedies across exchange environments and contractual instruments. Why, for instance, are common law employment contracts at-will rather than protected by expectation damages? Moreover, the formal study of interpretation is in its infancy. Models have very crude representations of the rules of interpretation, in part because the literature has not exploited the language formulated in Battigalli and Maggi (2002).

This sketch of these literatures points clearly to promising paths of future research. We need to meld the sophisticated analyses of exchange environments and contractual instruments to the simple models of nonideal legal institutions. The mechanism design literature might investigate the set of achievable allocations under nonideal legal systems. Imperfect enforcement will impede the realization of first-best allocations. How good must contract enforcement be to yield the first-best outcome? How costly is imperfect enforcement?

Relaxing the assumption of unambiguous interpretation is apt to be both more difficult and more fruitful. Contracting agents rarely use new or innovative language in their contractual instruments. Contractual terms that have been subject to extensive interpretation provide a more certain environment against which to contract. This observation suggests that many contractual terms might be suboptimal relative to the world in which interpretation is unambiguous and costless. Thus, at least some features of observed contracts likely respond to the failings of the courts and contract law.

In terms of a way forward, the first step is to work more on models that help us build empirical representations of the legal system. Theories create conceptual categories that should have analogues in practice. Second, what are the testable implications of these theories? There is surprisingly little discussion of how one could formulate an empirical hypothesis that can be brought to the data.

One of the real difficulties with attempting to study contract law is that it is impossible to build data on the universe of contracts. Litigated cases are the exception, rather than the norm. Moreover, when drafting a contract, parties draw on both litigated cases and industry practice. Hence, as Manski (1993) showed in the context of social networks, it will be very difficult to identify the causal impact of contract law on contract performance.

Inter-Firm Contracts

Evidence

Francine Lafontaine and Margaret E. Slade

1. Introduction

1.1. Background

Economics is sometimes described as the study of markets. Many market transactions, however, do not take place in arm's-length spot markets but instead are governed by long- or short-term contracts. Because those contracts restrict the actions of one or both parties, there must be offsetting benefits. Otherwise, parties would not voluntarily enter into agreements that limit their flexibility. In this chapter, we review empirical analyses of interfirm contracts, paying particular attention to the reasons for entering into contractual relationships and the associated costs and benefits. We consider not only studies of the incidence of such contracts—when different types of contracts and contract terms are chosen—but also studies of the effects of those choices on outcomes, such as profits, prices, sales, and firm survival. Because our goal is to review the empirical literature, we rely throughout on authors' institutional knowledge and their definitions and classification schemes for contracts and contract terms.

Given that interfirm contracts are found most extensively in the context of procurement and distribution, most contracts analyzed herein occur between firms that are vertically related. In particular, one party supplies either an input or a service to the other. Nevertheless, some contracts, such as licensing agreements, arise between firms in the same product market. Yet in the context of a licensing relationship, one firm, the licensor, in fact provides an input (a production technology and associated services) to the other, and in that sense the relationship is also vertical. With few exceptions, we do not discuss alliances and joint ventures, which are more common forms of relationships among firms in the same horizontal market. The interested reader is referred to Azoulay and Lerner (this volume) and Ménard (this volume) for a discussion of these types of relationships. Similarly, to keep the scope of the chapter manageable, we focus

We thank the volume editors, Robert Gibbons and John Roberts, as well as several colleagues, including Kenneth Corts, Ricard Gil, Desmond Ho-Fu Lo, Julie Mortimer, Emmanuel Raynaud, and participants in workshops at the National Bureau for Economic Research for helpful comments. We thank our respective institutions for their support. Margaret Slade also acknowledges financial support from the Leverhulme Foundation.

on procurement and distribution contracts rather than on contracts that occur between firms and their capital providers, be they banks or individuals. The latter tend to involve a different set of issues and are discussed further in Gertner and Scharfstein (this volume).

In our review of the empirical literature on interfirm contracting, we emphasize analyses of agreements that are framed in the context of transaction costs and contract theory. However, we also consider contributions that predate those developments. Many studies that fall into the latter category are analyses of contract terms known as vertical restraints, where one link in a vertical chain constrains the activities of another. Historically, such constraints have been viewed either as mechanisms by which firms can achieve (or at least move toward) the vertically integrated outcome without resorting to integration or as devices that enable them to enhance their market power.¹ By emphasizing the incentive aspects of vertical restraints, our coverage attempts to bring the findings from the vertical-restraints literature into the fold of organizational economics and the empirical analysis of interfirm contracts.

Interfirm contracts are often similar in structure to the contracts used within firms, including executive and certain types of labor compensation schemes. Empirical studies of within-firm contracts, however, are also beyond the scope of this chapter. Interested readers should consult Azoulay and Lerner (this volume) and Waldman (this volume). A related literature that is beyond the scope of the present survey is that which focuses on the contractual relationships of firms with growers in various agricultural sectors, including the hog and broiler industries. Because growers are usually individual farmers, this literature tends to emphasize agent risk aversion and heterogeneity, much in the same way as the within-firm contracting literature does.² Similarly, and for similar reasons, we do not consider contracts with talent, whether in the context of sports or movie production. Finally, we generally exclude studies of contracts where one party is the government. Both motivations and constraints can be quite different in such contexts.³ We focus instead on those transactions that parties have chosen to organize across firms.

The fact that we are considering agreements between firms already has implications for the parties' incentives (see, e.g., Gibbons 2005: 12). In particular, in such contexts, the parties are usually residual claimants, although their profits are likely to depend on each other's actions. Moreover, risk plays a less salient role in many of the models and empirical applications than it might if the transactions involved individuals.⁴ Similarly, many firms are, at least in theory, longer lived than individuals.⁵ Thus, the shadow of the future probably looms larger in their relationships with other parties, including, of course, other firms.

1. For analyses of vertical integration, see Bresnahan and Levin (this volume) and Lafontaine and Slade (2007). For a discussion of market-power motives for vertical restraints, see Lafontaine and Slade (2008).

2. Interested readers should consult, for example, Knoeber (1989), Allen and Lueck, (2002), Dubois and Vukina (2004), and Vukina and Leegomonchai (2006) for more on contracts used in these settings.

3. For more on government procurement contracts, however, see Banerjee et al. (this volume) and Moe (this volume).

4. Of course, risk is an important factor in analyses where one of the parties is a small firm, for example, an owner-operator or a partnership.

5. In reality the failure rate of firms is quite high, such that their life expectancy is probably lower than that of individuals. However, what matters is that managers and owners make decisions as if the firm were long lived, either because they do not know when the firm might fail or because they internalize the effects of their decisions on the value of the firm's assets upon failure.

1.2. Types and Terms of Common Contracts

Here, we introduce some standard forms of contracts and then go on to discuss some related contracting issues. Contracts can take many forms. Nevertheless, certain standard formats or contract types appear in many industries, time periods, and regions of the world. We devote most of our chapter to those standard forms and practices, of which the following are typical.

Perhaps the simplest contract is a *pricing contract* that just specifies a price at which a good or service can be bought or sold. Such contracts can be very short lived, in which case they are not very different from spot market interactions, or they can last for many decades. In the latter case, researchers have studied not only the contracts themselves but also their duration and the ways in which they can adapt to changed circumstances. Pricing contracts are common when the product is homogeneous, such as many fuel and nonfuel minerals, and in traditional franchising, such as gasoline and automobile sales.⁶ Finally, a special case of pricing contract involves only one item, such as a project, in which case it is referred to as a “fixed-price contract.”

Cost-plus contracts are very different from pricing contracts in that they do not specify a price. Instead the seller is paid her costs plus a fraction of those costs to compensate for the effort involved. This type of contract is often used to procure one item, such as a project or service, that is often unique to a buyer. Moreover, a cost-plus contract is frequently contrasted with a fixed-price contract, which is the other standard method of financing a single project. The choice between the two involves a trade-off between the flexibility of a cost-plus contract and the incentives for cost control that a fixed-price contract gives the supplier.

A *share contract* is a third standard type. This sort of contract is most often affine in revenues. Specifically, it tends to involve a fixed fee (which can be positive or negative) that is paid by the downstream firm, in addition to each party receiving a share of revenues. Share contracts are commonly found in business-format franchising,⁷ such as fast food and real estate sales, but also in many other contexts, such as technology licensing and retail leasing. Because each party receives a share of revenues rather than profits, such contracts are distortionary. As a result, it was once thought that they were inefficient and would disappear in modern economies. It is now well understood, however, that share contracts, which are also associated with countervailing benefits, are here to stay.

Vertical restraints are not types of contracts. Rather, they are restrictions, such as exclusive dealing, tying, and resale price maintenance, that are included in contracts and that limit the activities of one or more parties to the contract. Vertical restraints are most commonly found in retail settings, where they limit the downstream firm's activities. Most studies of vertical restraints have emphasized their potential for increasing horizontal market power. We do not consider that part of the literature. Instead we survey the studies of vertical restraints that emphasize their incentive properties in a vertical context and how they can be used to reallocate decision rights. Vertical restraints are thus special cases of the ways in which control rights are specified.

6. Traditional franchising refers to vertical relationships where a product is produced upstream and sold downstream by a separate firm under a franchise contract (e.g., gasoline and autos). It can be distinguished from business-format franchising, which is discussed below under share contracts.

7. One can contrast business-format franchising, where no production takes place upstream, with traditional franchising. With the former, the upstream firm sells a way of doing business and the right to use a trademark, whereas the latter involves upstream production and an associated dealer network.

Most of the studies that we survey involve explicit contracts. This is to be expected, because researchers typically analyze data on the terms and clauses that are written into contracts. Nevertheless, many “contracts” are unwritten but well understood by the parties. *Implicit contracts* are especially important in areas where the legal system is weak or corrupt, but they are also a common feature of modern economic systems.

Once a contract is agreed upon, enforcement becomes an issue. Moreover, many of the same mechanisms can be used to enforce explicit and implicit contracts, and those mechanisms tend to be implicit. In particular, most derogations are dealt with informally, and legal breach-of-contract proceedings are relatively rare. At least two mechanisms are commonly used to sustain agreements implicitly. The first is relational, which means that both parties expect to benefit from a continuing one-on-one relationship. This might be accomplished by ensuring that both expect to receive a stream of future rents. The second is reputational and involves group enforcement. In this case, failure to conform to accepted behavior will damage a party’s reputational capital more generally.

The chapter is organized as follows. In Section 2, we very briefly review some theoretical arguments that have been used to explain the structure of interfirm contracts. Our coverage of the theories is nontechnical. The interested reader can find a much more complete and rigorous treatment of that literature in Kornhauser and MacLeod (this volume) and Malcomson (this volume). In Section 3, we review some econometric issues that arise in the empirical assessment of inter-firm contracts. We emphasize some of the pitfalls that researchers face and solutions that have been adopted. To keep the chapter tractable, we do not revisit these issues when discussing the evidence. Our hope is that the reader will keep in mind that such issues affect the quality of the evidence in individual papers. We reserve the heart of the chapter for Section 4, which contains a detailed review of the empirical literature on the incidence and effects of contract forms and terms, such as fixed fees, revenue shares, contract duration, and price-adjustment clauses. Concluding remarks are found in Section 5.

2. The Theories

Given our description of the many forms that contracts between firms can assume, it is not surprising that no single model can capture all the complexities. Nevertheless, much of the empirical literature aims to assess whether the predictions of just a few theories hold in the specific contexts from which their data are obtained. Because our objective in this section is to provide a framework that can be used to organize the empirical work, our discussion of the theories is short and nontechnical. As mentioned previously, readers interested in more complete and advanced treatments are referred to Kornhauser and MacLeod (this volume) and Malcomson (this volume).

Throughout our discussion of the theories, we consider a vertical chain with at most three links: an upstream supplier, a manufacturer or franchisor, and a downstream retailer. We assume that the manufacturer is the principal who must decide how to interact with her agent, either her supplier or retailer. (Throughout the chapter, we refer to the middle link in our vertical chain, the manufacturer, as “she,” and use “he” for both suppliers and retailers.) Explicit interfirm contracts govern these relationships in all but the extreme cases of vertical integration (in which case there no longer are separate firms in the vertical chain), and pure arm’s-length transactions in markets (which only require agreement on spot prices and quantities purchased).

Contracts are normally designed so that, *ex ante*, it is in the parties' best interest to accept them. Nevertheless, contingencies can arise *ex post* that can cause one of the parties to want to break the contract. We begin with a discussion of explicit contracts that are legally enforceable, either by the courts or through some agreed-on arbitration scheme. Not all contracts are legally enforceable, however, either because the appropriate institutions do not exist or because reliance on third-party enforcement is prohibitively expensive. We therefore conclude this section with a discussion of contracts that are self-enforcing *ex post* as well as *ex ante*.

2.1. Agency Models

Agency theory is the theoretical lens that has been most relied on in the empirical literature to study the existence and the terms of one of the categories of contracts described above, namely, share contracts. The reliance on this theoretical framework in the empirical literature on share contracts is due in part to the fact that very early models were developed to explain sharecropping. As such, they focused their attention on contracts that had the property of being linear in (or rather an affine function of) output, as is the case for sharecropping. Stiglitz (1974), for example, derived implications about factors that would affect the choice of share parameter α in such a contract, implications that could be taken to data directly in a number of contexts where contracts take this form. In that sense, the theory "met the empiricists half-way."

In the pure risk-sharing version of his model, Stiglitz showed that increases in risk would lower the share of output α that the more risk-averse party, assumed to be the agent, should be awarded under the optimal second-best contract. More typically, however, the agency or moral hazard model of contracting involves a risk- and work-averse agent who must exert an unobservable effort. In this case, Stiglitz (1974: 244) showed that "if workers are risk averse, then $0 < \alpha < 1$, and α is larger the greater is the responsiveness of effort to an increase in the share α If workers are risk neutral, $\alpha = 1$." Thus, early agency-theoretic models yielded testable implications concerning the effect of risk, risk aversion, and the importance of agent effort on the optimal second-best contract terms (i.e., the share parameter).

One drawback of this theoretical framework, however, is that the focus on single principal-agent pairs leads to the conclusion that contracts should be tailored to the characteristics of individual agents and local circumstances. In other words, the theory suggests that differences in agent risk aversion, local exposure to risk, and other characteristics of the agent or transaction should lead the principal to offer different contract terms. Yet in many contexts, observed contracts are not tailored in these ways. Building on the work of Reid (1977), Rubin (1978), and Eswaran and Kotwal (1985), Bhattacharyya and Lafontaine (1995) argued that in many instances, it is not sufficient to give incentives to the agent. In the case of franchising, for example, the principal must also be given incentives to exert effort on, say, maintaining brand value. When this is true, there is moral hazard on both sides. Nevertheless, assuming that the principal is risk neutral, the second-best contract can still be implemented as an affine function of output. The share parameter, however, is now meant to give incentives to both parties. Bhattacharyya and Lafontaine (1995) show that, although traditional agency models give rise to different contracts for each principal-agent pair, under double-sided moral hazard and risk neutrality, the share parameter is much more likely to be the same or very similar across agents and/or sets of circumstances. Moreover, the prediction still holds from the traditional

agency model that the share going to the agent should increase with the importance of the agent's effort. This share, however, is now also decreasing in the importance of the principal's effort.

In reality, of course, contract design is much more than just an issue of choosing a share parameter. In particular, effort is not the only factor that is costly; contract administration, for example, is associated with documentation and enforcement costs. An ideal contract would therefore provide appropriate effort incentives to each party, share the risk in an optimal fashion, and elicit an appropriate quality and quantity of the goods or services that are traded while at the same time keeping administration costs at a minimum. In addition, unless the contract is very simple and short term, it should also provide efficient methods of adapting to unexpected changes in the economic environment. It is difficult to imagine that any single model could deal with this level of complexity. However, as noted by several authors, there are important complementarities among the various goals that the principal is trying to achieve. This suggests that we are likely to observe fixed packages of contract attributes. In other words, if there are n attributes, each of which can be high or low, we do not observe 2^n contract types. Instead, we usually observe only a few contracts, which often can be positioned along a linear scale between two extremes. The choice of the share parameter α in the theoretical model can then be viewed as a choice of location along such a scale. Table 1 illustrates this point. Assume that the agent receives compensation $s(x) = \alpha x + f$. In a procurement situation, where x is cost, $\alpha < 0$ is the share of costs that the agent pays, and $f > 0$ is a fixed price or payment that he receives. In a retailing or sales situation, x is output or sales revenue, $\alpha > 0$ is the agent's or retailer's share, and $f > 0$ is his fixed wage. Equivalently, in a franchise or licensing contract, $(1 - \alpha)$ and $-f$ are the royalty rate and fixed fee, respectively, that the agent pays to the principal. With both procurement and retailing then, $|\alpha|$ represents the power of the agent's incentives. In the procurement case, a higher share of cost borne by the agent gives him incentives to keep costs low. In the retailing or sales context, a higher share of sales revenues going to the agent, or a lower royalty rate paid to the principal, induces the agent to exert more effort toward increasing revenues. However, increasing the power of the agent's incentives necessarily implies reducing the power of the principal's incentives.⁸

Table 1 also can be used to illustrate how changes in exogenous factors lead to changes in contract terms (e.g., to changes in α). For example, it is usually assumed that the agent is the more risk-averse party, which means that when market or project risk increases, the need to insure the agent also rises, and $|\alpha|$ should fall as a consequence. In addition, as the marginal product of one party's effort rises, that party should be given a higher fraction of residual claims, which will cause $|\alpha|$ to rise or fall, depending on whether that party is the agent or principal. Finally,

8. See, for example, Shepard (1993), who places the three contract types in gasoline retailing in the United States along a scale with one standard contract, company-owned stations, representing vertical integration and at the other extreme, open dealers, a form of trade between independent firms. She puts lessee dealers—which she equates with franchising—somewhere between these two extremes. Similarly, Slade (1998a,b) describes the four standard contracts used in beer retailing in the United Kingdom and in gasoline retailing in the United States, respectively, along a similar continuum. Finally, in the labor context, Ichniowski et al. (1997) group human resource practices into four human resource management systems that they describe as different points along a scale from “most traditional” to “most innovative.”

Table 1. A moral-hazard classification of contracts

	$\alpha = 0$	$0 < \alpha < 1$	$ \alpha = 1$
Contract type	Cost plus vertical integration	Sharing	Fixed price market transaction
Characteristic			
Risk bearer	Principal	Agent and principal	Agent
Effort incentives	Low for agent; high for principal	Intermediate for agent and principal	High for agent; low for principal
Flexibility	High	Intermediate	Low
Documentation effort	High	Intermediate	Low
Quality incentives	High	Intermediate	Low

Source: Adapted from Bajari and Tadelis (2001).
Note: When positive, α is the share of output or revenue that the agent receives, and when negative, it is the share of costs that the agent pays.

when the principal is responsible for the costs, it is easier to implement changes in product design, because a fully compensated agent is less likely to object. However, cost-plus contracts are more costly to administer, because the agent must document all expenses.⁹

This simple classification scheme, moreover, can encompass a situation in which the agent must perform multiple tasks (as in Holmström and Milgrom 1991) in a straightforward way. To illustrate, the agent might have to exert effort on quality as well as on quantity production, and the former might be more difficult to measure than the latter. With a share contract of the form that we have been discussing, compensation tends to be based on (measurable) quantity. Thus, as quality measurement difficulties increase, $|\alpha|$ should fall. A move toward lower powered incentives occurs because high-powered incentives cause the agent to neglect the important quality dimension that is not emphasized by the compensation scheme.

The two extremes of our simple classification scheme, $\alpha = 0$ and $|\alpha| = 1$, also are worth noting, as they represent limiting contracting forms. First, if $\alpha = 0$, the agent bears none of the costs of production in the procurement case as, for example, in a cost-plus contract. In a retailing context, the agent is paid a fixed salary only. This case can be equated with vertical integration to the extent that fixed salaries are found mostly within firms. The opposite extreme, with $|\alpha| = 1$, is equivalent to spot market transactions, because the agent is the residual claimant with respect to his product or service. Furthermore, $\alpha = -1$ is also a linear or fixed-price contract, where the buyer pays either the prevailing market price or the one that is specified in the contract, namely f .¹⁰ All these situations are encompassed in Table 1.

Finally, even though our classification scheme focuses on the case of a single principal and agent, in empirical settings the principal may use a single contract with all or most of its agents.

9. Most of these comparative-static results are derived formally in Lafontaine and Slade (2007) for retailing and in Bajari and Tadelis (2001) for procurement.
10. Note that this is a linear contract for a single item.

If the optimal share parameter for each agent does not differ much, one can move from a theory where $\alpha \in [0, 1]$ is for a single agent to a group-level empirical analysis, where the many agents of a principal all operate under the same contract terms. As mentioned above, Bhattacharyya and Lafontaine (1995) show that share parameters are likely to vary less under double- than single-sided moral hazard. Moreover, the principal is more likely to use the same contract for all agents if the costs of administering different contract terms for different agents are high, either from an administrative perspective or because agents might be particularly concerned about opportunism when contracts differ (see McAfee and Schwartz 1994). Finally, in many of the settings where contracts are uniform across agents, they are offered on a take-it-or-leave-it basis. Though this is again outside the simple model above, the types of agent that will accept the offered contract are likely to be somewhat similar, in terms of risk aversion and taste for effort, for example, such that contract uniformity across agents again need not be costly for the principal (see Lo et al. 2011).

2.2. Transaction Costs

Transaction costs are the costs of establishing and administering business relationships within and between firms or individuals. Transaction cost theories can be traced back to Coase (1937), who focused on the costs of transacting under different organizational forms, particularly, the costs of writing and enforcing contracts. The theories have been developed further by Williamson (1971, 1979, 1983), Klein et al. (1978), and others.

The insight from transaction cost economics that is most often addressed in the empirical literature is as follows. Parties to a transaction often make investments that have greater value inside than outside the relationship. In other words, the value of the assets in their intended use is higher than their value in alternative uses. Examples include specialized tools that can only be used to produce the products of one manufacturer, training that increases worker productivity exclusively in using those tools, and supplier facilities that have been located in close geographic proximity to purchasers. Specific investments give each party to a relationship a degree of monopoly or monopsony power. Indeed, even when there are many potential trading parties *ex ante*, when investments are specific, parties are locked in *ex post*.

When specific assets are involved, interaction in spot markets is unlikely. Instead, parties are expected to turn to long-term contracts or vertical integration to protect themselves and their assets. If those contracts were complete, specificity would not create problems. The complete contract would specify exactly what will occur and who will control the assets under all possible contingencies. However, writing complete contracts is costly, and not all contingencies can be foreseen. Thus, real-world contracts are normally incomplete. Unfortunately, the combination of incompleteness and specificity gives the parties incentives to endeavor to capture the rents associated with the specific assets. Thus, they are likely to haggle with one another, thereby increasing the costs of writing and administering the contract. They are also more likely to attempt to renegotiate the contract or, more generally, engage in opportunistic behavior. These possibilities, which are the essence of the hold-up problem, clearly pose problems for long-term contracting. Moreover, those problems are exacerbated in volatile environments, making it more likely that the firms will turn to vertical integration to protect their specific assets.

Here again, forms of contracts that lie between full vertical integration (or hierarchy) and spot market transactions—hybrid organizational forms, as they are often called in this literature (see Williamson 1985, 1996)—are viewed as intermediate solutions to the problem of minimizing haggling, opportunistic behavior, and exploitation. These organizational forms thus are apt to be relied on when these problems are present yet not too severe. The theory moreover predicts that the contracts will be of longer duration when transaction costs are larger. However, as contract duration increases, the probability that the economic environment will change grows. When transaction costs are important and firms still choose to organize their activity via contract, the theory predicts that these longer duration contracts are more apt to incorporate flexibility. This can be done, for example, by including price and quantity adjustment clauses that specify how those variables can be altered, as well as provisions for efficient breach if the relationship becomes disadvantageous.

Finally, the theory provides a number of testable predictions concerning the circumstances under which transaction costs are likely to be important. Specifically, transaction costs are apt to be more problematic when transactions are complex, when they involve specific investments, when those specific assets are more durable, when the quality of those assets is difficult to verify, when the environment is uncertain, and when the quasi-rents generated by the relationship are large.¹¹

2.3. Property Rights

Property rights theories, which are more recent and more formal than transaction cost arguments, were developed by Grossman and Hart (1986), Hart and Moore (1990), Hart (1995), and others.¹² Those theories emphasize how asset ownership affects investment incentives. More specifically, they demonstrate how the allocation of property rights, which confer the authority to make decisions concerning the use of assets when unforeseen contingencies arise, changes *ex ante* investment incentives.

Because property rights theories deal with relationship-specific assets, incomplete contracts, and ex post bargaining,¹³ they are often thought to be closely related to transaction cost models. However, there are important differences. In particular, unlike the transaction cost literature, the property rights literature has not focused on ex post haggling, renegotiation, and opportunistic behavior. Instead, authors have developed formal models that have shown how costless ex post bargaining affects ex ante investment in noncontractible assets. Whinston (2003) moreover shows that the predictions from the two sets of theories can be quite distinct. However, if one equates the probability of vertical integration with $(1 - \alpha)$ in a contract, some of the comparative statics listed in Table 1 in relation to our discussion of agency theory emerge under property rights models as well. In particular, Grossman and Hart (1986) show that as the importance of the manufacturer's investment (or alternatively, decisions or effort) grows, manufacturer ownership (vertical integration or low-powered incentives for the supplier) becomes more desirable, whereas as the importance of the supplier's investment grows, supplier

11. For more on transaction costs, see Tadelis and Williamson (this volume).

12. For an in-depth discussion of property-rights theories, see Segal and Whinston (this volume).

13. Property rights theories can therefore also be traced back to Coase's (1937) seminal contribution.

ownership (vertical separation or high-powered incentives for the supplier) is more apt to dominate. These predictions are consistent with those of double-sided moral hazard models in particular.¹⁴

While the theoretical property rights literature historically has focused on asset ownership as the mechanism that confers control or decision rights as well as payoff rights, contract clauses can reallocate control rights away from asset owners. And indeed, Baker et al. (2011) depart from the assumption of costless bargaining *ex post* found in the Grossman-Hart-Moore framework to analyze maladaptation during the contract execution phase (see also Baker et al. 2008; Hart and Moore 2008). Their approach yields predictions concerning contract design and the allocation of decision rights separately from asset ownership. This theme—that contract clauses can allocate decision rights across fixed firm boundaries—is familiar also from an earlier empirical literature on vertical restraints, to which we now turn.

2.4. Vertical Restraints

We have thus far considered how contract design, which determines, for example, the power of the incentives that are given to each party as well as contract duration and flexibility, varies with the economic environment. Clauses that determine who can make important decisions, such as choose product prices and product lines, are also written into contracts. Any restriction imposed by one member of a vertical relationship on the other member is a vertical restraint. Here we focus on the possible efficiency aspects of traditional price and nonprice vertical restraints. The former refers to resale price maintenance, where, for example, a manufacturer either sets the price or sets a maximum or minimum price that retailers can charge, whereas the latter includes exclusive dealing, exclusive territories, quantity forcing, and tying. In all cases, the presence of these clauses in a contract constrains the behavior of some party to the contract while keeping fixed the boundaries of the firms.

There is an important body of literature in economics that considers the effects of such restraints. This is because they have been viewed with some suspicion by the antitrust authorities, raising concerns that they might be used to create or increase market power. The market power considerations for such restraints are beyond the scope of this chapter.¹⁵ From an organizational economics perspective, however, our interest is in considering when firms want to adopt such restraints for efficiency reasons. We thus take the view that such restraints are clauses that principals write into their contracts with agents to align up- and downstream incentives.

Empirically, vertical restraints most often arise in retail settings, with the upstream firm or manufacturer restricting its downstream retailers' choices. For example, a manufacturer might limit its retailer's product line or geographic market, or it might set the retail price. In describing the reasons these restraints might be used, we therefore focus on retail rather than procurement contracts. The restraints that appear in retail contracts can alleviate many different types of incentive problems. We discuss a representative few that are by no means exhaustive.

14. For more on the similarities between property-rights and moral-hazard models, see Lafontaine and Slade (2007).

15. Interested readers are referred to Lafontaine and Slade (2008).

First, the typical succession-of-monopoly problem arises when an upstream monopolist sells an input to a downstream firm at a price above marginal cost. If the downstream firm has market power, it is well known that it will choose a price that is higher, and a quantity that is lower, than the price and quantity that would maximize joint profits. The manufacturer can alleviate this problem in a number of ways, including setting the price or requiring certain minimum quantities.

Second, manufacturers who invest in improving retail outlets, promoting retail products, or training outlet managers might worry that dealers will free ride on those investments. For example, dealers might encourage customers who visit their store to switch to a competing brand that has a lower price—thereby making the sale easier—or that has a higher retail margin—thereby making the sale privately more profitable. Exclusive dealing resolves this problem by making it impossible for the dealer to propose an alternative brand to customers. In such a context, exclusive dealing is a mechanism that enables manufacturers to protect their investments against potential dealer opportunism. Furthermore, in its absence, potentially profitable investments might not be undertaken.¹⁶

Third, a dealer-incentive issue arises in situations where the manufacturer wants the dealer to invest *ex ante* in specific facilities or human capital that would allow him to provide better service to consumers. As per the property rights models mentioned above, unless the dealer can be assured that his investments are fully protected, he will choose to underinvest or not invest at all. Combined with a long contract duration, a vertical restraint, such as an exclusive territory, can provide the type of reassurance that the dealer needs.¹⁷

Finally, dealer services offered at the point of sale during the contract period can enhance the demand for a manufacturer's or franchisor's product. Retailers of course also benefit from providing such services. However, when there are multiple outlets in a retail chain, retailers do not fully internalize the benefit associated with their own decisions, as some of their satisfied customers will patronize other units of the same chain rather than returning to their unit in the future. In contrast, retailers bear the full cost of supplying the services. As a result, retailers are expected to provide a service level that is too low from the perspective of the upstream firm. In other words, in the context of retail chains, not only do dealers have incentives to free ride on the value of the brand, a vertical externality, they also have incentives to free ride on services offered by other dealers, a horizontal externality. Furthermore, the problem worsens as the fraction of repeat business that retailers face falls.

When this problem takes the form of a franchisee wanting to use lower quality inputs in the production process, it can be resolved with input-purchase requirements (tying) or approved-supplier programs as long as defection from such programs is not too difficult to detect.

When dealer service issues take other forms, Telser (1960) argued that minimum price restraints could solve the dealer service incentive problem by preventing retailers from competing on price and leading them to compete instead on quality or customer service. Klein and Murphy

16. This, of course, is a form of the standard underinvestment problem analyzed in the property rights literature.

17. For this solution to work, the upstream firm must be able to verify downstream investment and to terminate the contract if it is unsatisfactory. At the same time, the upstream firm must be able to commit to not terminating opportunistically.

(1988) instead proposed that manufacturers could use vertical restraints, such as minimum resale prices or exclusive territories, to ensure that their dealers earn above-normal returns, thereby creating rents that the dealers would lose if their contracts were terminated. Such rent, in combination with ongoing quality or service monitoring and the threat of termination, could entice dealers to provide desired levels of quality or service. In either case, because the quality and service levels in question are valued by customers—if it were otherwise, manufacturers would not value them—quantities sold and hence consumer satisfaction should be enhanced.

This last argument, which states that upstream firms can use vertical restraints in their retail contracts as part of a mechanism that creates rent for retailers (rent that retailers can lose if they do not abide by the terms of their contract and are thus terminated) was one of the early applications of the notion of self-enforcing contracts in the context of interfirm contracts, a topic to which we now turn.

2.5. Self-Enforcement

In many situations, parties to a contract cannot rely on formal enforcement of contractual terms. This can occur because formal institutions do not exist (or when they do, they are not effective), or because reliance on third-party enforcement is prohibitively costly. In such cases, parties must rely on informal enforcement. The notion of self-enforcing contracts, which was developed by Klein and Leffler (1981), Bull (1987), Klein and Murphy (1988), MacLeod and Malcolmson (1989), and others, builds on the legal concept of relational contracting (see Macneil 1978; Baker et al. 2002; Levin 2003).¹⁸ Very generally, the idea is that the breaching party must face some future loss when breach occurs. This could occur, for example, when a contract that is advantageous to the breaching party is terminated or when that party's reputational capital is damaged. Furthermore, the punishment can be inflicted by the party who is harmed in a bilateral relationship (in which case the contract is said to be "relational"), or enforcement can rely on group punishment (in which case other parties participate in sanctioning unacceptable behavior).

A relational contract is one that is sustained on the value of future interaction between the parties. In this literature, interaction is usually modeled as a repeated game with imperfect monitoring of the agent's effort.¹⁹ Because the agent's actions are unobservable, contracts cannot be written on effort. Moreover, because outcomes, while observed by the parties, are not verifiable, contracts on outcomes cannot be enforced by third parties. However, it is assumed that effort shifts the distribution of outcomes. In particular, high effort causes good outcomes to become more likely. In that setting, if the reward to good behavior is sufficiently high, the agent will eschew cheating in favor of high effort. In the context of interfirm contracting, this implies that the agent must earn higher than competitive rewards. In other words, he is not taken down to his reservation value. Relational contracting models are therefore similar to efficiency wage models.²⁰

18. For a recent survey of formal and informal enforcement, see MacLeod (2007).

19. See Telser (1980) for an early model of self enforcement in a repeated game context.

20. Akerlof and Yellen (1986) provide a collection of important contributions on efficiency wages.

Although an important mechanism, relational considerations are not the only means of sustaining contracts informally. Indeed, the notion of reputation as an asset that can be damaged by failure to live up to others' expectations is very general. Furthermore, many reputational models rely on group punishments rather than one-on-one interactions as a mechanism to sustain cooperation (see, e.g., Klein and Leffler 1981). If group punishment is to be effective, however, others must be able to attribute blame when a relationship dissolves. This can be accomplished by invoking social norms, as in Okuno-Fujiwara and Postlewaite (1995), or by word-of-mouth communication, as in Greif (1989). Furthermore, published scores based on past performance, such as credit ratings, can play a useful communication role.

As we noted earlier, the notion of self-enforcement has been used to explain a number of empirical regularities in interfirm contracting. In particular, Klein (1980, 1995) notes that explicit constraints on franchisee behavior are sustained by the value of the bilateral relationship, whereas implicit constraints on franchisor opportunism are sustained by group punishment. Similarly, Klein and Murphy (1988) argue that vertical restraints can play an important self-enforcement role. Specifically, a manufacturer who offers minimum resale prices or exclusive territories to dealers might do so to ensure that the latter earn rent. The presence of such rent in a manufacturer-dealer relationship creates something that the dealer will lose if he is caught misbehaving and is terminated as a consequence. The restraint thus ensures that the dealer will not go against the manufacturer's stated service requirements.

3. Methods of Assessment

Our focus in this chapter is on empirical assessment of models of interfirm contracts. Unfortunately, there are numerous pitfalls that researchers must face when attempting to tease out causal relationships rather than merely uncovering simple correlations, and some of the studies we discuss rely on simple econometric methods that are not adequate for the task. We highlight some of the pitfalls before turning to a discussion of the empirical studies, organizing our discussion of potential problems around incidence and effects.

3.1. Incidence

Most of the literature on incidence—that is, the literature that tries to identify circumstances under which parties to a contract will choose to rely on one contract form or another, or on one contract term or another—uses what amounts to a comparative institutions approach (see notably Williamson 1991). In other words, the papers consider how firms choose among a specific set of contractual alternatives. Examples include studies of franchising, where the alternative for a franchisor is to integrate vertically (e.g., Brickley and Dark 1987; Lafontaine 1992), while the alternatives for a franchisee might be to operate as an independent business person (e.g., Williams 1999; Mazzeo 2004) or work as an employee. In other cases, the authors examine whether a particular contracting practice is relied on—for example, one might consider whether contracts include take-or-pay provisions, as in Masten and Crocker (1985), or whether upstream firms grant exclusive territories, as in Brickley (1999). In these cases, the alternative is the absence of the contract clause of interest. Finally, in a few cases, contracting practices can be captured better by a continuous variable. Such is the case for, for example, contract duration

(Joskow 1987; Brickley et al. 2003), the share parameter in franchise contracts (Lafontaine 1992; Lafontaine and Shaw 1999), and the proportion of franchised outlets in franchised chains (Brickley and Dark 1987; Lafontaine 1992; Lafontaine and Shaw 2005).

When the dependent variable is continuous, authors have used ordinary least squares or in some cases a limited dependent-variable estimator, such as a Tobit, to examine how the characteristics of the contracting parties and the transaction affect the continuous choice. In this literature, most authors ignore the potential endogeneity issue. Nevertheless, it can be a problem. To illustrate, certain types of investments, which can become characteristics in the regression model, might be undertaken only if the contract is of long enough duration, which could be the dependent variable. Thus, a franchisee might not invest as much in specific assets (e.g., retrofitting a building to accommodate a particular style of restaurant) if her franchise contract is of short duration. This reverse causality would bias estimates in regressions of contract duration on investment levels (see, e.g., Brickley et al. 2003). The standard solution to the endogeneity problem is to use an instrumental variables technique. Of course, this method is only viable if valid instruments can be found. Unfortunately, the problem of finding good instruments is particularly acute in these studies, as in most empirical studies in organizational economics, because the factors that lead firms to choose particular characteristics are also likely to affect desired contracting practices or terms.

When the set of contractual alternatives is limited to just two (or a few), the standard empirical study uses a discrete choice model to relate the decision to use a contract term to the characteristics of the transaction and of the contracting parties. Methods for dealing with discrete dependent variables are well known. There are, however, several problems that are apt to surface in discrete choice studies of contractual practices, problems whose solutions are more complex than when the dependent variable is continuous.

First, the ubiquitous endogeneity problem surfaces again. To illustrate, outlet characteristics are usually included among the explanatory variables that determine the method of transacting between manufacturer and retailer (for gasoline retailing see, e.g., Shepard 1993; Slade 1996; Pinkse and Slade 1998). When an upstream firm decides to change the nature of the contract with the retailer, however, it might well decide to also change some of the outlet's characteristics and vice versa. This could be the case with gasoline retailing, for example, where stations that are changed from full to self-service also often increase their number of pumps and may be changed from independent to lessee dealer at the same time. In such circumstances, the direction of causality is particularly unclear. A standard method for overcoming the endogeneity problem in this context is to use two-stage least squares, where the probability that a transaction is organized in a given way is assessed under a linear probability model.²¹ However, the linear probability model has other undesirable features, including the fact that it is usually not possible to constrain the predicted probabilities to lie between 0 and 1. Other solutions to the problem of endogenous explanatory variables in the presence of limited dependent variables normally require strong assumptions (see, e.g., Wooldridge, 2002: 472–477).

A related empirical problem arises from the fact that contract terms play a role in attracting particular contracting parties—that is, we see endogenous matching as well as selection. For example, if agents are heterogeneous with respect to risk aversion, some might simultaneously

21. Of course, the problem of finding valid instruments is just as acute here as with continuous choice.

choose risky (safe) projects and contractual packages that are high (low) powered. If this selection problem is ignored, it can lead to the conclusion that when risk increases, agents are offered less insurance. In other words, the estimated coefficients will not only be biased but can also have the wrong sign. The bias can be eliminated if we include all relevant characteristics of contracting parties in the regression equation. Unfortunately, it is rarely possible to measure all relevant variables. In particular, risk aversion presents an often insurmountable problem. The solution suggested by Akerberg and Botticini (2002) requires instruments that affect the matching process but not the contract choice.

Second, the errors in a discrete choice model are likely to be spatially correlated, in the sense that the off-diagonal entries in the variance/covariance matrix at a point in time are nonzero. For example, retail outlets located in a city center might experience common shocks that are not experienced by the retail outlets in the suburbs; or outlets that sell brands of a common manufacturer might have common private information. One possible remedy is to use the correction for spatial and time-series correlation of an unknown form developed in Pinkse et al. (2006) in a discrete choice context.

Finally, a much broader problem with empirical studies of contract terms is that authors typically focus on just one component of the contract at a time. Unfortunately, contracts may be better described as sets of contract terms, where each choice interacts with the others. The issue of complementarity among contract terms has been mentioned in both the theoretical and empirical literatures, but the data requirements and empirical difficulties associated with correctly addressing those concerns have meant that only limited progress has been achieved on this front. We come back to this issue in Section 4.9.

3.2. Effects

The empirical literature on contracting has focused more on incidence than on the consequences of contracting decisions. This may seem surprising, given the interest in establishing the value of various contractual alternatives. Indeed, what matters at the end of the day is performance: is it beneficial for firms to rely on a given contract type, or do those that include a particular term in their contracts with their suppliers or retailers do better than those that do not? If so, should we suggest that the transaction be organized in this way? If not, why not? In other words, are there normative conclusions that can be drawn from analyses of interfirm contracts?

Unfortunately, studies of the effects of contract terms on firm performance or other outcome variables (e.g., prices, sales, profits, growth, and survival) are relatively rare for a reason. First, studies of profitability or cost differences require detailed data that are typically proprietary. For that reason, much of the literature focuses on firm growth or survival, which may not be as related to performance as one would want. Second, and more importantly, the endogeneity issue is particularly problematic in these studies. Simply put, the effects of various contractual decisions are difficult to identify empirically, given that firms do not make contractual choices randomly. Instead, parties to a contract choose certain options based on what they expect will give the best outcome in a given situation. This choice, of course, is exactly what the literature on incidence relies on and tries to capture. Unfortunately, it also raises important issues when assessing the effects of contractual practices.

There are well-established techniques, such as Heckman's (1978, 1979) selection and endogenous dummy variable models and treatment-effects models, that can be used to deal with

endogenous decisions on organizational form.²² But those techniques require valid instruments, and such instruments are particularly difficult to come by in the settings we are concerned with. After all, firm and transaction characteristics are to some extent the result of decisions made by managers, and in that sense all are endogenous. Authors thus often rely on various arguments to justify treating certain firm characteristics as exogenous, or at least predetermined, even in the incidence literature. When it comes to consequences, it is particularly difficult to argue that a variable postulated to affect the likelihood that a contract term is used will not also directly affect performance. To make matters worse, in the absence of nonsuspect instruments, it is impossible to perform a formal assessment of the validity of any instrument. Still, we see promise in the increasing availability of various forms of spatial information about competitor and own-outlet characteristics in the same or other markets as potential sources of instruments.²³

At the same time, due to the concern with endogenous selection, many studies of effects rely on external sources of variation in organizational form for identification. Specifically, they look for mandated changes in contracting practices (i.e., legislation) to assess effects. Some studies of this type use techniques developed in the natural experiments literature, whereas others use an event-study approach.

In the former category, for example, researchers have used data on firms that operate in regions where legislators ban a particular practice or restraint (the treatment group), as well as data on firms that operate in regions where the practice is not banned (the control group). Because the ban comes from outside the relationship, it is often assumed to be exogenous. But even though the endogeneity problem is lessened in this situation compared to cases where the firms choose the contract terms, it is not eliminated. To illustrate, suppose that franchised chains do better when they do not face state termination restrictions; that is, when they can terminate their franchise relationships at will. One might be tempted to conclude that the imposition of termination restrictions causes lower franchisor performance. However, it is also possible that termination restrictions are imposed exactly in those states where franchisors do poorly and thus have particularly strained relationships with their franchisees, leading franchisees to lobby for protection. Under those circumstances, the causality runs from poor performance to legislation.

If the underlying omitted factors that affect both the use of a particular form of contract and the performance variable of interest are time invariant—as might be the case, for example, for a manager's innate ability or the difficulty of monitoring a particular task—the endogeneity problem can be overcome through the use of panel data. In particular, with panel data, one can use a fixed-effects estimator to remove the influence of time-invariant unobserved regional, brand, or outlet characteristics that cause the endogeneity problem. With this procedure, however, the effect of a contracting practice is identified solely through time-series variation. In other words, one is essentially assessing how changes in the use of a contracting practice lead to changes in performance. Unfortunately, there is often little time-series variation in organizational form. Furthermore, with panel data it is tempting to use lagged endogenous variables as instruments

22. See Wooldridge (2002: 551–642) for a comprehensive discussion of econometric methods used for policy evaluation.

23. For a general discussion of how spatial data can be used to generate instruments in parametric and nonparametric contexts, see Pinkse et al. (2001) and Pinkse and Slade (2010). For contracting applications in a parametric context, see Schneider (2010) and Kosová et al. (2012).

in the hopes that they are predetermined. This hope will be thwarted, however, if the errors are serially correlated, as is highly likely.

An alternative approach is to use a before-and-after estimation strategy—a time-series model. This approach requires access to data on firm performance that include periods before and after a legally mandated change, such as the banning of a practice. The problem with this approach is that many things change over time, and although it is tempting to attribute any significant performance change to the new legal requirement, this attribution might not be valid.

Some studies use a before-and-after approach on a cross-section of firms when the data are not a panel. Those studies typically rely on data on stock prices to measure firm performance (i.e., event studies). Unfortunately, this approach reduces the set of firms whose actions can be examined empirically to publicly traded firms. This is problematic to the extent that the contracting practices of interest are used by relatively small firms, as in the case of franchise contracts.

Finally, recent work on within-firm incentives addresses the issues of selection and endogeneity by relying on data from field experiments (e.g., Lazear 2000; Shearer 2004; Bandiera et al. 2007). Unfortunately, it is very unlikely that researchers can obtain experimental data that would be suited to the study of many questions involving how firms interact with one another. As best we can ascertain, no study of interfirm contracts relies on such data.

Perhaps in part because experimental data are hard to come by, in the empirical literature in industrial economics authors increasingly use assumptions about utility functions, cost functions, and market equilibrium to generate estimating equations that allow them to identify underlying taste and technology parameters. These parameters are then used to perform counterfactual (what if) analyses. In recent years, this methodology has been applied to the study of effects of contracting practices, in particular by Asker (2005) on exclusive dealing, Brenkers and Verboven (2006) on exclusive dealing and exclusive territories, Villas-Boas (2007) and Bonnet and Dubois (2010) on nonlinear wholesale pricing, Mortimer (2008) on share contracts, Crawford and Yurukoglu (2012) on bundling, and Ho et al. (2012) on full-line forcing. As with all structural analyses, the requirements of the models in terms of data and industry knowledge are very stringent, even more so in these vertical settings, as the researcher needs to model horizontal games among upstream and among downstream firms as well as bargaining games among links in the vertical chain. Other problems with this approach include the fact that cost savings arising from better incentive alignment are difficult to capture in such models, and that evaluation of effects obtained from such models are valid only to the extent that the assumptions embedded in the model are valid. Despite these problems, we view this type of modeling as a fruitful area for future research on the effects of vertical contracting. Still, given the strong assumptions required to make these models tractable, we expect that reduced-form analyses with strong identification strategies will continue to be an important source of insights.

4. The Evidence

In this section, we discuss the empirical evidence on interfirm contracting, organizing this discussion around a series of themes related to contract types and contract terms or practices. We begin each section with a discussion of evidence concerning the incidence of a choice or practice, followed by a discussion of evidence on the consequences of the same choice or practice. In

the latter case, we focus on consequences from the firm's perspective, rather than from a public policy or total welfare perspective, as efficiency for the firm is the typical concern in the organizational economics literature. This is not to say that public policy concerns are absent from the empirical literature on interfirm contracts, but simply that the goal of organizational economics is to uncover the benefits that the firm derives from using different contracting options.

4.1. Pricing Contracts

Many simple contracts specify a price at which a variable quantity of an input can be purchased. Perhaps because they are so common, or because they do not differ much from spot market transactions, linear pricing contracts tend to be studied less often than, for example, share contracts, at least relative to their occurrence. In this section, we discuss some work on incidence, much of which comes from traditional franchising. Note that in this context, the alternative to contracting considered by the franchisor tends to be vertical integration (rather than spot transactions). In that sense, much of the vast literature on the make-or-buy decision in procurement includes tests of simple pricing contracts when the input under the buy option is supplied under contract.²⁴ The manufacturer's decision, however, is treated simply as a buy in that literature, and thus the form and terms of the contract that ties the supplier to the manufacturer are typically not emphasized or even described in any detail. Exceptions include work on shipping and contracting in mineral markets, both of which we discuss below.

4.1.1. Incidence

Several authors have examined the choice of contractual form in gasoline retailing. Often this involves the choice between transacting at a wholesale price (a pricing contract), which gives the station operator high-powered incentives, and vertical integration, which normally involves salaried employment. Most studies estimate discrete choice equations for organizational form (pricing contract versus vertical integration). The object and focus of each study, however, are different. To illustrate, Shepard (1993) finds that higher powered incentives (pricing contracts) are more apt to be relied on when monitoring is difficult, as is the case, for example, for stations with repair facilities. Slade (1996), in contrast, casts her analysis in a multitask setting and finds that higher powered contracts are less likely to be offered when tasks are complementary, where complementarities can occur in demand (as measured by cross-price elasticities) or through covariation in sources of risk. Both studies lend support to moral hazard models that emphasize incentive issues in choosing efficient contracts.

There is also evidence, however, that contract choice in gasoline retailing is influenced by competitive concerns. For example, Pinkse and Slade (1998) find that contract types (pricing contract versus vertical integration) tend to cluster in geographic space, which is consistent with a model in which market share motives (which are associated with similarity of offerings)²⁵ outweigh market power motives (which are associated with differentiation). Furthermore, Slade

24. See Bresnahan and Levin (this volume) and Lafontaine and Slade (2007) for recent reviews of the empirical literature on vertical integration.

25. Because there is a strong relationship between contract type and station offerings, contract clustering implies attribute clustering. See also Kalnins and Lafontaine (2004) on contract clustering in fast-food chains.

(1998b) finds evidence that supports strategic delegation of the pricing decision.²⁶ In particular, she finds that delegation (i.e., a pricing contract) is chosen more often in contexts where competition among operators is less aggressive, a situation in which delegation is predicted to yield a greater increase in profits. It is important to recognize, however, that these findings, which imply that contracting practices are affected by the intensity of local competition, are more likely to surface in such industries as gasoline retailing, which tend to be less competitive than those in which business-format franchising is the norm.

Shipping is another industry in which linear pricing contracts are common. Unlike gasoline retailing, however, with shipping the choice is often contracting versus market transaction. In addition to specifying rates (or formulas for rates), shipping contracts can contain incentive provisions, such as penalties for delays and take-or-pay clauses. Researchers who have studied such contracts have paid particular attention to the role of market thickness in determining contract choice, under the hypothesis that, when markets are thin, the advantages of contracting increase relative to spot market transactions. Pirrong (1993), who assesses ocean bulk-shipping contracts, and Hubbard (2001), who examines long- and short-haul trucking contracts, find support for this hypothesis. Furthermore, Hubbard finds that the thickness effect is strong for long but weak for short hauls and explains this regularity by the fact that, when hauls are short, the costs of writing contracts exceed the benefits.

4.1.2. *Effects*

Several studies of consequences consider how retail prices vary with contract choice (e.g., company ownership versus franchising with linear or affine prices versus spot market transactions). For example, Shepard (1993) compares consumer prices for gasoline in leasee-dealer (contract) and company units and finds evidence that, for some products, prices charged at leasee dealerships are higher. In contrast, Hastings (2004) makes a similar comparison and finds no difference in price levels.

The above studies consider the effect of contract choice on retail prices, which are relatively easy to observe. Normally, it is more difficult to assess prices in long-term procurement contracts, because data on those prices are not usually available to the public. A comparison of contract and spot prices is possible, however, for nonferrous metals (e.g., copper, lead, and zinc), because those commodities were traded in North America under two price systems. Indeed, spot and long-term contract prices, which coexisted between the end of World War II and the late 1970s, are available from public data sources. The price on which long-term contracts were based was known as the U.S. producer price, whereas the spot price was the cash settlement price from the London Metal Exchange. Both prices are transactions prices, because there was very little discounting off published prices. Nevertheless, although both prices were highly visible, differences between the two were often sizable and persistent. Not surprisingly, economists have compared the behavior of these two prices. Slade (1991), for example, has shown that on average there was little difference in the levels of these two prices but substantially greater variability in the spot price. Hubbard and Weiner (1989) find that the increased reliance on the spot price that occurred prior to the demise of the producer price led to faster adjustment of prices to supply and

26. With company operation, prices are chosen by the principal or company, whereas with franchising, they are chosen by the agent or station operator.

demand shocks. Note that prices in these industries are notoriously volatile. It therefore seems that firms entered into long-term supply contracts partially to reduce the amplitude of price fluctuations and to facilitate planning. However, as geographic markets became more integrated and competition increased as a consequence, it became more difficult, and less desirable, to maintain a two-price system for such homogeneous commodities.

Wolak (1996) explores similar issues in electric utility steam-coal markets and finds that, even though contract prices were systematically higher in that market, buyers entered into long-term contracts to insure against unforeseen supply interruptions and unwanted input price variability.

4.1.3. *Government Intervention and Effects*

In the above studies, the choice of contract type (vertical integration versus linear or affine pricing contract versus arm's-length transaction) was made by the firms involved in the transaction. There have been many instances, however, where local governments have intervened and prohibited certain types of contracts. Perhaps the most famous is the case of gasoline divorcement in the United States, where divorcement means prohibition of company operation (vertical integration) but not prohibition of ownership. In other words, firms were forced to transact using wholesale prices (to use a pricing contract) even with the branded stations that they owned. Divorcement laws, which have been passed by a number of U.S. state legislatures, usually result from lobbying on the part of franchised dealers, who claim that, when a company acts as both supplier and horizontal competitor, its behavior is influenced by considerations of foreclosure. The empirical literature (e.g., Barron and Umbeck 1984; Vita 2000; Blass and Carlton 2001), in contrast, shows that prices and costs rose and hours became shorter after oil companies were prevented from operating stations directly.

A different sort of divorcement is examined in Slade (1998a)—the forced move that occurred in the British beer industry from franchising with two-part tariffs (contracting) to market interaction under linear prices. In the British beer industry, similar to the U.S. gasoline industry, tenanted pubs are owned by the brewer but operated by the publican, and the publican sets the price. Slade finds that draft beer prices rose after divestiture and attributes the rise to double marginalization—successive oligopoly markups—that is apt to occur after the removal of fixed fees.

The evidence thus indicates that government intervention that prohibits contractual arrangements involving certain modes of operation or ownership structures (including some that replace vertical integration with pricing contracts and contracts involving two-part tariffs by arm's-length transactions) is inefficient. This is so not only for the firms involved, who would have voluntarily chosen the new arrangements had they considered them profitable, but also for consumers (see also Lafontaine and Slade 2008).

4.2. *Contract Duration*

The period over which a contract is binding can be very short, or it can span many decades. It is therefore natural for researchers to be interested in uncovering the determinants and effects of the choice of duration. Transaction cost theory is the main framework relied on to generate predictions concerning contract length. Specifically, the theory implies that contracts will be

longer when firms have more specific investments at stake, because the need to protect those investments is greater. They will be shorter, in contrast, when environments are more uncertain, because flexibility assumes greater importance in that case. To our knowledge, however, although this framework has generated studies of incidence (or, put differently, duration decisions), there are no empirical analyses of the consequences of such decisions for prices, quantities, or other performance measures.

In his seminal papers, Joskow (1985, 1987) relates the duration of contracts between U.S. electric utilities and coal companies, which can last as briefly as 1 year or as long as 50 years, to various proxies that capture the amount of relationship-specific investment (and thus quasi-rent) involved. He finds that mine-mouth plants (i.e., plants that choose to locate next to specific coal mines with the expectation that they will obtain their coal from those mines)—a classical case of site specificity—operate under much longer contracts than do other plants. Specifically, his baseline specification shows that mine-mouth contracts are on average 12–16 years longer. In addition, he finds that plants that use more coal, and those that operate in the East in contrast to the West or Midwest, use longer term contracts. He argues that the former reflects the increased difficulty of finding alternative buyers or sellers for large quantities, whereas the latter reflects differences in the types of coal produced and in the production and transportation options available in the three regions. In sum, Joskow finds strong support for the hypothesis that differences in relationship-specific investments determine the duration of electric utility–coal contracts.

Like Joskow, in their study of natural gas sales contracts, Crocker and Masten (1988) find that firms use longer term contracts when they face a greater likelihood of hold-up; for example, when they have fewer buyer, seller, or transportation options. However, the authors consider not only the benefit of long-term contracts in protecting specific assets but also the cost of using longer term contracts, which relates to the loss of flexibility in dealing with unforeseen events. Consistent with their hypothesis, they find that contract duration was reduced substantially by the 1973 oil embargo, which increased the amount of uncertainty in the market for natural gas. Saussier (2000) documents similar effects in his sample of coal procurement contracts for Électricité de France, even after endogenizing the degree of asset specificity in the transaction. Finally, Pirrong (1993) finds that contracts used in bulk shipping are of longer duration when markets are thin and carriers are specialized, and Hubbard's (2001) finding that shippers rely more on contract carriage compared to spot transactions for long hauls when local markets are thin has a similar interpretation. All these findings support transaction cost determinants of procurement-contract duration.

With business-format franchising contracts, which last about 15 years on average, duration varies substantially across firms both within and between sectors (see, e.g., Lafontaine 1992; Blair and Lafontaine 2005). Brickley et al. (2003) analyze the factors that affect the duration of franchise contracts and find that better-established franchisors rely on longer term contracts, as do those franchisors who require greater investment levels from their franchisees and those who face higher recontracting costs. They explain the result on franchisee investment using asset-specificity arguments and interpret the franchisor-experience effect in terms of reduced uncertainty. In other words, their analyses yield results that are consistent with those obtained in the procurement literature.

4.3. Flexibility and Adjustment Clauses

With long-term contracts, it is crucial to incorporate flexibility. The sort of flexibility that can be built into contracts includes, among other things, adjustment clauses for price or quantity and clauses that make breach easier. Moreover, flexibility is related to duration in the sense that shorter contracts are in essence more flexible. Not surprisingly then, like empirical analyses of duration, studies of flexibility are mainly cast in a transaction cost framework.

4.3.1. Incidence

Provisions for price adjustment in contracts can take many forms.²⁷ Most schemes, however, can be classified as either redetermination or renegotiation mechanisms, where the former specifies a formula and the latter specifies a process.²⁸ The choice between the two must take into account the trade-off between flexibility, which favors renegotiation, and freedom from opportunism, which favors redetermination. As conditions are apt to change more during the life of a longer term contract, transaction cost theory predicts that such contracts will include terms that yield more flexibility. Crocker and Masten (1991) assess that choice in natural gas contracts and find that flexible adjustment (renegotiation) is indeed more apt to be chosen in longer duration contracts. However, conditional on contract length, they find no evidence that increases in quasi-rents or market volatility affect the choice of adjustment mechanism.

In their study of contracts between producers and consumers of petroleum coke, Goldberg and Erickson (1987) found that more than 90% of the contracts contained some form of adjustment mechanism. Moreover, those mechanisms ranged from price indexing based on crude oil prices, to renegotiation when that price was above or below some limits, to negotiation at fixed periods. After 1973, however, when the volatility of the market increased markedly, indexing clauses that were meant to be in force for the duration of the contract became less common, as they were replaced by renegotiation clauses. These authors also found that, after 1973, the period between price changes fell substantially, and termination became easier. This evidence also can be rationalized in terms of transaction costs.

Adjustment clauses are but one form of flexibility that can be built into contracts. Contracts also differ in the degree of detail, penalties, legal sanctions, and other specifics that they include, making some documents long and complex, while others are short and simple. Murrell and Paun (2008) study contract complexity in agreements among Romanian firms and find that complexity increases (decreases) with seller (buyer) relationship-specific investment and with the quality of the legal system. Similarly, Lyons (1994) assesses the probability that British engineering subcontractors will formalize their relationships with customers rather than relying on more informal agreements. He finds evidence that pricing contracts tend to be more formal in cases where subcontractors are more vulnerable to customer opportunism; namely, when customers account for larger shares of the engineering firm's output and when output tends to be more specifically designed to the customer's requirements or requires significant specific investment on the part of the engineering firm. These findings and those of Murrell and Paun (2008) are interpreted as supportive of modified versions of transaction cost economics.

27. For an early discussion, see Goldberg (1976).

28. This distinction is due to Crocker and Masten (1991).

4.3.2. *Effects*

A large segment of the literature on adjustment clauses attempts to distinguish between efficiency and market-power-enhancing effects of contract flexibility. The most favored nation (MFN) clause, which guarantees buyers (sellers) the lowest (highest) price that is offered to others in a region, is perhaps the most studied. Given the antitrust authorities' stance on the anticompetitive nature of such contracts (see, e.g., Salop (1986) on the Ethyl case), it is not surprising that most authors have modeled the use of MFN clauses as practices that facilitate oligopolistic coordination. In particular, MFN clauses are expected to eliminate the possibility of selective price discounts and thus enhance cartel stability. However, Crocker and Lyon (1994) argue that MFN provisions facilitate efficient price adjustment in long-term contracts. In contrast to most research in this area, which is theoretical, they use data from natural gas contracts to distinguish empirically among competing explanations.²⁹ After noting that market power and thus collusion opportunities reside with buyers in this market, Crocker and Lyon claim that the evidence in favor of efficiency rather than collusion is twofold. First, they find that the use of MFN becomes much more likely as the number of buyers increases, which they argue is inconsistent with the notion that MFN clauses facilitate buyer collusion. Second, they show that the nondiscrimination regions over which MFN clauses are defined are small and correspond more closely to sellers' alternative market opportunities than to buyers'. Yet to be effective as practices that facilitate buyer collusion, MFN clauses would need to be applied to the set of competitors that buyers face rather than the set of competitors that sellers face. In addition, they note that MFN adoption patterns parallel those of clauses indexing gas prices to those of other fuels—evidence, they argue, that further supports their efficiency argument.

The effect of take-or-pay provisions, which obligate buyers to pay for a contractually specified minimum quantity, called a "take percentage," even when delivery is not taken, has also been studied. With these provisions, flexibility increases as take percentages fall, but protection of specific investments also declines, creating a tension between these two goals. Various explanations for the existence of take-or-pay provisions (e.g., risk sharing) have been proposed. However, Masten and Crocker (1985) argue that they provide an efficient means for contract breach. They test this hypothesis in natural gas markets. Specifically, they explain take percentages as functions of buyer and seller numbers and find that take percentages fall (flexibility increases) when sellers are few and buyers are many. These results are consistent with their efficiency rationale for the provision, as both of those factors raise the alternative value of gas reserves and make breach more desirable. Mulherin (1986) also argues that take-or-pay and MFN clauses are efficiency rather than market-power enhancing in natural gas markets and provides some empirical evidence consistent with the idea that the use of these clauses is related to bilateral contracting hazards.

A different, but related, question concerns just how flexible stipulated contract prices really are. To answer this question, Joskow (1988, 1990) compared realized coal contract prices to market prices. He found that, because most coal contracts were indexed to cost factors, in periods of stable or predictable growth in demand, contract prices were relatively flexible to changing cost conditions, and thus contractual relationships did not break down. When demand turned

29. See also Arbatskaya et al. (2004), who, in a noncontractual context, use informal techniques and data obtained from newspaper advertisements to argue that low-price guarantees do not facilitate collusion.

down, however, the market price for coal was reduced, and substantial deviations between market and contract prices arose. In other words, the contract prices and associated pricing rules did not track changes in market conditions well. Nevertheless, in spite of unfavorable conditions for buyers, most long-term contracts remained in effect. In some cases, parties were able to renegotiate their contracts, relying either on scheduled reopener provisions or on changed quantity commitments. But this occurred because the contract or specific conditions permitted it. In general, the formal contract terms remained binding: with clear contractual promises, litigation and breach were the exception, not the rule.

4.4. Fixed Price versus Cost Plus

Recall that, with a cost-plus contract, the seller is paid a percentage of costs, where the percentage exceeds 100. The fixed-price contract, in contrast, pays the seller a fixed amount that is determined *ex ante*. Most empirical studies of cost-plus contracts involve neither a choice between contracting and vertical integration nor between contracting and spot market transactions. Instead, the choice is between two forms of contracts. Specifically, taking the existence of a contract for granted, it is the decision to rely on a particular type of contract—cost plus versus fixed price—that is assessed. As little is known about the effects of this decision, we limit our discussion to incidence.

4.4.1. Incidence

Since cost-plus contracts adjust automatically to changed circumstances affecting costs, they are more flexible, and one would expect them to prevail when (1) projects are highly uncertain, (2) the technology is complex or untested, (3) quality is important but difficult to verify, and (4) trading parties trust each other. In contrast, since fixed-price contracts are associated with better incentives for cost control, they are more apt to be chosen when (1) the project is fairly standard, (2) the measurement of costs is problematic, and (3) important changes in specification are not anticipated.

Some researchers have examined whether these theoretical predictions hold up in practice. Leffler and Rucker (1991) assess private timber harvesting contracts, Banerjee and Duflo (2000) look at contracts for Indian customized software, Kalnins and Mayer (2004) and Shi and Susarla (2011) assess contracts for the provision of information technology services and computer-related hardware, Corts and Singh (2004) and Kellogg (2011) look at contracts between oil exploration and production companies on the one hand, and independent drilling contractors on the other, and Bajari et al. (2009) consider private sector construction contracts. To summarize, they find evidence that cost-plus contracts are preferred when presale measurement costs are high and monitoring is relatively cheap (Leffler and Rucker 1991); when firms are older, where age is equated with reputation (Banerjee and Duflo 2000); when costs are uncertain *ex ante*, the cost of measuring quality *ex post* is high, and the project does not involve the buyer's hardware or proprietary technology (Kalnins and Mayer 2004); and when development rather than exploratory wells are involved, because drilling activities for the former are more complex (Corts and Singh 2004). Bajari et al. (2009), moreover, find that more complex projects are more likely to be awarded via negotiation than through an auction mechanism, which, they note, amounts to saying that complex projects will be cost-plus rather than fixed price. Finally, Shi and Susarla

(2011) find that vendors that can be trusted to negotiate fairly or to keep costs low are more likely to be awarded fixed-price and cost-plus contracts, respectively. All these findings are supportive of the theoretical predictions.

Theoretical predictions concerning other effects, however, are more ambiguous. In particular, the issue of how previous experience with the same trading partner affects the choice of contract cannot be signed *a priori*. Indeed, as Corts and Singh (2004) argue, whether repeated interaction makes fixed-price or cost-plus contracts more attractive depends on how such interaction affects incentive provision relative to contracting costs. On the one hand, experience with a partner can lower the need for high-powered incentives and thus favor reliance on cost-plus contracts. On the other hand, it can lower contracting/recontracting costs and thus favor fixed-price contracting.³⁰ Like the predictions, the empirical findings concerning previous interaction are also somewhat mixed. Specifically, Banerjee and Duflo (2000) find that the choice of contract for software procurement is unaffected by whether the software firm has previously worked for a client, whereas Corts and Singh (2004), Kalnins and Mayer (2004), Kellogg (2011), and Shi and Susarla (2011) find that frequent interaction leads firms to rely more on cost-plus contracting in drilling and information technology service procurement. The results of these studies thus suggest that, at least in these industries, repetition reduces the need for high-powered incentives more than it reduces contracting costs. We return to these issues in Section 4.8.

4.5. Share Contracts

With a share contract, which may involve fixed fees, each party receives a portion of some output variable, usually revenues. Relative to their occurrence, share contracts have received a large amount of attention in the empirical literature. Much of this literature, however, has been about contracts that arise within firms (e.g., executive compensation) or in contexts where at least one of the two parties is an individual (e.g., sharecropping or compensation of talent in the legal, real estate, or movie production industries). Still, other analyses have focused on interfirm share contracts, such as those used in business-format franchising and technology licensing. The main question addressed in the empirical work is the rationale for these contracts or the question of incidence. However, interest in assessing consequences has grown recently.

4.5.1. Incidence

Table 2 summarizes several studies that examine how firms choose to interact with other firms using a share contract versus some other option(s). The table shows the sector of the economy in which the firms operate, the authors of the study, the date of its publication, what the parties share under the share contract, the type of data or empirical technique used, the dependent variable for the study, and the principal conclusions that the authors draw.

The research in Table 2 illustrates the different settings in which sharing among firms arises in the economy. In addition, the results from the studies support three main conclusions. First, share contracting is often used in contexts in which incentive issues are important. Specifically, parties choose to share the outcome of their efforts when both of them need to cooperate in a form of team production and neither contribution is easily assessed by the other. This is one of

30. See also Crocker and Reynolds (1993), who examine government procurement contracts, on this issue.

Table 2. Empirical evidence on the incidence of share contracts

Reference	Industry setting	Share of	Data/analysis	Main focus	Main conclusions of study
Licensing					
Contractor (1981)	International technology by U.S. manufacturers	Licensee revenues	Cross-section	Returns and costs of contract, contract terms	Royalties based on licensee sales occur in 80% of agreements, average 4%, and are the most important source of licensor returns.
Caves et al. (1983)	Technology by U.S. chemical, electrical, and equipment manufacturers	Licensee revenues	Cross-section/ survey data	Contract terms	Incomplete rent extraction occurs due to uncertain value of technology to licensee and incomplete contracts. Firms licensing core technologies impose more restrictions on licensees.
Macho-Stadler et al. (1996)	Spanish licensees, all industries	Licensee revenues	Cross-section/ administrative data	Contract terms	Royalty payments are more important in contracts involving know-how.
Bessy and Brousseau (1998)	Technology in French manufacturing	Licensee revenues	Cross-section/ survey data	Propensity to license, contract terms	Contracting practices vary due to different goals of licensing firms and industry settings where licensing occurs.
Anand and Khanna (2000)	Technology in U.S. manufacturing	Licensee revenues	Cross-section	Contract features	Technology licensing is highly concentrated in a few manufacturing sectors. Robust cross-industry differences exist in incidence of licensing, use of exclusives, cross-licensing, ex ante deals, and repeat transactions. Authors suggest differences in strength of intellectual property rights drive these differences.

Franchising					
Caves and Murphy (1976)	Various retailing and service sectors	Franchisee revenues	Descriptive	Propensity to franchise	Reliance on franchising versus company ownership reflects divergent efficient scales of activities and need for incentives locally.
Brickley and Dark (1987)	Various retailing and service sectors	Franchisee revenues	Cross-section	Propensity to franchise	Reliance on franchising versus company ownership reflects a trade-off among agency problems, including downstream effort and free-riding incentives.
Lafontaine (1992)	Various retailing and service sectors	Franchisee revenues	Cross-section	Propensity to franchise, contract terms	Double-sided moral hazard is best supported. Risk effect is absent or has wrong sign. Empirical model explains reliance on franchising better than it does contract terms.
Lafontaine (1993)	Various retailing and service sectors	Franchisee revenues	Cross-section	Propensity to franchise, contract terms	Information asymmetries between franchisor and franchisee and the resulting need for signaling franchisor type do not explain contract terms or stake of franchisor.
Scott (1995)	Various retailing and service sectors	Franchisee revenues	Cross-section	Propensity to franchise	Company ownership is a substitute instrument to royalty payments for franchisor incentives to maintain quality.
Lafontaine and Shaw (1999)	Various retailing and service sectors	Franchisee revenues	Panel data	Contract terms	Considerable heterogeneity exists in financial contract terms (royalty rates and franchise fees) across franchised chains, but there is persistence over time within. When changed, they may go up or down with no systematic pattern.
Lafontaine and Shaw (2005)	Various retailing and service sectors	Franchisee revenues	Panel data	Propensity to franchise	Reliance on franchising goes up during the first 7 or so years in franchising—a period of adjustment—then remains quite stable over time. Large differences in reliance on franchising across franchisors are explained by differences in brand name value.
Lafontaine and Oxley (2004)	International, various sectors	Franchisee revenues	Cross-section	Contract terms	U.S. franchisors use the same terms with franchisees in Mexico as in the United States.

Movie distribution					
Cachon and Larivière (2005)	Movie video	Video store revenues from movie	Cross-section	Reliance on revenue sharing, contract terms	Revenue sharing is a better channel coordination mechanism.
Filson et al. (2005)	Movie	Theater revenues	Cross-section	Reliance on revenue sharing	Revenue sharing in this industry is best explained by risk sharing.
Gil and Lafontaine (2012)	Movie	Theater revenues	Panel data	Contract terms	Sharing allows better week-to-week pricing of the movie by upstream firm, and thus it yields better downstream incentives to keep movies on the screen.
Mortimer (2008)	Movie video	Video store revenues from movie	Cross-section	Reliance on revenue sharing	Revenue sharing enhances upstream and downstream profits and contributes to increased consumer welfare.
Commercial leasing					
Wheaton (2000)	Retail real estate	Retailer revenues	Cross-section	Reliance on revenue sharing	Revenue sharing is the solution to a double-sided moral hazard problem.
Gould et al. (2005)	Retail real estate	Retailer revenues	Cross-section	Reliance on revenue sharing, contract terms	Revenue sharing induces efficient actions from anchor and nonanchor stores and developers in the presence of externalities.
Joint ventures					
Bai et al. (2004)	All industries	Joint venture revenues	Cross-section	Contract terms	Revenue sharing terms are consistent with double-sided moral hazard.

the conclusions that authors who have examined franchising, licensing, real estate leasing, and joint venture contracts in particular have reached.

Second, we find another type of explanation arising in settings where the value of the good being exchanged is unknown to both parties at the time of contracting and depends on factors outside their control.³¹ This is the case, for example, for movie distributors selling copies of movies to video rental stores (Cachon and Larivière 2005; Mortimer 2008). The level of revenues that the video rental store can earn from stocking copies of the video is unknown at the time of contracting. If the video rental store must purchase all copies of the video at a fixed price *ex ante*, it will be wary of buying too many copies. Just as auction participants underbid if they are concerned about the value of the good that they are buying (i.e., underbidding is the best response to the “winner’s curse”), the downstream firm, worried about overevaluating revenue streams for a video, will “underbid.” In this context, underbidding will take the form of choosing a lower quantity (i.e., purchasing fewer videos). From the distributor’s perspective, this practice increases the chances of stock-outs downstream and thus hurts the revenue stream of the movie distributor as well as that of the video rental store. Specifying the price of the video as a function of the revenues it brings in *ex post*, which is what revenue sharing achieves, can thus serve as a flexible pricing device that prevents underbuying. Moreover, it reduces the need for *ex ante* search and for renegotiation *ex post* (Leffler and Rucker 1991; Lafontaine and Masten 2002; Gil and Lafontaine 2012).³²

Third, and finally, the findings of these studies are important in what they do not support: the notion that risk sharing is an important factor explaining the use of share contracting. In fact, authors have tended to find a positive relationship between sharing and risk in contexts where alternative contracts would much better insure the risk-averse party. This relationship is inconsistent with risk sharing but consistent with the notion that uncertainty exacerbates monitoring problems and induces different levels of delegation, which in turn leads to more sharing (Lafontaine 1992; Lafontaine and Bhattacharyya 1995; Prendergast 2002).

A smaller group of studies considers how share parameters vary across contracts. These include Lafontaine (1992, 1993), Lafontaine and Shaw (1999), and Brickley (2002) on franchising and Wheaton (2000) and Gould et al. (2005) on retail-lease contract terms. In general, these authors find results consistent with the findings from the empirical literature on the choice of organizational form (i.e., the decision to use sharing). Lafontaine (1992), for example, finds that the explanatory variables used to capture double-sided moral hazard issues have the same sign in royalty rate (share parameter) regressions as they do in regressions for the extent of franchising in a chain. However, the variables in question explain much less of the variance in royalty rates and franchise fees than they do in the proportion of outlets that are franchised.³³ Similarly, for licensing contracts, Taylor and Silbertson (1973), Contractor (1981),

31. See Goldberg (1976) for an early statement of this argument.

32. The argument also relates to the measurement-cost argument of Barzel (1982) and to the self-enforcement argument of Kenney and Klein (1983, 2000) on the use of block booking.

33. One factor that explains some of the variance in royalty rates is the franchisor’s reliance, in some sectors, on input sales as an alternative form of profit extraction. Lafontaine (1992) finds that royalty rates are lower, for example, in chains that sell more to their franchisees. Rao and Srinivasan (1995) provide related evidence that royalty rates are lower for franchisors in retail compared to those that sell services.

and Caves et al. (1983) find that the variation in fixed fees and royalty rates across industries is difficult to explain. However, Gil and Lafontaine (2012) show that, in the context of movie distribution, the shares to distributors vary in predictable ways when viewed as a mechanism to extract downstream value. Specifically, distributor shares are higher (and decline more slowly) for movies that are expected to do better at the box office. They are lower, however, for movies shown in older and larger theaters and for those shown in theaters whose owners have more local market power.

Finally, and not surprisingly, state laws that protect franchisees in business-format franchising have been found to affect the use of franchising as well as the terms of these contracts. Specifically, Brickley et al. (1991) find that franchising is used less relative to company ownership in states that have enacted franchise termination laws. They also find that the value of franchised companies operating in a state is negatively affected by the passage of such a law. Moreover, Brickley (2002) shows that franchisors headquartered in states with termination laws—laws that make franchisee termination more costly—charge higher royalty rates and lower franchise fees, such that the prices paid for franchises by franchisees are higher in those states. These results are all consistent with the notion that franchisors value termination rights, a result that suggests that franchisee behavior in business-format franchising is controlled at least in part by the threat of losing future benefits from the relationship. We come back to these issues briefly below.

In sum, the literature on incidence has shown that share contracting between firms tends to occur most often when incentive problems arise for both parties to a contract. In addition, the empirical literature suggests that in some contexts, sharing is a response to the difficulties of setting the right price and minimizing renegotiation costs in markets where transactions are heterogeneous and values are uncertain *a priori*.

4.5.2. *Effects*

A typical study of consequences considers the effects of sharing on firm outcomes relative to what would have happened under another organizational form (e.g., a comparison of firm profitability, service quality, or survival between company and franchised units of a chain, or for chains that franchise versus those that do not). Shelton's (1967) analysis is a classic in this respect. He uses data on costs, revenues, and profits for outlets in a single chain to examine the effect of switching from franchising to company ownership and from company ownership back to franchising. He finds no difference in revenues across the two governance regimes. However, under company ownership, costs are higher, and thus profits are lower, than under franchising.

The main advantage of Shelton's study is that its within-outlet design holds most things constant as the mode of organization changes. Its main drawback is that units in this chain are operated under company ownership only during periods of transition. In other words, franchising is the preferred mode, and company ownership is only a transitory phase. Consequently, company ownership is likely to be inefficient, and inefficiently implemented, in this particular chain. This circumstance, then, might explain Shelton's findings.

Other authors have looked for price or cost differences between franchised and company units of chains when the firm chooses which outlets are franchised and which are operated by the company. In particular, Krueger (1991) found that company employees were paid slightly more and faced somewhat steeper earnings profiles than did employees in franchised units. He argued that the lower powered incentive contracts of the managers of company restaurants

make it necessary to offer greater incentives to employees in the form of efficiency wages and steeper earnings profiles. Freedman and Kosová (2012) revisit this question using data on housekeeper compensation in the hotel industry, a context where they argue agency issues are apt to be especially pronounced. They find even stronger evidence of differences in pay schemes between franchised and corporately run hotels, with greater emphasis on performance pay and steeper earnings profiles in franchised hotels. Finally, Kosová et al. (2012) compare revenues, occupancy rates, and prices among the hotels of a large multichain company. They find significant differences between these outcomes for franchised and nonfranchised hotels in aggregate data patterns and in analyses that treat organizational form as exogenous. However, the differences are small even in aggregate data, and when they use information about the company's other local operations to instrument for organizational form at a given hotel, the differences between franchised and company operations become statistically and economically insignificant.³⁴

Some studies have also looked for quality differences between franchised and company units of the same chain. Bradach (1998: 109), in particular, interviewed managers in five fast-food chains and concluded that the two arrangements exhibited similar levels of (standard adherence) uniformity. For the two firms in his sample that used third-party evaluators to assess quality, the average score was 94.6 (out of 100 points) for the franchised units and 93.9 for the company units in the first chain, and 89.7 and 90.6, respectively, for the second. He concluded that there was no quality difference between franchised and company-owned restaurants within these chains. Using data on quality ratings published by *Consumer Reports*, Michael (2000) found that quality was negatively associated with franchising in both the restaurant and hotel industries, and concluded that free riding was a problem for franchised chains. Jin and Leslie (2009) also found evidence that hygiene scores (a measure of quality) were higher among company-owned restaurants than among the franchised units of the same chains. A new policy requiring that restaurants post their hygiene scores, however, eliminated this difference.

Whether franchising affects firm survival is a question that has received some attention in the literature as well. Most studies have been concerned with whether affiliation with a franchised chain augments the likelihood of survival for an entrepreneur. For example, Bates (1995a,b) used the Characteristics of Business Owners (CBO) database produced in 1992 by the U.S. Census Bureau to assess the rate of failure among a representative sample of small businesses, both franchised and nonfranchised. He found that failure rates of franchised small businesses were greater than those of independent businesses, though not significantly so. Specifically, he observed that over a 5-year period, 34.7 percent of franchised businesses failed as opposed to 28.0 percent for independents. Bates (1998) then further distinguished units sold to new franchisees and those sold to existing franchisees. He found that the vast majority (84 percent) of new franchised units are opened by existing multi-unit operators, and that these units were very likely to survive, much more so than independent businesses. New units opened by new franchisees, however, were less likely to survive than were independents.

34. In contrast, Arruñada et al. (2009) find that company-owned car dealerships in Spain are much less productive than franchised car dealerships. However, they explain these performance differences not based on organizational form per se but rather on the pro-labor legal environment, which affected the terms of labor contracts more in vertically integrated dealerships, making them particularly inefficient.

Early empirical evidence had suggested that franchising attracts people who would not have chosen to open a business by themselves (Hunt 1972; Stanworth 1977). Consistent with these findings, Williams (1999) used the same CBO database to document differences in human capital, such as formal training and business experience, between individuals who choose to purchase a franchise and those who go in business for themselves. He found that those who opt for franchising tend to have higher education and more work experience but lower levels of business experience than those who opt for independent businesses. He then showed that those who choose franchising are substantially better off as franchisees than they would have been if they had tried to start businesses on their own.

As for franchisor, as opposed to franchisee, survival, several studies have documented a high rate of failure for them (e.g., Shane 1996; Stanworth 1996; Lafontaine and Shaw 1998). To our knowledge, no study compares the exit rates of franchised and nonfranchised companies explicitly. Instead, authors examine factors that affect the likelihood of survival of franchised chains. Lafontaine and Shaw (1998), for example, show that the chain's characteristics at the time it begins franchising, including contract terms (e.g., royalty rates and franchise fees), have little predictive power regarding success or failure. The number of years in business prior to the start of franchising was one of the very few factors that increased the likelihood of success in franchising. Silvester et al. (1996) found that a franchisor's initial financial investment in the business and his or her strategy of choosing franchisees with prior experience also affect the survival and growth of the chain. Azoulay and Shane (2001) suggest that offering exclusive territories to franchisees increases the likelihood of survival for young franchised chains. Finally, using a unique unbalanced panel dataset covering about 1,000 franchise chains annually from 1980 to 2001, Kosova and Lafontaine (2010) show that the usual variables from the industry dynamics literature, namely age and size, affect franchised chain growth and survival most, even after controlling for chain fixed effects and other characteristics, such as contract terms. They also confirm the result in Lafontaine and Shaw (1998) for the effect of the number of years that the franchisor spends developing the franchise concept before starting to franchise. As for the chain's contracting practices, they find that a larger proportion of company units in the chain is positively related to growth and survival in franchising. Moreover, though these effects were not always statistically significant, they find that higher ongoing revenue streams for franchisors (in the form of royalties or other such fees) and lower up-front requirements for franchisees are positively associated with both franchise chain growth and continued involvement or survival in franchising.

Few studies have considered the consequences of share contracting outside of franchising. One such study, by Mortimer (2008), analyzes the move from linear pricing to revenue sharing in video rental stores, a change that was brought about by a fall in the cost of monitoring transactions on a per movie basis. Not surprisingly, since the change was voluntarily undertaken by the up- and downstream firms—studios and retailers—she finds that it enhanced profits for both. More interestingly, using a structural econometric model of firms' contracting choices, she is able to quantify the benefits for both upstream and downstream firms. She finds that both up- and downstream firm profits increased by 10% for popular, and even more so for less popular, titles. She also shows that small retailers benefit more from revenue sharing than larger retailers do, and that consumer welfare increased as a result of the adoption of revenue sharing in this industry. Both of these effects would have been hard to predict *a priori*. A second

study, by Gil (2009), shows that for movies whose revenues are most difficult to predict, namely, nonblockbuster movies, reliance on revenue sharing in movie distribution contracts does not fully align distributor and exhibitor incentives. Consequently, movies of vertically integrated distributors are shown longer in distributors' own theaters than in vertically separated theaters despite the systematic reliance on revenue sharing in this industry.³⁵

4.6. Vertical Restraints

Vertical restraints are restrictive contract clauses that one link in a vertical chain imposes on another. Usually, the manufacturer or upstream firm restricts the retailer or downstream firm in some way. Vertical restraints are therefore instruments of control. There are many other ways in which one level in the vertical chain can exercise control over another or transfer certain rights across firm boundaries. Those methods are discussed in Section 4.7. Here we limit discussion to the traditional vertical restraints that the antitrust literature has focused on.

In contrast to the share-contracting literature, the bulk of the vertical restraints literature evaluates the consequences of employing various forms of restraints, not the incidence. This emphasis is likely due to its focus on competition policy. Still, although the literature has often just mentioned where these restraints occur and then examined their effects, a few studies have tried to arrive at some conclusions as to why these are used by analyzing where they occur most. We begin with a few examples of the use of specific vertical restraints and then discuss some reasons for employing them.

4.6.1. Incidence

Exclusive dealing—where a manufacturer requires that a retailer sell only her products—is perhaps the most common form of vertical restraint. Indeed, all franchising involves some form of exclusive dealing arrangement. However, one also finds exclusive dealing outside of franchise relationships. For example, the GM–Fisher Body contract involved exclusive dealing (Klein et al. 1978), as did the contracts between boat captains and tuna processors studied by Gallick (1984). Exclusive dealing also is used by manufacturers with their distributors: Heide et al. (1998) found that 46 of the 147 manufacturers they surveyed—all of them from the industrial machinery and equipment or the electronic and electric equipment sectors—used exclusive dealing clauses in their contracts with distributors.

An exclusive territory is granted when a manufacturer assures a downstream firm that he will be the exclusive reseller of a brand in a geographic market. As noted by Marvel (1982), exclusive territories often accompany exclusive dealing clauses. Not surprisingly then, they are commonly granted to industrial sales forces and wholesale distributors. It is also customary, for example, for cleaning-service franchises to grant exclusive territories. In fact, about 3 out of every 4 franchised chains grant some form of exclusive territory to their franchisees (Blair and Lafontaine 2005: 223). In their studies of manufacturing firms in the industrial machinery and equipment and the electronic and electric equipment sectors, Dutta et al. (1999) found that 69 of the 147 firms in their final sample used territorial restrictions.

35. See Lach and Shankerman (2008) for estimates of the effects of royalty rates on effort and outcomes in a different context, namely public and private universities licensing activities.

"Tying" refers to situations in which a manufacturer requires its customers to purchase product B as a condition for obtaining what they really want, namely, product A. Well-known examples include IBM, which required that purchasers of computers also buy punch cards, and movie distributors who practiced block booking in the early days of the industry. Block booking is a form of bundling that requires that exhibition houses rent packages of, rather than individual, films. Perhaps the most famous recent tying case involved Microsoft's attempt to tie the use of Internet Explorer to its Windows operation system (see Whinston 2001).

With resale price maintenance (RPM), the upstream firm exerts control over the price that the downstream firm can charge. RPM takes many forms including setting a specific price or a price floor or ceiling. Because RPM is or has been illegal in most countries, examples often come from antitrust challenges, which have included cases involving firms in such sectors as gasoline distribution, recreational equipment, and brewing and distilling. Franchisors in particular have been known to exert downward pressure on the prices charged by their franchisees (i.e., maximum RPM; see Blair and Lafontaine 2005), while in other contexts, manufacturers, including high-end electronics and fashion firms, have successfully implemented minimum pricing requirements.

Going beyond mere examples, Ippolito (1991) examined the population of all 203 reported cases of RPM in the United States between 1975 and 1982, a period during which a fairly broad interpretation of what constitutes RPM was adopted by the courts, and during which she argues the courts adhered quite strictly to the *per se* standard. She shows first that vertical restraints are often used together. Firms simultaneously relied on other vertical restraints in 122 of the RPM cases, most frequently using territorial, tying, or customer restrictions (49, 31, and 32 of the cases, respectively). Cases of RPM also often involved other charges, in particular, horizontal price fixing in 30 and refusal to deal in 40 of the cases. In addition, Ippolito finds evidence that a nontrivial portion of RPM cases (65% of all private and 68% of all public cases in her data) arise in contexts where products can be classified as complex, new, or infrequently purchased, which are the types of products where the special services theory for RPM is most likely to hold. She also finds another largely overlapping segment of both private and public cases arising in contexts where dealers can influence the quality of the final good or the customer's experience in important ways. Here again, manufacturer-controlled pricing can alleviate the fundamental principal-agent problem that efficiency motives and organizational economics emphasize. Yet another set of (mostly franchising) cases seems well explained by concerns over vertical sales-effort externality problems. She concludes that collusion is not the primary explanation for the RPM practices that were prosecuted during this period.

Heide et al. (1998) focus on exclusive dealing, which historically has not been treated as harshly as RPM by the U.S. antitrust authorities. As a result, they were able to obtain survey data that they used to examine what leads manufacturers to use exclusive dealing in their contracts with distributors. They found that manufacturers who were more concerned that their promotional efforts, training, or general support of distributors might benefit their competitors were much more likely to adopt exclusive dealing arrangements. In contrast, when it was difficult for manufacturers to assess whether their dealers sold other manufacturers' products (i.e., when monitoring the behavior of dealers was difficult *ex post*), or when manufacturers perceived that their customers had a preference for multiproduct distribution, they were less likely to rely on exclusive dealing. Again, these results are consistent with the type of efficiency or principal-agent arguments one finds in the organizational economics literature.

Finally, Zanarone (2009) compares contracts used by 19 car manufacturers with their dealers in Italy before and after the European Commission prohibited the use of location clauses in car distribution in 2002. These clauses prevented dealers from selling cars outside their territories. Zanarone shows that once exclusive territories became illegal, the number of car manufacturers who imposed price ceilings, required dealers to abide by a variety of explicit standards, and required dealers to contribute to an advertising fund that the manufacturer controlled went up significantly. He explains the latter two changes as direct responses to the reduced dealer incentives to advertise and provide pre-sales services. As for price ceilings, he suggests that they may have become necessary to prevent dealers from circumventing their quantity floors, something they could do, he argues, by selling aggressively outside their territories while maintaining above-normal prices in their own, perhaps isolated, markets.

4.6.2. *Effects*

The results of studies that have examined the effects of vertical restraints on firm performance and on downstream prices and quantities have been summarized in Cooper et al. (2005) and Lafontaine and Slade (2008). In both cases, the authors find that, on the whole, vertical restraints imposed by manufacturers on their resellers tend to be associated with lower costs, greater consumption, higher stock returns, and better chances of upstream firm survival. In other words, they are efficient devices for aligning incentives, eliminating free riding, and controlling opportunistic behavior, as the studies on the incidence of these practices summarized above also suggest. Moreover, there is little evidence of foreclosure.

The evidence also suggests strongly that mandated restraints, such as the exclusive territories that car manufacturers are required to provide to their dealers in most states, lead to higher prices, higher costs, shorter hours of operation, lower consumption, and fewer dealerships. For example, in his study of the effect of state laws protecting the territories of car retailers, all of whom operate under exclusive dealing contracts, Smith II (1982) found that car prices and dealership values rose, while hours of operation fell, after the state laws were enacted. In line with the results in Zanarone (2009) mentioned above, Brickley (2002) finds that franchisors adjust the terms of their contracts after the passage of laws protecting franchisees against termination such that, when all is said and done, franchisees are no better off.³⁶ So although the focus of the latter is not traditional vertical restraints, the conclusions reached are the same as in that literature.

The authors of both survey papers conclude that manufacturer and consumer welfare tend to be aligned when it comes to vertical restraints, as manufacturers have every incentive to develop lean distribution systems that get their products to their customers at the lowest possible cost. In contrast, retailers and distributors do better (or at least anticipate doing better) in the more protected, or less competitive, environments that government-mandated restraints sometimes afford them.

36. Similarly, the benefits of increased state regulation governing car manufacturer-dealer relations accrue to incumbent dealers at the time they are enacted, in that these dealers either derive greater profits or other benefits directly, or can resell their dealerships at higher prices. Thus, the state regulation encourages potentially excessive investment levels by dealers. See Lafontaine and Scott Morton (2010).

Although the results from the reviews of the literature on effects of vertical restraints are striking, they cannot be definitive if for no other reason than the small number of studies from which these conclusions are drawn, especially when one considers the number of different restraints and industries covered. Tests of the effects of vertical restraints are rare despite the intense interest of antitrust authorities in these issues, because of the challenges associated with endogeneity and the difficulty in obtaining the right type of data. In particular, efficiency motives for these restraints imply changes in costs, yet cost data are often unavailable. The recent work by Asker (2005) on exclusive dealing, Crawford and Yurukoglu (2012) on bundling, Ho et al. (2012) on full-line forcing, and finally Ferrari and Verboven (2012) on restricted licensing and franchise fees, much of which post dates the surveys mentioned above, relies on structural approaches (along with detailed data and institutional knowledge) to estimate demand and costs and evaluate the effects of the restraints. Consistent with the literature reviewed in the surveys mentioned above, Asker (2005), Brenkers and Verboven (2006), and Ho et al. (2012) find that the restraints cannot be explained by anticompetitive motives—respectively, foreclosure, strategic delegation, and leveraging of monopoly power. Also consistent with prior literature on the cable industry, Crawford and Yurukoglu (2012) find that bundling of services is costly to consumers in that industry.

Clearly, much more work is needed in this area. Hopefully, this discussion of the literature on vertical restraints will encourage empirical researchers to consider those restraints as well as other types of contract clauses in their analyses of governance and to bring vertical restraints more squarely into the realm of organizational economics and contract theory.

4.7. Control Rights Allocation

All studies of contracting practices in some sense are about the allocation of control rights. Indeed, except for the very simplest fixed-price contracts, virtually all contracts specify who can make certain decisions and/or who owns and controls the use of certain assets. For example, the choice between company operation and franchising, whether traditional or business-format, also largely determines who has the right to hire employees and set wages and prices. Similarly, the vertical restraints discussed in Section 4.6 allocate decision rights to one party or the other. Some empirical analyses of contracts, however, focus more directly on the issue of how different control rights are allocated. Moreover, the more recent studies of this type often test aspects of the theory of incomplete contracts, which emphasizes the importance of allocating decision or control rights to those parties whose decisions, investments, and/or efforts will have the greatest impact on final outcomes. These studies then explain the presence of various clauses based on the potential impact of allocating decision rights to the parties involved. To our knowledge, there has been no attempt to empirically assess the effect of this allocation.³⁷ As a result, this section focuses on incidence only.

37. Ciliberto's (2006) analysis of joint ventures, which he treats similarly and for which he finds similar results as for vertical integration, could be viewed as an exception. He notes that in the relationship between hospital and physicians, the asset is the physician's patients. Under a joint venture, he argues that the hospital gains some control over this asset. He then shows that joint ventures between hospitals and doctors positively affect hospital investment in new technologies, just like vertical integration does.

Some of the empirical work on contractual agreements that predates the development of incomplete contract theory includes detailed descriptions of the various components of contracts, often in the form of frequency tables for various clauses from a cross-section of contractual agreements. For example, Udell (1972) analyzes a total of 172 contracts for 167 distinct contract provisions in business-format franchise contracts, many of which entail the allocation of control rights. He finds, among other things, that 59% of the contracts include exclusive-territory clauses, 58% specify the days (hours) of operation for the franchised unit, thereby allocating to the franchisor the right to make such decisions, and 60% include clauses stipulating that the franchisor controls the products, services, or menus offered by the franchisee. Similarly, Contractor (1981) provides information on the frequency of various restrictions imposed on licensees in international license contracts.

Table 3 summarizes information about the main contract clauses described in these and in more recent studies, such as Lerner and Merges (1998) and Ryall and Sampson (2009), who analyze control rights allocation in technology alliances in the biotech industry and the telecommunications and microelectronic industries, respectively. The table also includes a study by Arruñada et al. (2001), who focus on the contracting practices of car manufacturers with their dealers in Spain.³⁸ In these studies, authors often comment that contracting practices are not easily labeled or classified. Not surprisingly then, categorization schemes vary across studies, making them particularly difficult to summarize. In addition, often due to data constraints, different studies focus on certain aspects of agreements while ignoring others. Finally, some studies are concerned with franchising, while others are about licensing and yet others about procurement. In spite of this heterogeneity, a few themes emerge from Table 3.

First, and not surprisingly, we find that there is much variety in contracting practices, even within contract types (i.e., when one examines only franchising arrangements, only licensing agreements, and so on). This variety reflects the use of these contracts by numerous firms engaged in a variety of business activities.

Second, despite the variety, we find that the same issues are addressed repeatedly: typically, the contracts specify the terms of the exchange, including prices and sometimes quantities, and then limit the rights of the agent (licensee, franchisee, or supplier) explicitly to a time and place. They also give the principal the capacity to monitor the behavior of the agent and to terminate the contract at will or under certain conditions. Finally, they spell out what happens after termination. In other words, these contracts resemble leasing arrangements, with the principal providing an asset—whether it be a brand and business format, a technology, or simply some desirable business (as in the case of information technology procurement)—and then spelling out the limits within which the agent can use and profit from this asset. These limits, in turn, protect the principal's ongoing interest in the value of the asset.

Third, the data in the table reflect the fact that the number or extent of restrictions imposed on the agent typically increases with the value of the asset involved in the transaction (see also Table 2). Thus, when a firm licenses its core technology, Caves et al. (1983) find that it imposes more restrictions on its licensees than when the technology is more peripheral to the licensor's business. Brickley (1999) analyzes the tendency of a large sample of franchisors to rely

38. See also Elfenbein and Lerner (2003) on contracts for portal alliances. This paper is not included in the table, because the paper does not provide simple frequencies for the contract clauses they focus on.

Table 3. The allocation of control rights

Reference	Data/setting	Asset ownership ^a	Control over (sample clauses)
Udell (1972)	172 fast-food franchise contracts in the United States, 167 clauses	Franchisor owns/leases property, 62%; intangible trademarks, brand, 52%; building design and décor, 21%	<i>Input purchases:</i> Equipment, may or must, 66%; supplies, may or must, 52%; vendor approval, 50% <i>Monitoring:</i> Franchisor right (obligation) to inspect, 71% (13%); to audit books, 44%; periodic reports by franchisee, 76%; must use franchisor's bookkeeping system, 58%; penalties for violations, 20% <i>Vertical restraints:</i> Franchisor controls price, 28%; franchisee cannot own competing business, 27.5% <i>Operations:</i> Standards, 64%; cleanliness, 72%; operating manual part of contract, 43%; franchisors sets: days, 58%, hours, 57%, product line, 60%; franchisee must be full time, 13% <i>Sale/transfer rights:</i> Franchisor approval required, 74%; franchisor right of first refusal, 32%; right of inheritance, 33% <i>Duration/termination:</i> Duration, 10–20 years; option to renew, 54%; conditions for termination, 98%; conditions for immediate cancellation, 42%; grace period, 69%; noncompete years, 56%; noncompete distance, 49%
Contractor (1981), first sample	International technology licensing, 37 U.S. licensors, all industries	Technology flow-back clauses, 71%	<i>Input purchases:</i> Materials to be purchased from licensor or designated agents, 12% <i>Monitoring:</i> Quality control on: materials, 29.4%, finished product, 55.9%; royalties on sales revenue lead to creative accounting <i>Vertical restraints:</i> Territorial limitations on manufacture, 82%; limitation on: export quantity, 15%, export price, 6%; export through designated agent, 23%; exclusive dealing, 23%
Contractor (1981), second sample	102 international technology licensing agreements, all industries	Patent mentioned, 64%; technology flow-back clause, 40%	<i>Vertical restraints:</i> Territorial limitations on: sales, 43%, output, 16%, both, 7% <i>Duration/termination:</i> Mean duration, 12.6 years
Caves et al. (1983) ^b	257 contracts of 28 licensors in chemical, electrical, and equipment manufacturing	Transfer of technology, 75%; purchase right to infringe on licensor patent, 25%; technology flow-back clauses, 43%	<i>Vertical restraints:</i> Licensee may not sell outside specified markets, 34%; production location restriction, 34%; exclusive territory for licensee, 33% <i>Duration/termination:</i> If performance clause (growth) is not met, exclusivity clause is terminated

Dnes (1992) ^c	19 franchised systems in the United Kingdom, traditional and business format	Lease control, 63%	<i>Input purchases:</i> Franchisor controls: displays, (14/15), store design, (14/15) <i>Monitoring:</i> Inspection, 15/18; periodic reports by franchisee, 15/15 <i>Vertical restraints:</i> Maximum prices, 14/15 <i>Operations:</i> Best endeavors by franchisee and franchisor, 15/15; franchisor can hire management or all personnel, 7/15 <i>Sale/transfer rights:</i> Franchisor approval required, 15/15; franchisor right of first refusal, 8/15 <i>Duration/termination:</i> Duration: 5–26 years; noncompete, 12/15; franchisor may repurchase franchisee assets on termination, 10/15
Bessy and Brousseau (1998)	46 license agreements	Technology flow-back, 65%	<i>Vertical restraints:</i> Exclusive territory, 72%; territorial restriction, 59% <i>Sale/transfer rights:</i> No resale of technology, 37% <i>Duration/termination:</i> Duration: patent life, 20%, <7 years, 35%, 7–12 years, 28%, >12 years, 17%
Lerner and Merges (1998)	Random sample of 200 technology alliances in biotech	Pharma takes equity stake, 51%; know-how transfer, 45%; partial or full ownership of patent by pharma, 82%	<i>Monitoring:</i> Seat on R&D firm's board, 21% <i>Vertical restraints:</i> Pharma has exclusive right to market, 80% <i>Operations:</i> Pharma has right to manufacture, 63%; pharma controls top project management, 6% <i>Sale/transfer rights:</i> Pharma has right to sublicense, 26% <i>Duration/termination:</i> Mean minimum length, 3.9 years; right to extend, 22%; right to terminate alliance without cause, 32%; right to shelve projects, 93%
Anand and Khanna (2000)	1,365 license agreements, U.S. manufacturing	Cross-licensing agreements, 13%	<i>Vertical restraints:</i> Exclusive territory for licensee: world, 11%, other, 26% <i>Duration/termination:</i> Duration always less than 10 years
Arruñada et al. (2001)	23 Spanish car distribution networks accounting for 99% of market in 1993–1995	Dealer owns dealership, car, and parts inventory, 100%	<i>Input purchases:</i> Manufacturer has right to set size and design of showroom, 100%; machinery and tools, including workshop design, 100% <i>Monitoring:</i> Fulfillment of sales targets, 100%; premises inspection, 100%; dealer must provide data, 87%; right to audit, 52%, right to poll dealer clients, 74% <i>Vertical restraints:</i> Manufacturer has right to set maximum prices, 100%; dealer exclusive territory, 52%; nonlinear pricing (sales discounts), 87% <i>Operations:</i> Manufacturer sets: sales targets, 100%, number of trial vehicles, 52%, inventory levels, 100%; advertising requirements, 100%; has right to set personnel, number and qualifications, 100%; training, for salesforce, 65%, training for after sales personnel, 100%; manufacturer can specify stock of spare parts, 100% <i>Sale/transfer rights:</i> Changes in ownership of dealership can lead to termination if not authorized, 100% <i>Duration/termination:</i> Contract specifies conditions for termination, 100%

Bai et al. (2004)	200 joint venture contracts, 1986–1996, in China; all industries but agriculture and mining	Intellectual property exchanged, 100%	<i>Input purchases:</i> Domestic procurement decisions by Chinese partner, 98%; overseas procurement by foreign partner, 97% <i>Operations:</i> Foreign partner recruits local (Chinese) staff, 10%
Ryall and Sampson (2009)	52 joint technology development contracts in the telecom and microelectronic industries	Intellectual property rights defined, 33%; equity between partners, 30%; joint venture creation, 11%	<i>Monitoring:</i> Seven types of clauses, with frequencies between 15% and 46% <i>Operations:</i> Output specifications, 42%; timeframe for completion, 52%; number of employees (specific employees) to be contributed, 15% (27%) <i>Duration/termination:</i> Termination date fixed, 81%; right to terminate for underperformance (separate from breach), 33%
Zanarone (2009)	19 Italian car distribution networks pre- and post-EU competition policy change (1995, 2002)	Dealer owns dealership, car, and parts inventory	<i>Vertical restraints (1995, 2002):</i> Dealer exclusive territory (100%, 0%); price ceiling (5%, 57%); quantity floor (15%, 52%) <i>Operations (1995, 2002):</i> Manufacturer sets advertising contributions (15%, 52%), advertising budget (26%, 15%), number of personnel (52%, 47%), qualification of personnel (15%, 36%), customer satisfaction targets (27%, 52%), mandatory training (68%, 73%), standards (10%, 63%)

Notes: Percentages indicate the proportion of contracts with specific clause. Missing categories in the last column mean that the paper was silent on these potential dimensions of the contract.

a. A flowback clause means that the licensee is required to share with the licensor any advances or improvements in the technology, usually free of charge.

b. The authors conducted a second survey, of licensees, but do not quantify the allocation of control rights in this survey. Elfenbein and Lerner (2003) examine control rights in portal alliances, but they do not provide descriptive statistics on the frequency of various control rights.

c. Ratios are used to describe Dnes (1992) because of changing sample sizes.

on area-development agreements (which he equates with the provision of an exclusive territory, though in reality they also entail some expansion rights) or their decision to allow passive ownership (which dictates whether the franchisee can pursue other work or business activities while a franchisee). Brickley also analyzes their decision to mandate advertising levels. He argues and finds that franchisors are more likely to impose restrictions when there are significant externalities across outlets in a chain—that is, when the brand is high value. Similarly, Arruñada et al. (2001) find that contracts allocate more rights to manufacturers when the potential cost of dealer moral hazard is higher and when manufacturers' opportunism is better controlled by reputation. The evidence in Lafontaine and Shaw (2005) goes even further, as it establishes that the likelihood that there will be a contract (i.e., the probability that a principal will be willing to "lease the asset" to an agent) decreases with the value of the asset, which in their study is the value of a business format and franchise brand.

4.8. Rent, Reputation, and Repetition

As with any repeat-business situation, the rent that parties earn in their relationship, or the difference between the profits that they can expect if they remain in their relationship compared to what they could earn outside of it, can play a crucial role in the maintenance and day-to-day functioning of the relationship. Firms can rely on this difference, along with some monitoring, to ensure that their contractual partners behave as requested or expected. Alternatively, firms can rely on the reputation of their contracting partner, and the cost the partner would bear if this reputation were damaged, to ensure performance.

4.8.1. Incidence

In a series of interviews, and subsequent analyses, Contractor (1981) found that licensor executives did not attempt to maximize their own profits by extracting all rent from licensees. Caves et al. (1983) similarly note that contracts generally fail to capture for licensors the full rent that licensees can be expected to obtain. These authors conclude that leaving rent with licensees can mitigate moral hazard and attending control issues. Specifically, they note that licensees are expected to provide inputs that raise the value of the technology, inputs whose provision cannot be specified or priced easily in the contract. "With the licensee gaining no specific recompense for these inputs, letting him share the general profits benefits the licensor by mitigating their underprovision" (Caves et al. 1983: 264). Similarly, in his series of interviews of railroad carriers and shippers, Palay (1984) found that those involved in the transport of such goods as cars, where the transport itself requires specific investments, were much more willing to make necessary adjustments to their agreement than parties involved in the transport of goods requiring no such equipment. He notes that shippers, in particular, wanted to keep carriers viable.

The franchising literature also provides empirical support for the idea that franchisees earn rent. In particular, Brickley et al. (1991), Dnes (1992), Kaufmann and Lafontaine (1994), and Michael and Moore (1995) find evidence suggesting that rent, combined with the threat of termination, plays an important role in franchising.

To illustrate, Brickley et al. (1991) exploit variation in the existence and timing of state laws requiring good cause for termination of franchise contracts to show that franchisors use franchising less in states where they face laws that restrict their ability to terminate franchisees.

This tendency holds especially for franchisors operating in industries with mostly transient customers, as the consumption decisions of such customers do not directly discipline franchisees that free ride. Those authors also find evidence that the passage of a law requiring good cause for termination in California in 1980 was associated with relatively large losses for the shareholders of publicly traded franchisors with operations in that state. Based on these results, the authors conclude that those laws, by making it more difficult to use termination, increase the cost of controlling quality in chains.

Kaufmann and Lafontaine (1994) examine the profit and loss statements from typical McDonald's outlets and the resale prices of a small set of such outlets. They conclude that McDonald's indeed leaves rent with its franchisees, rent that the franchisees lose if they are found in violation of firm policy and are terminated.³⁹ Moreover, McDonald's does not require franchisees to pay up front for the full amount of ex post rent. In other words, it allows franchisees to earn rent from an ex ante perspective. The authors explain this tactic in part based on the type of franchisees that McDonald's desires, namely, individuals who will devote themselves to their role as owner-operators of their restaurants. The authors also note that the company reserves the right to decide which franchisees are granted expansion rights, that is, which franchisees are allowed to own additional McDonald's restaurants, based on a franchisee's degree of compliance with firm policies. The prospect of additional ex ante rents thus also creates incentives for current franchisees at McDonald's, encouraging those who aspire to grow their businesses to continue to function within the bounds set by their franchise contracts. Moreover, the option of adding restaurants is made especially valuable, because the contract requires franchisees to work full time at their business and "keep free from conflicting enterprises or any other activities which would be detrimental to or interfere with the business of the Restaurant" (McDonald's Franchise Agreement 2003: 105).

Finally, Dnes (1992) dedicates a whole chapter in his book to what he calls the "wider" franchise contract, where he discusses the relational aspects of the contract, namely, a number of business understandings that have evolved over time in franchise relationships. These include a tendency in some franchise networks to let franchisees sell unauthorized goods, to grant implicit territorial protection, to support a distressed franchisee directly (e.g., by reducing royalty or lease payments or providing discounts), and to repurchase franchised outlets if needed. These aspects of the franchise relationship are implicit and are sustained only to the extent that the value of the relationship to both parties is sufficient to prevent them from altering their "understandings."

4.8.2. *Effects*

A different perspective on the issues of repetition and reputation is obtained from studies of industries where relationships are shorter term than in the franchising context, but where firms choose to repeatedly do business with the same partner. Anand and Khanna (2000), for example, find that 30% of licensing deals in their data involve firms with prior relationships or otherwise related firms, whereas 34% of international deals are concluded by firms with prior relationships. In their study of contracts for customized software, Banerjee and Duflo (2000) find that 41% of external projects involve firms that have worked with the same clients before. Repetition is not

39. Michael and Moore (1995) show that other franchise systems also leave rents with their franchisees.

ubiquitous in interfirm contracting, however. For example, only 6% of the technology alliances in Lerner and Merges (1998) involve firms that have been alliance partners before.

Most relational and reputational contracting models rely on repeated interaction to sustain cooperation, a factor that lends itself to empirical assessment. As discussed earlier, Banerjee and Duflo (2000), Corts and Singh (2004), Kalnins and Mayer (2004), Kellogg (2011), and Shi and Susarla (2011) examine the effect of repeated interaction on the choice of fixed-price or cost-plus contracts. The last four find that repetition reduces the need for high-powered incentives, but Banerjee and Duflo find no significant effect of repetition on contract choice. However, they find a strong effect for reputation, measured by the age of the software firm producing the customized product for the client. Specifically, young firms (which, they argue, have less reputational capital) are much more likely to be hired under a fixed-price contract than are older firms. This result suggests that firms use high-powered incentives for agents who have no reputation at stake but are more willing to rely on more flexible lower powered cost-plus contracts when the supplier comes to the relationship with more reputational capital. Shi and Susarla (2011) find that larger suppliers, who also presumably have more reputational capital, are more often hired under cost-plus contracts. Robinson and Stuart (2007) find that pharmaceutical companies take a smaller equity position in their biotech partners when partners are central or well embedded in the network of prior alliances in the sector. They interpret this result in terms of reputational capital as well, which, they argue, allows firms to rely less on explicit control mechanisms, such as equity.

The issues that underlie relational and reputational contracting assume particular importance in environments where the legal system is not well developed, such as developing economies. McMillan and Woodruff (1999a, b) examine relational contracting in Vietnam and find that prior experience with a trading partner and prior information gathering on that partner (presumably when the information gathered is good) are associated with increased provision of credit, which they equate with enhanced trust. Furthermore, because they find that customers who are located through business networks also receive more credit, they conclude that networks are used in group sanctions or punishments. However, they also find that retaliation is not as forceful as one would expect in a standard repeated game framework, as renegotiation often follows breach.⁴⁰

Whereas the studies mentioned above examine the effects of repetition or reputation on the mode of contracting, Gil and Marion (2012) consider effects on costs directly. Specifically, they examine how the stock of prior interactions between contractors and subcontractors in highway construction affect the bidding behavior of contractors. They find that prior interactions with the subcontractors included in a bid allow contractors to bid more aggressively and participate in more auctions. They interpret these results as evidence that prior interactions improve relationship-specific productivity. They note, however, that past interactions may improve learning or lower coordination costs, rather than provide the type of incentives through repeated business effects that authors are trying to capture in this literature. And indeed, Kellogg (2011) documents important productivity benefits associated with repeat interactions in on-shore drilling. Gil and Marion (2012), however, then show that the effect of prior relationships

40. See also Gil (2012) and Gil and Lafontaine (2012) on contracting and renegotiation, and, for example, Lafontaine et al. (2011) for an analysis of the effect of regulatory uncertainty on contracting in the hotel industry.

on bids and auction participation depends crucially on the number and dollar value of contracts expected to be up for bid in the relevant region in the coming year. They conclude that past interactions affect costs only when firms also have expectations of future business opportunities. Along similar lines, Lyons (2001) finds evidence that firms can support specific investments by reputation and rent through the establishment of partnership agreements, whereby firms agree to work together in the future, or preferred supplier agreements, which also imply longer term relationships.

Viewed as a whole, this empirical literature suggests that explicit incentives become less important when either reputation or repeated interaction, and associated rents, are present and thus can be used to support transactions. Conversely, explicit incentives become especially important in the absence of reputation or expectations of future interactions, as long as the legal system is capable of enforcing those explicit provisions. But Ryall and Sampson (2009) find that repeat interactions are associated with an increase in contract detail in their sample of technology development agreements, suggesting a type of complementarity between formal and informal contracting. Similarly, Lafontaine and Raynaud (2002) argue that self-enforcement mechanisms complement residual claims allocations in providing incentives to franchisees. This issue of complementarity among contract terms or contracting practices has taken many forms in the literature. We turn to it in the next section.

4.9. Complementarities

Most of the literature on contract terms focuses only on some aspects of contractual relationships (e.g., financial terms, quantity clauses, contract duration, or control rights). Though authors emphasize individual contract characteristics, individual terms are often but one component of complex sets of contracting practices that interact and work together as a group. This interaction is similar to that characterizing human resource practices as described by Ichniowski et al. (1997). Indeed, in his study of the practices of five fast-food restaurant chains, Bradach (1997) argues that the mechanisms and systems that franchisors rely on to govern their relationships with their franchisees interact with one another, as do the mechanisms employed in the managerial employment contract on the company-owned side of these firms. He further suggests that the two separate forms of governance complement one another, so that franchisors who use both company and franchised units can better address what he describes as the main managerial challenges that retail chains face.

Formally, complementarities occur when the marginal profitability of one action (e.g., practice or contract clause) increases with the level of another. In other words, there are synergies among the choices. Although the idea that one needs to consider complementarities in analyses of the choice of mode of governance has gained momentum since the mid-1990s, in reality, this notion did not go unnoticed by early authors in this literature. For example, Goldberg and Erickson (1987) note that because many decisions about contractual provisions and about organizational form are made simultaneously, they can interact, and thus empirical studies should strive to jointly estimate decisions concerning the set of contractual provisions and organizational decisions.

Overall, the empirical evidence supports these claims. In particular, Lafontaine and Raynaud (2002), who approach the problem descriptively, review the agency and self-enforcement arguments for franchise contracts and describe in some detail the set of clauses that support

each. Echoing Klein (1995), they conclude that explicit and implicit incentive-provision mechanisms are themselves complements rather than substitutes. They note that while the ownership stake of a franchisee and his residual claims give him reasons to work hard on the day-to-day operations of the business, these same residual claims can also lead him to free ride. Free riding can take the form, for example, of cutting costs in a way that can harm the brand and thus the chain, or of catering to local customers to a degree that is excessive from the chain's point of view. The self-enforcing aspects of the contract give the franchisor an opportunity to control exactly those behaviors that can arise as side effects from the allocation of residual claims and ownership rights to franchisees. Hueth et al. (2008) show a similar tendency for explicit and implicit contracting to be positively correlated in their study of California fruit and vegetable intermediaries' contracts. Finally, as mentioned above, Ryall and Sampson (2009) find that contracts are more detailed when a firm engages in many deals with the same or different partners. They interpret this finding to mean that formal contracting complements relational aspects of contractual relationship in high-tech industries.⁴¹

If one can characterize the relationship among the contracting parties using just a few important characteristics, it becomes possible to examine all possibilities. Brickley (1999), for example, examines three specific nonfinancial contract terms, namely, restrictions on passive ownership, area development plans, and mandatory advertising requirements. He finds that the occurrence of these provisions is positively correlated and thus concludes that they are apt to be complementary instruments of control.

In most real-world contexts, however, there are numerous contract terms to consider. This complication, in turn, leads to the problem of dimensionality: if there are n factors to assess, then there are $n(n - 1)/2$ possible two-way interactions, which in many cases is intractable. One must therefore put some structure on the problem. Unfortunately, this is not always done in a satisfactory manner. To illustrate, a standard practice in estimating a linear equation for the choice of organizational form, for example, is to include the set of other contractual provisions in the choice equation. Although this practice allows each provision to affect the firm's choice of organizational form, it does not allow for interactions among factors leading to that decision. Moreover, although most discrete choice models that include other contracting practices among the regressors imply that the marginal effect of one clause depends on the others (because the model is nonlinear), that dependency is not flexible. Instead, it is mostly determined by the assumed distribution of the error term.⁴²

An alternative and promising way to address the problem is to group contracts among a smaller set of types, focusing on major groups rather than on small variants within groups. This, of course, is the comparative institutions approach emphasized by Williamson (1991, 1996) applied to contracts and contract terms, where the latter often lend themselves quite well to grouping.⁴³

41. See also Lin et al. (2011) on the interaction between performance-based and ownership-based incentives in the hotel industry.

42. To illustrate, with a logit, if there are n practices or clauses, once the pattern of complementarity or substitutability between an arbitrary clause x_i and the remaining $n - 1$ clauses is determined, all other relationships are known.

43. This approach has been useful in other contexts as well. For example, clustering or grouping is the approach used by Ichniowski et al. (1997) in their study of the productivity effects of human resource management practices.

To illustrate, Bessy and Brousseau (1998) use cluster analysis to classify their sample of technology licensing contracts into five categories from simple transactional contracts to complex multidimensional and very incomplete contracts. They argue that the characteristics of industries and intellectual property regimes largely explain the choice that firms make among these different types of contracts. Arruñada et al. (2001) also group sets of rights found in the car dealership contracts that they study. They find positive correlations among their categories of rights (completion, monitoring, and termination), and between these and the financial terms of the contract, namely, the level of discounts offered to dealers. They also find that these correlations are much lower after controlling for characteristics of the transaction, however, suggesting that these characteristics, and thus the same underlying factors, affect the use of different contract terms. Still, they find a significant positive relationship between completion and termination rights, and between monitoring rights and discount levels (incentives), even after controlling for common sources of variation. Similarly, Kaplan and Strömberg (2003) show that their 213 venture capital contracts can easily be classified into five separate groups, and that the clusters thus generated are easily ordered in terms of either cash flow rights that are relinquished by the founder or board and voting rights allocated to the venture capitalist. Thus, the first (fifth) cluster is one where the venture capitalist (founder) obtains most of the cash flow and control rights. In other words, the rights “move” together to create the desired set of incentives and venture capitalist control.

In essence, researchers also group contract clauses when they contrast, say, franchising versus company ownership, cost-plus versus fixed-price contracts, or independents versus affiliated businesses. Of course, looking at these categories as discrete alternatives is not a perfect solution. In particular, there may remain much variation among the members of each group. For example, franchise contracts can differ importantly across chains, and this variety is interesting in its own right. Still, franchising is also fundamentally different from company operation, so that contrasting these governance modes facilitates assessment of incidence and effects. Empirical studies of franchising find that factors suggested by theory explain the choice of how much to franchise better than they do financial contract terms. This finding further supports the idea that contractual relationships may best be understood as combinations of contractual practices rather than as phenomena requiring that every component be analyzed separately.⁴⁴ Consistent with this approach, Bajari and Tadelis (2001) suggest that, even though they are limit cases, fixed-price and cost-plus contracts are fundamentally different from linear contracts, where the supplier is reimbursed for a portion of his costs (i.e., the case where $0 < \alpha < 1$ in the notation in Table 1). The Lafontaine and Slade (2007) approach of relating the decision to vertically integrate or contract with an independent agent to the agency-theoretic model predicting the optimal share parameter also relies on the introduction of some nonconvexity (in this case a cost of contracting) when the share parameter α is not zero.

Finally, the theoretical (e.g., Holmström and Milgrom 1991) and empirical (e.g., Slade 1996) literature on multitasking is also an examination of complementarity and substitutability, because it shows how the characteristics of one task affect compensation for another. Thus, models that assess compensation for one activity in isolation are incapable of capturing the full

44. That franchise contract terms do not vary much with time, or at all across franchisees that join at a given time suggests that firms adjust to different circumstances more by the choice among the two types of contracts than by designing new forms of the same contract type.

picture in this case. Moreover, the theory makes it clear that the problem worsens when the outputs of some tasks are difficult to measure and are thus not compensated directly. Under these circumstances, low-powered incentives for all tasks may be preferred, because such incentives are not associated with a diversion of effort from hard- to easy-to-measure tasks.

One should perhaps not be surprised that contract types can often be classified as described above. After all, in most industries, contracting parties and their lawyers have devised a set of templates or standard forms that many industry members rely on. As Bajari and Tadelis (2001) note, the central clauses found in such standard forms have the advantages that they are well understood in the industry, and their interpretation has been clarified through a substantial body of case law. Moreover, these templates can still provide much flexibility when it comes to specifics (see MacLeod 2007; Kornhauser and MacLeod, this volume). Perhaps what is more surprising is that the use of such templates seems to offer at least a partial solution to the dimensionality problem inherent to the study of contracts in the presence of complementarities.

5. Conclusion

In this chapter, we have reviewed a large body of empirical literature that deals with interfirm contracts. We have made a conscious effort to include within the purview of the chapter some literature that predates the development of many of the theoretical models that now guide much of this work. By doing so, we hope to have brought some focus back onto these earlier, often more descriptive, contributions to our understanding of interfirm contracts. We also hope to have convinced researchers interested in questions of organizational theory that the literature on vertical restraints is an important component of the larger literature on how firms organize their relationships.⁴⁵

Even though our chapter and references cover a lot of ground, we have also chosen to exclude certain areas of research. In particular, we have focused on firms' relationships with other firms in their supply chain rather than on their relationships with the providers of capital, be they banks or venture capitalists. Readers interested in organizational issues related to firm finance should consult Gertner and Scharfstein (this volume). Due to constraints on length, we have chosen to emphasize mostly early and recent work on particular issues rather than review the entirety of the literature on a topic. This approach gives readers an appreciation for where the literature started and where it now stands, providing the most relevant information for those interested in contributing further to this literature. Finally, to keep the discussion manageable, we have focused on the literature in economics, although we have tried to include some of the more recent or relevant contributions from the growing literature on contracts that appears in management journals.⁴⁶

In addition to taking stock of the literature, our goal is to generate interest in the area of interfirm contracts. This chapter has highlighted the need for much more empirical research on a variety of topics. Indeed, our understanding of numerous issues is still quite primitive. Those

45. Although many theoretical analyses of vertical restraints rely on considerations of incentive provision, this body of literature is not well integrated into the more orthodox study of organizational economics.

46. See also Argyres et al. (2007) and the references therein for more on the management literature on contracts.

issues include how firms choose the many terms of their contracts; when and why contract terms tend to vary significantly across firms but little over time within firms; how contracting practices interact with one another; and how explicit and implicit contracting are affected by learning, reputation, and the value of future trade. In particular, we stress that in contrast to the theory, the entire area of dynamics (e.g., relational and reputational contracting) is underexplored from an empirical point of view. In addition, there is a need to develop empirical models that can capture flexible patterns of complementary interactions while remaining empirically tractable.⁴⁷ Given the importance of interfirm contracts in the economy, we hope that our summary of the evidence will encourage researchers to develop further theory and empirical work in the area, and a stronger link between the two.

47. One could perhaps borrow from the empirical literature on differentiated products to structure such models. For example, the distance-metric approach of Pinkse et al. (2001) could be used to organize the numerous possible interactions. To illustrate, if it were possible to assign characteristics (or clauses or attributes) to groups (e.g., factors that measure the importance of the agent's effort or the riskiness of the market, or clauses related to control), one could model a common (presumably) substitution pattern within each group but allow a flexible pattern of complementarity or substitutability across groups.

Relational Incentive Contracts

James M. Malcomson

1. Introduction

This chapter is about relational contracts, agreements for which the ongoing relationship between the parties plays an essential role in determining what happens. Its concern is with *relational incentive contracts*, those that involve incentives for taking actions, and not, for example, those involving only risk sharing, such as the relational contracts studied by Thomas and Worral (1988) and surveyed in Malcomson (1999: 2300–2311). It focuses on supply relationships between firms, not purely financial contracts, sovereign debt (discussed in Obstfeld and Rogoff 1996: 349–428), or employment (surveyed in Malcomson 1999: 2337–2364). The same underlying principles apply to all these, though obviously details may differ, but because of the present focus the terminology of supply relationships between firms is used here even for results originally derived in other contexts. This chapter also focuses primarily on theory. Empirical evidence on interfirm contracts is surveyed in Lafontaine and Slade (this volume).

Some decades ago, Macaulay (1963) observed that many contractual relationships between firms in the United States were not tightly specified in legal terms. A striking example is the so-called battle of the forms. Orders for supply of goods are made on standard forms with, on the front, details of what is to be supplied and, on the reverse, the purchaser's standard terms of business. The supplier's acknowledgement of the order also has standard terms of business specified on the reverse. But the purchaser's and the supplier's terms differ, and no attempt is made to reconcile them. Such informality concerned lawyers interviewed for Macaulay (1963), some of them in-house lawyers for large firms employed to give legal advice on contracts who might thus be expected to influence the contracts used. Yet purchasing and supplying agents persisted in using loosely specified contracts with, seemingly, the view that there was so much business between the parties that they would work something out if either was dissatisfied. One

I thank the many people, too many to list individually, who have assisted me in writing this chapter. I am, however, particularly indebted to Robert Gibbons, Bentley MacLeod, John Roberts, Giancarlo Spagnolo, and Michael Whinston, who read and commented on complete drafts. I also thank Leverhulme Trust Major Research Fellowship F/08519/B for financial support of my research on relational contracts.

purchasing agent went so far as to say: “One doesn’t run to lawyers if he wants to stay in business because one must behave decently” (Macaulay 1963: 61).

The literature on relational contracts is concerned with the impact of the ongoing nature of the relationship on trade between the parties, on their payoffs, on the nature of any legally enforceable contract used to supplement the relational contract, and on the design of organizations. Legal aspects of relational contracts have been explored by Macneil (1978). The underlying economic idea was explored early on by Telser (1980) and Klein and Leffler (1981). If a supplier does not deliver something acceptable, the purchaser can look elsewhere in future. Provided the supplier anticipates a profit from continuing to trade with the purchaser, that acts as an incentive to provide what the purchaser wants. So there is a tension between providing something less costly, but less acceptable, now and keeping business in the future. It is a tension widely recognized in the business world. But the future incentive applies only if the supplier anticipates a strictly positive profit in the future, so the relationship has to be one in which free entry does not compete away all profits, perhaps because there are relationship-specific investments, perhaps because the parties learn information about each other that is not available about other potential purchasers and suppliers, or perhaps just because other potential purchasers and suppliers are wary of dealing with those who have had trading relationships come to an end for no apparent good economic reason. Moreover, the supplier will not incur more in costs to keep the relationship going than the value of any future profits. That limits what can be sustained. Those agreements that can be sustained in this way are said to be “self-enforcing,” because they do not need courts to enforce them.

There are a number of strands to the literature on the economics of relational incentive contracts. One strand builds on the traditional principal-agent literature. In the most basic version, there is a principal (purchaser) who uses a single agent (supplier) to provide something with characteristics for which there are no verifiable measures that can be used to write a formal contract. That is the starting point for Section 3 of this chapter. This starting point is extended to cases in which there is some verifiable measure, but it does not capture all the parties care about and in which there are multiple agents (suppliers), issues taken up in Sections 4–8. In this strand, the principal does not contribute to the relationship except to pay for, and make use of, what is provided. In a second strand, all parties take actions that contribute to what is produced, as in a partnership, team, or joint venture. This raises the issue, discussed in Section 9, of how each party is rewarded as a function of whatever measure of joint output is available. Yet another strand is concerned with organizational design—whether the purchaser and supplier remain separate firms or are vertically integrated to produce components in-house, and who has the right to make what decisions, issues taken up in Section 10. The chapter concludes with some other issues arising from relational contracts (Sections 11–13). But first, in Section 2, it discusses some classic applications of relational contracts and the issues they raise for theory.

2. Classic Applications of Relational Contracts

Although this chapter is primarily about theory, it is helpful to illustrate the issues that arise in relational contracts with two classic cases, the relationship between Fisher Body and General Motors (GM) in the period 1919–1926 studied in detail in Klein et al. (1978) and Klein (2000),

and the relationships between large Japanese automobile and electrical goods manufacturers and their suppliers studied by Asanuma (1989).

Klein (2000) describes the GM–Fisher Body relationship as follows. In 1919, GM agreed a 10-year exclusive dealing contract with Fisher Body for the supply of bodies for its automobiles. This was a relational contract, supplemented by a cost-plus contract for each unit delivered specifying that GM would pay an amount equal to Fisher’s variable cost plus 17.6%. The relationship worked well up to 1924 but then became problematic for two reasons given by Alfred Sloan, the chief executive of GM. First, the cost-plus contract became unduly burdensome with the increase in the volume of bodies required by GM. Second, Fisher Body became unwilling to put up large amounts of capital to establish body plants near GM assembly plants: especially “Fisher’s refusal to make the investment in plant and equipment to move Fisher’s production of Buick bodies from Detroit to a site near the GM Buick assembly plant in Flint” (Klein 2000: 116). The upshot was that GM took over Fisher Body. The interpretation Klein (2000) places on these reasons is that the “plus” element in the probably legally enforceable cost-plus contract became excessive in relation to capital and overhead costs, given higher than anticipated volume and given that the specific investments required to build body plants near GM assembly plants were too large to keep the arrangement within the zone of a self-enforcing relational contract.

Klein’s interpretation of these events has been disputed—see, for example, the other papers in the issue of the *Journal of Law and Economics* in which Klein (2000) appears. But, whether or not correct, it raises interesting questions for theory. First, in what way might a larger specific investment make it more difficult to sustain a relational contract? Second, what is the role of an additional explicit contract, such as GM’s problematic cost-plus contract with Fisher Body, within a relational contract? And third, what does theory have to tell us about when vertical integration, which brings the incentive issues within a single firm, is to be preferred to a relational contract between two firms? All these issues are discussed in this chapter.

Asanuma (1989) carried out a detailed investigation of the contractual relationships between large Japanese companies in automobile and electrical machinery manufacturing and their suppliers. As he describes it, these large purchasers typically each use a small number of associated companies. They normally have a basic contract lasting initially for 1 year but renewed unless there are objections by either party. The basic contract specifies general obligations. It also specifies that orders (or monthly schedules in the case of automobiles) are to be regarded as contracts once accepted by the supplier and the frequency at which prices are to be renegotiated (typically 6 months). There is a general expectation that suppliers will reduce prices over time as a production run lengthens and that less highly regarded suppliers will be used as capacity buffers.

Asanuma (1989) attaches considerable importance to the rating system purchasers use for suppliers. To explain this system, he considers suppliers in three categories. The first are those he terms “suppliers in general,” those who supply off-the-shelf goods (purchased goods), for example, from catalogs. For these goods, a long-term relationship may not be important. The other two categories are for suppliers of ordered goods. Here suppliers are differentiated into “common subcontractors,” who produce components to designs provided by the purchaser (drawings supplied) and “excellent subcontractors,” who produce components to their own design that has been approved by the purchaser (drawings approved). The latter are subcontractors who have shown themselves to be responsible suppliers in the past and are given a more responsible role

in production. Typically, any change in status is associated with a change in design of the part supplied (with, e.g., a new model of automobile), when the supplier would have to make new specific investments in any case. It is rare for a purchaser to switch supplier during the lifetime of a product model, so it is times at which a model changes that are most competitive.

The description provided by Asanuma (1989) raises some further questions for theory. When purchasers face, and want to find out more about, suppliers of potentially different types, what difference does it make to the relational contracts between the parties? And what does theory have to say about the process of dividing suppliers into different rating categories on the basis of past experience, giving more-highly rated ones additional responsibilities?

3. Two Basic Models

The role of relational contracts is isolated most clearly when a single purchaser buys from a single supplier and there is no measure of the supplier's performance that is verifiable in court. The purchaser's profit in period t from being supplied with quality $q_t \in [\underline{q}, \bar{q}]$ is $y_t(q_t) - P_t$, where P_t is the payment to the supplier. Quality can be multidimensional, with q_t a vector. It is essentially a short-hand term for anything under the control of the supplier that is of concern to the purchaser. Suppose that y_t is strictly increasing and concave (so when $y_t(q_t)$ is twice differentiable, $y'_t(q_t) > 0$, and $y''_t(q_t) \leq 0$ for all q_t), and that $y_t(\underline{q}) = 0$, so that the purchaser would not be prepared to pay for quality at the lowest level. The supplier incurs cost $c_t(q_t)$ from supplying quality q_t and so makes profit $P_t - c_t(q_t)$ in period t if paid P_t for doing so. Conventionally, c_t is continuous, strictly increasing, and strictly convex (so when $c_t(q_t)$ is twice differentiable, $c'_t(q_t) > 0$ and $c''_t(q_t) > 0$ for all q_t), $c_t(\underline{q}) = 0$, and $\lim_{q_t \rightarrow \bar{q}} c_t(q_t) = \bar{c}$ with $\bar{c}$ finite. If the parties choose not to trade with each other in period t , the purchaser receives payoff $\pi_t > 0$ (perhaps from producing the component in-house) and the supplier payoff $u_t > 0$ (from using the capacity to supply elsewhere). The parties have a common discount factor $\delta_t \in (0, 1)$. The purchaser checks the quality supplied with probability $\rho \in (0, 1]$.

When quality is unverifiable, it is not possible to write a legally enforceable contract that makes payment conditional on quality. However, as Bull (1987) and MacLeod and Malcomson (1989) observed, the parties can still use conditional payments provided the relationship is structured in such a way that it is worthwhile for the purchaser to make them. For that reason, it may be useful to have the payment P_t consist of two components, a legally enforceable component p_t that cannot be conditioned on quality and a voluntary bonus $b_t \geq 0$ that can. How these components relate to the types of payments actually made in practice is discussed later. Following Levin (2003), we can think of the purchaser and supplier agreeing informally a plan for q_t , p_t , and b_t for the duration of their relationship. This is their *relational incentive contract*.

3.1. Employment Model

In what has been termed the "employment model" in the literature, once the cost of supply has been incurred, the supplier cannot hold back supply until payment is made. The timing

Figure 1. Timing of events for period t in the employment model.

of events for period t in this model is shown in Figure 1. At the beginning of each period, the purchaser commits to the legally enforceable payment p_t .¹ The supplier then decides what quality to deliver. The purchaser monitors the quality delivered with probability ρ , pays p_t , and decides whether to pay b_t . Finally in this period, the relationship may be terminated by either party, either because it is no longer even potentially mutually beneficial or because one or the other party decides to end it for some other reason.

The term “employment” should not be taken too literally. Although this model is clearly appropriate for employment, it also applies to the supply of many types of services. With this structure, no supply occurs if the relationship lasts for at most one period. With no future to be concerned about, the purchaser has no incentive to pay a positive bonus. Anticipating this, the supplier has no incentive to deliver quality above $\underline{q}$. When $q_t = \underline{q}$, the joint gains from the relationship, $y_t(\underline{q}) - c_t(\underline{q}) = 0$, are less than the joint payoffs $\pi_t + u_t$ the parties could get from making alternative arrangements, so there is no price p_t at which they would trade with each other. Thus, the possibility of trade depends on the relationship being at least potentially ongoing.

In a potentially ongoing relationship, the supplier’s future payoff from t on for a relationship started at τ , if both parties stick to their agreement, consists of the payment $p_t + b_t$ less the cost of supply $c_t(q_t)$ in period t plus the expected payoff from the future. It can be written as

$$U_t = p_t + b_t - c_t(q_t) + \delta_t U_{t+1}, \quad \text{for all } t \geq \tau. \quad (1)$$

If, however, the supplier delivers quality in breach of the agreement, this is undetected with probability $1 - \rho$, and everything then continues as if no breach had occurred, with the supplier receiving payoff $p_t + b_t + \delta_t U_{t+1}$. The breach is detected with probability ρ , but the worst that can happen to the supplier is that the relationship comes to an end with payment of p_t , but without payment of the bonus b_t , because the supplier can always choose to quit at the end of period t . Let $\tilde{U}_{t+1}$ denote the supplier’s payoff from $t + 1$ on in those circumstances. Thus, by setting $q_t = \underline{q}$, the supplier can obtain a payoff from t on of no less than

$$p_t + (1 - \rho)(b_t + \delta_t U_{t+1}) + \rho \delta_t \tilde{U}_{t+1}, \quad \text{for all } t \geq \tau. \quad (2)$$

1. In the employment model of Section 3.1, p_t could be paid at this stage, thus eliminating the need for it to be legally enforceable. But in models discussed later, p_t is conditioned on verifiable information not available until after the supplier has set q_t , and then the commitment is to a legally enforceable contract specifying these conditional payments.

From (1) and (2), it is certainly better for the supplier to set $q_t = \underline{q}$ than to stick to any agreement with $q_t > \underline{q}$, unless the following incentive compatibility condition holds:

$$\delta_t \{ \text{future gain to supplier} \} \equiv \delta_t (U_{t+1} - \tilde{U}_{t+1}) \geq \frac{c_t(q_t)}{\rho} - b_t, \quad \text{for all } t \geq \tau. \quad (3)$$

The interpretation of this condition is most straightforward when $\rho = 1$: the future gains from having the relationship continue at the end of period t must then exceed the cost $c_t(q_t)$ of complying minus the current period incentive to supply provided by the bonus b_t . Moreover, for the supplier to continue in the relationship when there has been no breach, the following individual rationality condition must also hold:

$$U_t \geq \bar{U}_t, \quad \text{for all } t \geq \tau, \quad (4)$$

where $\bar{U}_t$ denotes the supplier's payoff from t on if the relationship ends for reasons unrelated to the performance of either party. In principle, $\bar{U}_t$ need not be the same as $\tilde{U}_t$.

If both parties stick to their agreement, the purchaser's future payoff from t on for a relationship started at τ consists of the value $y_t(q_t)$ derived from supply less the payment $p_t + b_t$ in period t plus the expected payoff from the future. It can be written as

$$\Pi_t = y_t(q_t) - p_t - b_t + \delta_t \Pi_{t+1}, \quad \text{for all } t \geq \tau. \quad (5)$$

If the purchaser does not pay the agreed bonus, the worst that can happen is that the relationship comes to an end, because the purchaser can always choose to quit at the end of period t . Let $\tilde{\Pi}_{t+1}$ denote the purchaser's payoff from $t + 1$ on in those circumstances. Thus, by setting $b_t = 0$, the purchaser can obtain a payoff from t on of no less than $y_t(q_t) - p_t + \delta_t \tilde{\Pi}_{t+1}$. Thus, it is certainly better for the purchaser to pay no bonus than to stick to any agreement with $b_t > 0$ unless the following incentive compatibility condition holds:

$$\delta_t \{ \text{future gain to purchaser} \} \equiv \delta_t (\Pi_{t+1} - \tilde{\Pi}_{t+1}) \geq b_t, \quad \text{for all } t \geq \tau. \quad (6)$$

Moreover, for the purchaser to continue in the relationship when there has been no breach, the following individual rationality condition must clearly hold:

$$\Pi_t \geq \bar{\Pi}_t, \quad \text{for all } t \geq \tau, \quad (7)$$

where $\bar{\Pi}_t$ denotes the purchaser's payoff from t on if the relationship ends for reasons unrelated to the performance of either party. In principle, $\bar{\Pi}_t$ need not be the same as $\tilde{\Pi}_t$.

Let $S_{t+1} = U_{t+1} + \Pi_{t+1}$ denote the joint payoff (or *surplus*) the parties receive from $t + 1$ on if the relationship continues and $\tilde{S}_{t+1} = \tilde{U}_{t+1} + \tilde{\Pi}_{t+1}$. Then (3) and (6) can be added to give the pooled incentive compatibility condition

$$\delta_t (S_{t+1} - \tilde{S}_{t+1}) \equiv \delta_t (U_{t+1} - \tilde{U}_{t+1} + \Pi_{t+1} - \tilde{\Pi}_{t+1}) \geq \frac{c_t(q_t)}{\rho}, \quad \text{for all } t \geq \tau. \quad (8)$$

It is clear from the way they have been derived that (4), (7), and (8) are necessary conditions for the parties to stick to any agreement with $q_t > 0$, that is, for the agreement to be self-enforcing. Following the argument in MacLeod and Malcomson (1989), they are also sufficient. Formally, provided an agreement satisfies (4), (7), and (8), there exist strategies implementing the agreement that form a subgame perfect equilibrium. Hence, (4), (7), and (8) provide a complete characterization of subgame perfect equilibria with qualities strictly greater than $\underline{q}$.²

The right-hand side of (8) is the cost of delivering quality q_t adjusted for the probability that cheating on the agreement is detected. That is sometimes referred to as the “reneging temptation.” The left-hand side of (8) is the joint future gain to the parties from continuing the relationship at the end of period t . Thus, (8) requires that the joint future gain exceeds the reneging temptation. The joint future gain is independent of the payments made by the purchaser to the supplier—these cancel when U_{t+1} and Π_{t+1} are added—so the only element of the relational incentive contract that affects whether (8) is satisfied is the sequence of qualities $(q_t, q_{t+1}, \dots)$ from t on. For any sequence of qualities that satisfies (8), it is always possible to find a sequence of bonuses $(b_t, b_{t+1}, \dots)$ such that (3) and (6) are both satisfied for all t . Only the joint future gain, not its division between purchaser and supplier, enters (8), for the following reason. Future gain to the supplier affects the quality that can be delivered directly via the supplier’s incentive compatibility condition (3). But future gain to the purchaser can do so too, because it can be used to induce the purchaser to pay a bonus via the purchaser’s incentive compatibility condition (6) and that bonus affects the quality that can be delivered via (3).

As already explained, in a one-shot game the purchaser would never pay a positive bonus, so the supplier would always set quality at the lowest level. Thus, the one-shot game has a prisoner’s dilemma type structure, and one can apply the intuition for the standard Folk Theorem in a repeated prisoner’s dilemma game. Suppose δ_t is constant at δ for all t . The Folk Theorem tells us that, for a repeated prisoner’s dilemma game, any individually rational cooperation can be sustained for a discount factor δ sufficiently close to 1 by strategies that revert to those of the one-shot equilibrium if either party deviates. Consider any sequence of quality $(q_t, q_{t+1}, \dots)$ from t on for which the left-hand side of (8) is positive for all t . As $\delta \rightarrow 1$, that left-hand side goes to infinity, so any such sequence satisfies (8). Equality in (8) specifies the critical value of the discount factor for sustaining any particular sequence.³ Provided supply of this sequence of qualities is mutually beneficial, there also exists a sequence $(p_t, p_{t+1}, \dots)$ such that (4) and (7) are satisfied for all t . Then the ongoing nature of the relationship enables the purchaser to elicit quality above the minimum level from the supplier when that would not be possible in a one-period relationship.

Any sequences that satisfy (4), (7), and (8) can be sustained as equilibria. But some equilibria may be better than others. Let q_t^* denote efficient quality defined by

$$q_t^* = \arg \max_q y_t(q) - c_t(q), \quad \text{for all } t \geq \tau. \quad (9)$$

The purchaser and supplier can increase their joint payoff $U_\tau + \Pi_\tau$ at the start of the relationship (at τ) unless, for each $t \geq \tau$, either (a) $q_t < q_t^*$ and (8) holds with equality, or (b) $q_t = q_t^*$.

2. This result does not depend on payment of p_t being legally enforceable, for the reason given in note 1.

3. But see Blonski et al. (2011) on whether this value is actually critical for determining whether the parties sustain such a sequence.

To see why, note that the component of the joint payoff at date t' , $U_{t'} + \Pi_{t'}$, arising at date $t \geq t'$ is just $y_t(q_t) - c_t(q_t)$, which q_t^* maximizes. Thus, the joint payoff $U_{t'} + \Pi_{t'}$ is always increased by having q_t move toward q_t^* for $t \geq t'$. So moving q_t toward q_t^* increases the left-hand side of (8) for all dates prior to t . Suppose $q_t > q_t^*$. Then the parties can always increase their joint payoff at τ , because reducing q_t increases the joint payoff for all dates up to t (thus relaxing the constraint (8) for all dates prior to t by increasing the left-hand side) and also relaxes the constraint (8) for t by reducing the right-hand side. Appropriate choice of p_t and b_t can ensure that neither U_t nor Π_t is reduced. Suppose now $q_t < q_t^*$. If (8) held with strict inequality at t , q_t could be increased without violating that constraint, which would also increase the left-hand side of (8) for all dates prior to t , thus relaxing the constraint for all dates prior to t . Thus, increasing q_t would increase the joint payoffs at all dates up to t without resulting in any of the constraints (4), (7), and (8) being violated.

The argument just given establishes that any constrained efficient self-enforcing equilibrium (ESE) has, for each $t \geq \tau$, either (a) $q_t < q_t^*$ and (8) holding with equality, or (b) $q_t = q_t^*$. In the model in Ray (2002), any ESE also maximizes the supplier's payoff from some finite $t' > \tau$ on as long as $q_t < q_t^*$ for all $t \geq \tau$. In that model, the purchaser is committed to the agreement at each t , which allows no scope for a discretionary bonus b_t . The result in Ray (2002) then follows from (3) with $b_t = 0$ for all $t \geq \tau$. For any $t \geq \tau$ with $q_t < q_t^*$, quality can be closer to the efficient level if $U_{t+1} - \tilde{U}_{t+1}$ is increased, which must therefore be maximized in any ESE. But that is not necessary if discretionary bonuses are included in the relational contract agreement.

Pooling of incentive compatibility conditions, as done to derive (8) from (3) and (6), is a standard feature in the literature that will recur in what follows. It is, though, important to recognize that it depends on the parties being risk-neutral. Also a standard feature in the literature is the limit on bonuses implied by (6), because the purchaser cannot receive a payoff from the future higher than is consistent with the supplier being prepared to continue the relationship. The result that conditions (4), (7), and (8) are necessary and sufficient does not depend on an environment, agreement, or payoffs that are stationary over time. But, as Levin (2003) shows, in a stationary environment the parties cannot do better than use a stationary agreement, one with q_t , p_t , and b_t the same for all t . Kranz and Ohlendorf (2009) consider the renegotiation proofness of relational contracts.

3.2. Outsourcing Model

In the employment model, once the cost of supply is incurred, the supplier cannot hold back supply until payment is made. But supply is sometimes of intermediate products produced on the supplier's own premises. That complicates the picture somewhat, because the supplier could then withhold the product and use it as a bargaining chip for payment. This scenario has been termed the "outsourcing model" in the literature. The timing of events for this model is shown in Figure 2. It differs from Figure 1 for the employment model, because at the third stage in period t the supplier, as well as the purchaser, can decide whether to stick to their agreement.

If both parties decide to stick to their agreement at this stage, the supplier delivers the already-produced quality to the purchaser, and the purchaser simultaneously pays the agreed bonus. If either decides to breach the agreement, the supplier retains the product and the purchaser pays no bonus. To complete the model, one must specify the alternative actions available to the parties

Figure 2. Timing of events for period t in the outsourcing model.

in the event of breach. A common assumption in the literature is that the outcome of those actions corresponds to a Nash bargain, but the precise formulation is unimportant here. For the present purpose, it suffices to denote by $z_t(q_t)$ the payment the supplier can get for quality q_t by withholding supply and bargaining. This payment will reflect not only what the product is worth to the purchaser but also what it can be sold for to some alternative purchaser. In this model, if the supplier were to decide not to provide the agreed quality and so risk breakdown of the relationship, it would not necessarily be optimal to set quality to $\underline{q}$, because the product could still be sold for some payment. It simplifies the exposition here without compromising later use to set $\rho = 1$, so that substandard quality is always detected by the purchaser. Then the optimal quality to deviate to is

$$\tilde{q}_t = \arg \max_{q \geq \underline{q}} z_t(q) - c_t(q). \quad (10)$$

This is precisely the quality the supplier would produce if there were no relational contract and all transactions were via a spot market. The payoff to deviating from the agreed-on quality corresponding to (2) with $\rho = 1$ is then

$$p_t - c_t(\tilde{q}_t) + z_t(\tilde{q}_t) + \delta_t \tilde{U}_{t+1}, \quad \text{for all } t \geq \tau, \quad (11)$$

and the incentive compatibility condition corresponding to (3) with $\rho = 1$ becomes

$$\begin{aligned} \delta_t \{\text{future gain to supplier}\} &\equiv \delta_t (U_{t+1} - \tilde{U}_{t+1}) \\ &\geq c_t(q_t) - c_t(\tilde{q}_t) + z_t(\tilde{q}_t) - b_t, \quad \text{for all } t \geq \tau. \end{aligned} \quad (12)$$

In the outsourcing model, the supplier also has another decision to make, whether to supply the intermediate good once it has been produced. That will be worthwhile only if the bonus b_t combined with the benefit of having the relationship continue is more valuable than deviating by selling the good for $z_t(q_t)$ and having the relationship end. Formally, that requires

$$\delta_t (U_{t+1} - \tilde{U}_{t+1}) \geq z_t(q_t) - b_t, \quad \text{for all } t \geq \tau. \quad (13)$$

By the definition of $\tilde{q}_t$ in (10), the right-hand side of (12) is necessarily at least as large as the right-hand side of (13), so the former is always the critical incentive compatibility condition for the supplier.

The purchaser will pay the bonus for the agreed quality only if doing that and having the relationship continue is worth more than defaulting, paying $z_t(q_t)$ to get the supply despite defaulting, and having the relationship end. Thus, the incentive compatibility condition for the purchaser corresponding to (6) becomes

$$\delta_t \{ \text{future gain to purchaser} \} \equiv \delta_t \left(\Pi_{t+1} - \tilde{\Pi}_{t+1} \right) \geq b_t - z_t(q_t), \quad \text{for all } t \geq \tau. \quad (14)$$

The overall incentive compatibility condition corresponding to (8) with $\rho = 1$ is obtained by adding (12) and (14):

$$\begin{aligned} \delta_t \left(S_{t+1} - \tilde{S}_{t+1} \right) &\equiv \delta_t \left(U_{t+1} - \tilde{U}_{t+1} + \Pi_{t+1} - \tilde{\Pi}_{t+1} \right) \\ &\geq c_t(q_t) - c_t(\tilde{q}_t) + z_t(\tilde{q}_t) - z_t(q_t), \quad \text{for all } t \geq \tau. \end{aligned} \quad (15)$$

To see the incentive differences between the employment and the outsourcing structures, compare (15) with (8) when $\rho = 1$, so that the environments are otherwise identical. The incentive compatibility condition (8) for the employment structure depends only on the quality q_t specified by the relational contract. That for the outsourcing structure (15) also depends on the quality $\tilde{q}_t$ that the supplier would produce in the absence of a relational contract. Thus the structure of the relationship makes a difference to the quality that can be sustained. It is tempting to conclude that (15) is weaker than (8) when $z_t(q_t) \geq z_t(\tilde{q}_t)$. One must, however, be careful about this conclusion, because it may be that $\tilde{U}_t$ and $\tilde{\Pi}_t$ take different values in the outsourcing model than in the employment model. One obvious reason is that, in the outsourcing case, the supplier is willing to supply $\tilde{q}_t$ even in a spot market without a relational contract, because the product can always be sold for $z_t(\tilde{q}_t)$. In contrast, in the employment model, no supply would occur without a relational contract.

The argument used in Section 3.1 for the employment model to show that the purchaser and supplier can always increase their joint payoff if $q_t > q_t^*$ for any t does not work with the outsourcing model, because reducing q_t may increase the right-hand side of (15) if it reduces $z_t(q_t)$ more than it reduces $c_t(q_t)$. But it remains the case that the purchaser and supplier can increase their joint payoffs $U_\tau + \Pi_\tau$ at the start of the relationship (at τ) unless, for each $t \geq \tau$, either (15) holds with equality or $q_t = q_t^*$. Otherwise, moving q_t marginally in the direction of q_t^* would not violate (15) and would increase the joint payoffs for all dates up to t .

Because of its simpler structure, much of the discussion that follows is based on the employment model underlying (8) rather than on the outsourcing model underlying (15). But many of the arguments can be extended to the outsourcing model, and that model has been used in the literature to illustrate points that cannot be made using only the employment model.

4. Specific Investments

Basic as it is, the employment model of Section 3.1 can be used to address the first question arising from the interpretation Klein (2000) places on the relationship between GM and Fisher Body: in what way might a larger specific investment make it more difficult to sustain a relational contract? But first the model must be adapted to include a specific investment. A specific investment by the supplier of $I \geq 0$ at τ in general affects both the output from, and the cost of,

delivering quality, so write these as $y_t(q_t, I)$ and $c_t(q_t, I)$, respectively, for $t \geq \tau$. It thus also affects the surplus from the relationship S_t . Furthermore, it may affect the ease of monitoring quality, which can be captured by writing the probability of monitoring $\rho(I)$. In addition, it may affect the supplier's payoff from breaching the relational contract. If, as in the GM–Fisher Body example, the specific investment involved moving the body plant, it may have reduced the payoff to trading with other potential purchasers. Denote that payoff by $\tilde{U}_{t+1}(I)$. Finally, if the supplier is to make the investment, the payoff in the period of investment τ must be large enough to make the investment worthwhile, that is, $U_\tau \geq \tilde{U}_\tau + I$.

Consider a stationary environment and a stationary relational contract, for which t subscripts can be dropped. Then $S = [y(q, I) - c(q, I)] / (1 - \delta)$. Define $\tilde{u}(I)$ and $\tilde{\pi}$ by, respectively, $\tilde{U}(I) = \tilde{u}(I) / (1 - \delta)$ and $\tilde{\Pi} = \tilde{\pi} / (1 - \delta)$, so $\tilde{S} = [\tilde{u}(I) + \tilde{\pi}] / (1 - \delta)$. Then (8) becomes

$$\frac{\delta}{1 - \delta} [y(q, I) - c(q, I) - \tilde{u}(I) - \tilde{\pi}] \geq \frac{c(q, I)}{\rho(I)}. \quad (16)$$

It follows that a worthwhile specific investment that increases $y(q, I) - c(q, I)$ for a given q can make it harder to sustain the relationship only if it increases

$$\frac{c(q, I)}{\rho(I)} + \frac{\delta}{1 - \delta} [\tilde{u}(I) + \tilde{\pi}]. \quad (17)$$

The specific investment would thus have to do at least one of the following: (a) increase the variable cost of producing the given quality, with the benefits of the specific investment arising from an increase in $y(q, I)$ of more than the increase in $c(q, I)$; (b) make monitoring quality more difficult, corresponding to a decrease in $\rho(I)$; or (c) increase the payoff $\tilde{u}(I)$ the supplier receives from breaching the relational contract. This chapter focuses on theory and so does not consider in detail whether the higher specific investments that GM wanted Fisher Body to make could have operated in this way, but there are a number of straightforward considerations.

An obvious efficiency gain from siting a body plant close to an assembly plant would be a reduction in the cost of transporting bodies to the assembly plant. If that were all, it would be worthwhile only if it involved a net saving after taking into account the cost of transporting materials, that is, only if it reduced the cost $c(q, I)$ for given q of delivering bodies to the assembly plant. Also plausible is that it would reduce the payoff $\tilde{u}(I)$ the supplier could get from breaching the relational contract, because the plant would be farther from other potential purchasers. Moreover, it is not obvious why moving the body plant should increase the difficulty of monitoring quality. Thus, the reduction in transportation cost would seem to make it easier to sustain the relational contract. It may, of course, be that the specific investment increases the marginal benefit of quality $\partial y(q, I) / \partial q$ or decreases the marginal cost of quality $\partial c(q, I) / \partial q$, in which case it will change the efficient quality level defined by (9). Thus, it may be that, at a lower level of specific investment, efficient quality is attainable with a relational contract but not at a higher level of specific investment. But that does not, in itself, make it harder to sustain the relational contract.

The outsourcing model of Section 3.2 may, however, be more appropriate to describe the relationship between GM and Fisher Body, though the value of a Buick body to another auto-

mobile assembler is questionable. Then the relevant incentive compatibility condition is (15) instead of (8). In that case, the specific investment might affect the quality $\tilde{q}_t$ defined in (10) that the supplier would produce if planning to breach the relational contract. Then, in an obvious notation, (16) is replaced by

$$\begin{aligned} & \frac{\delta}{1-\delta} [y(q, I) - c(q, I) - \tilde{u}(I) - \tilde{\pi}] \\ & \geq c(q, I) - c(\tilde{q}(I), I) + [z(\tilde{q}(I), I) - z(q, I)], \end{aligned} \quad (18)$$

and so (17) is replaced by

$$c(q, I) - c(\tilde{q}(I), I) + [z(\tilde{q}(I), I) - z(q, I)] + \frac{\delta}{1-\delta} [\tilde{u}(I) + \tilde{\pi}].$$

There is then the additional consideration of how the specific investment affects the difference in cost $c(q, I) - c(\tilde{q}(I), I)$ between producing q and producing $\tilde{q}(I)$, and how it affects the difference in the payment $z(\tilde{q}(I), I) - z(q, I)$ the supplier could get by withholding supply and bargaining.

These considerations apply to the continuation of the relational contract once the specific investment has been made. One of the issues arising between GM and Fisher Body, however, was the latter's unwillingness to make the specific investment in the first place. For a specific investment at τ to be worthwhile for the supplier, the supplier's payoff from τ on, U_τ , would have to increase by more than the cost of the investment. The previous section showed that, for any given sequence of qualities $(q_t, q_{t+1}, \dots)$ that it is feasible to support in a continuation equilibrium, there exist continuation equilibria with any feasible U_t and Π_t that satisfy $U_t \geq \bar{U}_t$ and $\Pi_t \geq \bar{\Pi}_t$. So, as long as the specific investment is jointly worthwhile in the sense of increasing $U_\tau + \Pi_\tau$ by more than it costs, there exists a continuation equilibrium with the increase in the supplier's payoff sufficient to cover the cost of the investment without reducing the purchaser's payoff. But it is possible that Fisher Body's concern was with whether GM would in fact play such a continuation equilibrium. Predicting which equilibrium will be played in a multiple equilibrium context is problematic. But the usual assumption in the relational contract literature is that the parties will play a Pareto superior equilibrium, provided it is incentive compatible. Indeed, this assumption is implicit in Klein's (2000) view that, up to 1924, the relational contract arrangement between GM and Fisher Body was efficient.

Whether, of course, they actually do play a Pareto superior equilibrium is an empirical question that is not the subject of this chapter. But it is worth noting that there are many experimental studies indicating that participants cooperate even in the absence of third-party enforcement of agreements (for a survey, see Fehr and Falk 2002). Especially relevant here is Brown et al. (2004), in which the party acting in the role of purchaser could specify a payment corresponding to p_t and a performance level corresponding to q_t . In treatments in which these were a contract enforced by the experimenters, participants behaved very much in the way predicted by competitive market theory. But when they were not an enforceable contract, repeated interaction resulted in huge increases in the performance level over that in one-off interactions, though not to the level in the enforceable contract treatment. The possibility

of choosing to terminate the relationship was important for this outcome. The experimental finding less consistent with the model used here is that, although each experiment lasted only a known finite number of periods, performance did not drop to the minimum level possible even in the final period. Indeed, performance in the final period increased with the generosity that the partner had shown in previous periods. The authors term this a “reciprocity effect.” MacLeod (2007a) models this effect as arising from a small disutility of breaching an agreement. But, in an important sense, such an effect is complementary to the model here. It implies that cooperation does not necessarily unravel when the time horizon is actually finite, and the experimental findings emphasize that repetition increases performance beyond what the reciprocity effect alone delivers. What an experiment lasting just a few hours obviously cannot pick up is how long lived such reciprocity effects are likely to be in practice.

Ramey and Watson (1997) analyze an employment type model in which the specific investment is made by the purchaser, not the supplier, at a stage when the future environment is uncertain. There are just two possible levels of quality, $\underline{q}$ and $\bar{q}$. The purchaser can choose the level of specific investment I . Uncertainty about the future can be represented in the incentive compatibility condition (16) by reinterpreting ρ (independent of I in Ramey and Watson 1997) as a random variable taking one of two values, $\bar{\rho}$ and $\underline{\rho}$, with $1 > \bar{\rho} > \underline{\rho} > 0$, whose realization is unknown at the time the investment decision is made. For I sufficiently high, (16) is satisfied for quality $\bar{q}$ whether ρ takes the value $\bar{\rho}$ or $\underline{\rho}$, but for lower I it is satisfied only for $\bar{\rho}$. It is never satisfied for $\underline{q}$. When $\underline{\rho}$ is sufficiently unlikely, the purchaser’s optimal level of I is such that (16) is not satisfied, and the relationship is not continued, if $\underline{\rho}$ occurs (termed a “fragile contract”). Ramey and Watson (1997) use this model to study the pattern of separations in a market equilibrium in which new trading partners cannot be immediately located and there are aggregate shocks. Improvements in the probability of rematching may result in greater use of fragile contracts. Ramey and Watson (2001) extend the model to the case in which both parties make specific investments and identify cases in which there is an optimal positive level of market friction that implements efficient investment.

5. Verifiable Performance Measures

The GM–Fisher Body relational contract contained a 10-year exclusive dealing arrangement supplemented by a cost-plus contract for each unit delivered. Klein (2000: 125) is of the view that a court would presumably have enforced the cost-plus contract. For it to be legally enforceable, the number of units delivered and the cost of provision would have to be verifiable. Of course, if everything the parties care about is verifiable, there would be no need for a relational contract. But there is an obvious question of when, if only some of the relevant information is verifiable, it is advantageous to use a supplementary legally enforceable contract using that information within a broader relational contract.

Outside one-shot simultaneous action games, it may, as Bernheim and Whinston (1998) show, be actively harmful to constrain the actions of the parties when there is verifiable information to do so. Although their formal results apply only to finite-horizon games, the essential point, as they show, carries over to infinite-horizon games. Indeed, it can be seen from the basic model set out above. In that model, provided payments are verifiable, it would be perfectly possible to fix by formal contract the bonus b_t that the purchaser pays to the supplier. But to do so

would prevent the purchaser tailoring the payment to the unverifiable quality delivered by the seller.

Use of a supplementary formal contract can, nevertheless, enable a relational contract to work under a wider set of conditions, as Baker et al. (1994) show. This can be seen in the employment model of Section 3.1 with the addition of a verifiable outcome measure $x_t = \mu_t q_t$, where $\mu_t > 0$ is the realization of a random variable that is observed by the supplier before choosing q_t but is not observed by the purchaser. For simplicity, let $\rho = 1$, because this probability plays no role in the discussion. In a one-period relationship, basing payment on x_t alone distorts incentives but enables quality above the minimum level (see Baker 1992). Specifically, with legally enforceable payment $p_t(x_t)$ (assumed by Baker to have constant slope $p'_t(x_t) = \beta_t > 0$), actual quality depends on μ_t , even though efficient quality does not. With an ongoing relational contract, suppose the purchaser commits to the enforceable payment just described. (Baker et al. (1994) impose $b_t = 0$, but that is not essential to the argument.) Incentive compatibility for the purchaser is unchanged, because $p_t(x_t)$ has to be paid in any case. However, if the supplier is going to deliver substandard quality, it is optimal to do so in a way that maximizes the current period variable payoff $p_t(\mu_t q_t) - c(q_t)$. That is, the supplier will deliver quality $\tilde{q}_t(\beta_t \mu_t)$ defined by $c'_t[\tilde{q}_t(\beta_t \mu_t)] = \beta_t \mu_t$. Thus, the supplier's incentive compatibility condition (3) becomes

$$\delta (U_{t+1} - \tilde{U}_{t+1}) \geq c_t(q_t) - c_t[\tilde{q}_t(\beta_t \mu_t)] - \beta_t \mu_t [q_t - \tilde{q}_t(\beta_t \mu_t)] - b_t, \quad \text{for all } t \geq \tau.$$

Added to the purchaser's incentive compatibility condition (6), this inequality implies that the pooled incentive compatibility condition (8) is replaced by

$$\delta (S_{t+1} - \tilde{S}_{t+1}) \geq c_t(q_t) - c_t[\tilde{q}_t(\beta_t \mu_t)] - \beta_t \mu_t [q_t - \tilde{q}_t(\beta_t \mu_t)], \quad \text{for all } t \geq \tau. \quad (19)$$

For any $q_t > \tilde{q}_t(\beta_t \mu_t)$, the right-hand side of (19) is smaller than the right-hand side of (8), so higher quality at t is sustainable for any given future gain $S_{t+1} - \tilde{S}_{t+1}$, and this makes it feasible to sustain quality closer to the efficient level when that level is not sustainable without the formal contract. But β_t high enough to achieve efficient quality q_t^* when μ_t is low may result in $\tilde{q}_t(\beta_t \mu_t) > q_t^*$ when μ_t is high. Quality can still be kept to the efficient level, provided that level satisfies (19), by the purchaser not paying the bonus if quality is too high as well as if it is too low, but it may not be possible to choose β_t to sustain efficient quality for both high and low realizations of μ_t . Even so, appropriate choice of β_t enables the purchaser and supplier, at least on average, to come closer to the efficient level. It is thus optimal for the parties to use a formal contract to supplement their relational contract, even though it is based on imperfectly verifiable information.

The existence of such imperfectly verifiable measures is not, however, necessarily an unmixed blessing. It may increase the payoffs $\tilde{U}_{t+1}$ and $\tilde{\Pi}_{t+1}$ the purchaser and the supplier receive after breaching, because it may enable them to guarantee to other potential partners that an alternative match will be productive even if they are no longer trusted to stick to a relational contract. Baker et al. (1994) show that, for certain configurations, it may even destroy the incentive compatibility of the relational contract. Di Tella and MacCulloch (2002) provide a

related application in which better outside alternatives can crowd out informal incentives. In their case, more generous state provision of unemployment benefit reduces informal intrafamily insurance more than one-for-one, so total transfers to the unemployed fall.

This model brings out a general point: a supplementary enforceable contract affects a relational contract through its impact on the payoffs the parties receive in the event one of them defaults on what they agree. In it, however, the verifiable outcome measure x_t is of no direct concern to the purchaser. It does not, therefore, actually capture the contractual arrangement between the Japanese manufacturers and their suppliers described by Asanuma (1989), and that between GM and Fisher Body, where the quantities ordered were treated as a formal contract and quantity was clearly of direct concern to the purchasers. That situation is captured by Schmidt and Schnitzer (1995), using the multitask agency approach of Holmström and Milgrom (1991). Suppose $q_t = (q_t^1, q_t^2)$ has two components, q_t^1 measuring quantity that is verifiable and q_t^2 measuring quality that is not, with $c_t(q_t^1, q_t^2)$ increasing in each argument. In the absence of a supplementary formal contract, the only difference to the analysis in Section 3.1 is that $\tilde{U}_{t+1}$ and $\tilde{\Pi}_{t+1}$, and hence $\tilde{S}_{t+1}$, need to reflect the possibility that the parties can trade without a relational contract using a legally enforceable contract on q_t^1 alone if that is worthwhile when q_t^2 is set at its lowest level $\underline{q}^2$. But this possibility applies whether or not the parties supplement their relational contract with an enforceable contract on q_t^1 and so does not affect whether, given the possibility of a supplementary enforceable contract, it is worthwhile using one. If the parties specify q_t^1 in a supplementary enforceable contract, it is optimal for the supplier, if defaulting, to deliver quality $q_t^2 = \underline{q}^2$ in quantity q_t^1 . Thus, the incentive compatibility condition for the supplier (3) when $\rho = 1$ becomes

$$\delta \left(U_{t+1} - \tilde{U}_{t+1} \right) \geq c_t \left(q_t^1, q_t^2 \right) - c_t \left(q_t^1, \underline{q}^2 \right) - b_t, \quad \text{for all } t \geq \tau.$$

When added to the purchaser's incentive compatibility condition (6), it implies that the pooled incentive compatibility condition (8) is replaced by

$$\delta \left(S_{t+1} - \tilde{S}_{t+1} \right) \geq c_t \left(q_t^1, q_t^2 \right) - c_t \left(q_t^1, \underline{q}^2 \right), \quad \text{for all } t \geq \tau.$$

This condition is weaker than (8) with $\rho = 1$ and so enlarges the set of q_t that can be sustained as equilibria when the efficient level is otherwise unattainable. Thus, specifying quantity in an enforceable contract is certainly worthwhile. As in Baker et al. (1994), however, by improving the payoffs that can be attained without a relational contract, the possibility of specifying quantity in an enforceable contract may make it harder to sustain a relational one. Iossa and Spagnolo (2011) show that, even if q_t^1 is of no value to the purchaser (as a result of which delivery is not enforced in equilibrium), contracting on it can help sustain a relational contract by enabling an additional penalty to be imposed on a defaulting supplier. Daido (2006) analyzes a related model in which neither component of q_t is verifiable but y_t has two components, each randomly related to the corresponding component of q_t , and one of which is verifiable.

The model in Schmidt and Schnitzer (1995) does not fully capture the relationship between GM and Fisher Body, because the enforceability of the cost-plus contract would require that Fisher's cost was verifiable. In the model, that would remove the need for a relational contract altogether, so, to retain the role for a relational contract, it would need to be enriched further. But

the model reemphasizes the result in Baker et al. (1994) that it may be valuable to supplement a relational contract with a legally enforceable one conditioned on verifiable information.

A different role for a legally enforceable contract to supplement a relational one arises when verifiable measures of performance are imprecise and the supplier is risk averse. Some individual suppliers are much smaller than such purchasers as GM and Toyota, and so they might be expected to be more risk averse. Asanuma and Kikutani (1992) show that the relations between the big Japanese automobile manufacturers and their satellite (as opposed to intermittent) subcontractors contain mechanisms through which the manufacturer absorbs the risks involved in their transactions to a substantial degree. Using a technique from Kawasaki and McMillan (1987), Asanuma and Kikutani estimate that four large Japanese auto manufacturers each bear close to 90% of the risk and estimate a corresponding degree of absolute risk aversion for the satellites.

Pearce and Stacchetti (1998) adapt the employment model to a risk-averse supplier in a relational contract. The purchaser remains risk neutral. The environment and the contractual arrangements are stationary. The outcome y in period t (from a finite set) is now a random variable with verifiable realization y_t that is independent and identically distributed (iid) conditional on the quality q_t (also from a finite set) delivered by the supplier in period t . The distribution of y can thus be written $F(y|q)$. Quality remains unverifiable but is observed by the purchaser. (In this respect, the model differs from the repeated principal-agent model in Radner (1985), in which the agent's effort is not observed by the principal.) With y_t verifiable, the parties can use a legally enforceable contract that specifies payment $p(y)$, required by Pearce and Stacchetti (1998) to be nonnegative. But they can improve on such a contract by adding a relational element with voluntary bonus $b(y)$ conditional on the agreed quality being delivered. The incentive compatibility condition for the purchaser to pay the bonus, corresponding to (6), then becomes

$$\delta [\Pi(y) - \tilde{\Pi}] \geq b(y), \quad \text{for all } y, \quad (20)$$

where $\Pi(y)$ is the future payoff to the purchaser in the continuation equilibrium when y occurs. Pearce and Stacchetti (1998) show that, if total compensation $P(y) = p(y) + b(y)$ is not independent of y (as it would be with efficient risk sharing), it is optimal to have (20) hold with equality for every y for which $p(y) > 0$. The intuition is that, if incentive compatibility for the purchaser were not a concern, lowering $p(y)$ and increasing $b(y)$ by the same amount would strengthen the supplier's incentive to deliver the agreed quality while leaving unchanged the overall payoffs to both parties when y occurs. This would provide scope for adjustment of payments to decrease the variation in total compensation to the risk-averse supplier and shift risk to the risk-neutral purchaser, a Pareto improvement that remains feasible until either $p(y) = 0$ or (20) holds with equality. Pearce and Stacchetti (1998) also show that a higher current total payment to the supplier [$P(y') > P(y'')$] is associated with (a) a higher current legally enforceable payment [$p(y') > p(y'')$]; (b) a higher future payoff to the supplier [$U(y') > U(y'')$]; and (c) a lower current bonus [$b(y') < b(y'')$]. To see why, suppose it is desirable for incentive reasons to reward the agent more for outcome y' than for outcome y'' . To smooth rewards intertemporally, it is then desirable to have both the present payoff to the supplier $P(y)$ and the future payoff $U(y)$ higher for y' than for y'' . Because shocks are iid and hence the future joint surplus is independent of y , $U(y') > U(y'')$ implies $\Pi(y') < \Pi(y'')$. With

(20) as a binding constraint, that in turn implies $b(y') < b(y'')$. But then $P(y') > P(y'')$ only if $p(y') > p(y'')$. This result yields the empirically testable prediction that a higher total payment at t' than at t'' consists of a higher fixed payment but a lower bonus payment.

The discussion so far in this section applies to the employment model. For the outsourcing model, a formal contract based on the verifiability of the quantity supplied can play a further role, as Itoh and Morita (2011) show. In the absence of a formal contract, the overall incentive compatibility condition is (15). Suppose the parties supplement their relational contract with a formal contract that the supplier will provide the intermediate product for the payment p_t and a court will enforce specific performance of the contract, so that, if the intermediate product is produced, it must be delivered to the purchaser and the purchaser must pay p_t . (Quality q_t cannot, of course, be the subject of a legally enforceable contract, because it is unverifiable.) Then the supplier cannot extract a payment other than p_t for delivery whatever quality is produced, and the situation is equivalent to the employment model with overall incentive compatibility constraint (8) and $\rho = 1$. Clearly, this condition is weaker than (15) for given q_t if $z_t(\tilde{q}_t) - c_t(\tilde{q}_t) > z_t(q_t)$, for which a necessary condition is obviously $z_t(\tilde{q}_t) > z_t(q_t)$. That might be the case when producing quality q_t instead of $\tilde{q}_t$ makes the intermediate product sufficiently more specific to the purchaser to reduce the payment the supplier could get for it by bargaining.

The results above that depend on verifiable delivery should not, however, be overplayed. With verifiable delivery, it may be possible to achieve efficient quality even without a relational contract. Suppose, in the spirit of the discussion of specific investments in Hart and Moore (1988), the parties were to contract on a fixed price $p_t = y_t(q_t^*)$ for delivery, where q_t^* is the efficient quality defined in (9), but the purchaser has the right to refuse to accept delivery. Then, even in a single-period model with no relational contract, it is optimal for the supplier to supply quality q_t^* , because the purchaser will not accept delivery of quality less than q_t^* at price p_t but will accept delivery of quality q_t^* at that price. An upfront payment by the supplier can be used to divide the gains from trade between the parties in any proportion. In Itoh and Morita (2011), a random variable, whose realization is not observed until after quality has been determined, also affects the value y_t to the purchaser, so it is not possible to determine the exact price in advance in the way just specified. But even then, provided delivery is verifiable, an alternative mechanism can still achieve efficient quality without a relational contract. Specifically, the parties can agree a legally enforceable contract giving the supplier the right to set any price at all for delivery after the uncertainty is resolved and the purchaser the right to choose whether to accept delivery at that price. Then it is optimal for the supplier to produce whatever quality is efficient, given the information available at the time the quality decision is made, and to set the price at the purchaser's valuation of that quality, given the realization of the random variable. Evans (2008) shows how powerful contracts of this type can be at achieving efficiency under quite general conditions.

The discussion thus far has taken as given what is verifiable and so can be made legally enforceable. But it may be possible for the parties to influence, at a cost, the extent to which an agreement is legally enforceable. In Kvaløy and Olsen (2009), the probability that a breach of the relational contract will be verifiable to the courts can be increased by incurring an enforcement cost. They use the employment model with either reliance or expectation damages. For spot market trading to be worthwhile, the parties must incur the enforcement cost. A relational

contract reduces the benefit of incurring the enforcement cost, though, under appropriate conditions, it is still worth incurring some enforcement cost. However, the resulting equilibrium quality may be lower, despite the joint gains being higher because of the savings on the enforcement cost. Moreover, under a relational contract, higher δ (which Kvaløy and Olsen (2009) interpret as a proxy for greater trust between the parties) may actually result in lower quality.

Battigalli and Maggi (2002) develop a framework for analyzing when it is worth incurring the cost of describing contingencies to enable the parties to write a legally enforceable contract on them. Battigalli and Maggi (2008) extend that framework to repeated interactions with relational contracts. They consider an outsourcing model in which q_t is a vector of qualities, each of which is binary, with $c_t(q_t)$ additively separable in these qualities. All qualities are potentially verifiable at a cost, but efficient quality decisions may change over time because of exogenous events. The formal contracts the parties can write can contain a different type of clause for each element of q_t : a *contingent clause* specifying that element conditional on exogenous events, a *spot clause* specifying that element for period t only after the exogenous events for period t are known (formally this is a noncontingent clause that is modified after the events are observed and corresponds to settling for $z_t(q_t)$ in the outsourcing model), and an *enrichment clause* that starts off as a noncontingent clause but is changed to a contingent clause when a relevant contingency first occurs. Different types of clauses have different writing costs. The choice between clause type depends on the cost of describing contingencies relative to the cost of describing the quality to be delivered. For a contingent clause, both costs must be incurred, but only once. For a spot clause, the cost of describing contingencies is avoided, but the cost of describing the quality to be delivered must be incurred each period. An enrichment clause incurs the cost of describing the quality to be delivered at the start, postponing the cost of describing contingencies until an event occurs for which the noncontingent quality is inappropriate but then incurring the cost of describing quality a second time. Alternatively, the parties can allow an element of q_t to be enforced informally by a relational contract. Naturally, for δ high enough to satisfy a condition corresponding to (15) whatever exogenous events occur, it is optimal to rely on relational contracting, because it saves on writing costs. But for lower δ , it becomes optimal to specify those elements of q_t with high costs of supply in a formal contract. Contingent clauses have a single upfront cost and so do not affect incentive compatibility in the future, whereas spot and enrichment clauses have expected future costs that have to be deducted from the future gains to continuing the relationship, the left-hand side of (15). In this situation, an increase in writing costs or uncertainty leads to an increase in the number of elements of q_t enforced by the relational contract. For δ sufficiently low, a relational contract is ineffective, and all elements of q_t are optimally governed by a formal contract.

6. Private Information: Nonpersistent Types

It is clear from the discussion in Asanuma (1989) that Japanese auto and electrical machinery manufacturers are concerned to find out about the differences in characteristics of their suppliers and to treat them accordingly. From a theoretical perspective, we can think of suppliers being of different inherent types that the purchaser does not observe directly but that are important to the relationship. This is not captured by the models of Section 3 because there it is assumed that the purchaser knows everything about the supplier that is relevant, even though some things

are not verifiable. In this section and the next, we consider a supplier with private information about type (the cost of supply) that is not known to the purchaser. We start in this section with the case in which type is not persistent, so that learning about the supplier's type in one period reveals no useful information about the supplier's type in the next period. The supplier's cost of maintaining quality may be higher in one period because of unusually high demand from other customers, because critical employees are off sick, or because quality control equipment is not working properly. That is not the situation Asanuma (1989) had in mind, but it is the case most fully discussed in the literature, notably by Levin (2003) and MacLeod (2003).

In Levin (2003), as in Pearce and Stacchetti (1998), the outcome y in period t in the employment model is a random variable that is iid conditional on q in period t and distributed $F(y | q)$, with corresponding density function f . Differences from Pearce and Stacchetti (1998) are that, as in the employment model of Section 3.1, the realization y_t is unverifiable, and the supplier is risk neutral. Moreover, before choosing q_t , the supplier observes a parameter of the cost function $\theta_t \in [\underline{\theta}, \bar{\theta}]$ that is an iid draw for period t . The cost of delivering quality q_t , now denoted $c(q_t, \theta_t)$, is differentiable and increasing in θ_t , and it satisfies the standard single-crossing property, corresponding to $\partial^2 c(q_t, \theta_t) / \partial q_t \partial \theta_t > 0$ when it is twice differentiable. Levin (2003) considers two cases. In one, the hidden information case, the purchaser observes q_t but not θ_t . In the other, the moral hazard case, the purchaser observes θ_t but not q_t . Both cases can be handled together by specifying the performance outcome as a subset $\phi_t \subseteq \{\theta_t, q_t, y_t\}$ that is observed by both purchaser and supplier and allowing the voluntary bonus to be conditioned on ϕ_t . In this stationary environment, there is no loss from restricting attention to stationary contracts in which total payment to the supplier can be written $P(\phi_t) = p + b(\phi_t)$, but it adds flexibility in this stochastic environment to no longer require that the bonus be non-negative.

The crucial difference from the models in previous sections is that it is now optimal to agree quality as a function $q(\theta)$ of type, with efficient quality $q^*(\theta)$ defined by

$$q^*(\theta) = \arg \max_q E_y [y | q] - c(q, \theta), \quad \text{for all } \theta \in [\underline{\theta}, \bar{\theta}],$$

where E_y is the expectations operator over the random variable y . But the purchaser observes only one of q_t and θ_t and so does not know whether the supplier actually delivered what was agreed. Thus, the supplier cannot be punished directly for breaching the agreement about quality, so the incentive compatibility condition for the supplier to deliver quality has to take the form familiar from one-period principal-agent models:

$$q(\theta) \in \arg \max_q E_y [P(\phi) | q] - c(q, \theta), \quad \text{for all } \theta \in [\underline{\theta}, \bar{\theta}]. \quad (21)$$

The incentive compatibility conditions for the parties not to breach the agreement on the bonus depend on whether both purchaser and supplier observe the outcome y_t or only the purchaser does. Start with the former, which Levin (2003) calls the case of an "objective performance measure." Because the agreed bonus can be either positive (in which case the purchaser pays the supplier) or negative (in which case the supplier pays the purchaser), we require incentive

compatibility conditions for both. For the purchaser not to default on the largest positive bonus requires, analogous to (6),

$$\delta \left(\Pi - \tilde{\Pi} \right) \geq \sup_{\phi} b \left(\phi \right) . \quad (22)$$

Similarly, for the supplier not to default on the largest negative bonus requires

$$\delta \left(U - \tilde{U} \right) \geq - \inf_{\phi} b \left(\phi \right) . \quad (23)$$

These two conditions can be added to give a pooled condition that, like (8), is independent of the distribution of the gains from the relationship. Levin (2003) calls this pooled condition the “dynamic enforcement” constraint:

$$\delta \left(S - \tilde{S} \right) \equiv \delta \left(U + \Pi - \tilde{U} - \tilde{\Pi} \right) \geq \sup_{\phi} b \left(\phi \right) - \inf_{\phi} b \left(\phi \right) . \quad (24)$$

This constraint imposes a restriction on the maximum difference in the bonuses that can be used and hence on the incentives that can be provided. This maximum difference is determined by the need to make payment of the bonus incentive compatible, given the limited future surplus that is available to induce the parties to pay it. Levin (2003) shows that a quality schedule $q \left(\theta \right)$ generating surplus S can be implemented if and only if (21) and (24) are satisfied. These replace (8) for the employment model of Section 3.1 which, in effect, combines the incentive compatibility constraint (21) and the dynamic enforcement constraint (24) for θ a fixed value known to the purchaser as well as the supplier. To see this, note that (3) corresponds to the constraint (21). With (3), the highest bonus required to induce the supplier to provide quality q_t is $c_t \left(q_t \right) / \rho$. The lowest bonus is zero. Thus the right-hand side of (8) corresponds to the difference between the highest and the lowest bonuses exactly like the right-hand side of (24), but with the supplier’s incentive compatibility condition substituted for the highest bonus.

To understand the hidden information case (in which the purchaser observes q_t but not θ_t), suppose there were only the highest cost type $\bar{\theta}$. Then, with $\rho = 1$ as assumed in Levin (2003), the incentive compatibility condition (8) would be

$$\delta \left(S - \tilde{S} \right) \geq c \left(q \left(\bar{\theta} \right), \bar{\theta} \right) .$$

With a continuum of types as in Levin (2003), type θ must not prefer the quality for some other type to $q \left(\theta \right)$. The conditions for that are familiar from standard, one-period adverse-selection models (see Baron 1989; Milgrom and Segal 2002): $q \left(\theta \right)$ must be nonincreasing, and type θ must receive the information rent over the highest cost type $\bar{\theta}$ of $\int_{\theta}^{\bar{\theta}} c_{\theta} \left(q \left(\tilde{\theta} \right), \tilde{\theta} \right) d\tilde{\theta}$. So the incentive compatibility constraint for type θ becomes

$$\delta \left(S - \tilde{S} \right) \geq c \left(q \left(\theta \right), \theta \right) + \int_{\theta}^{\bar{\theta}} c_{\theta} \left(q \left(\tilde{\theta} \right), \tilde{\theta} \right) d\tilde{\theta} . \quad (25)$$

With $q(\theta)$ nonincreasing, the right-hand side of (25) is nonincreasing in θ , so the constraint is tightest for $\theta = \underline{\theta}$. Levin (2003) shows that $q(\theta)$ nonincreasing and (25) satisfied for $\theta = \underline{\theta}$ are necessary and sufficient conditions for $q(\theta)$ to be implemented. He then shows that, for a concave cost distribution, if the efficient $q^*(\theta)$ does not satisfy (25) for $\theta = \underline{\theta}$, an optimal $q(\theta)$ satisfies one of the following:

1. *pooling*: $q(\theta) = \tilde{q}$ for some $\tilde{q} < q^*(\theta)$, for all θ ; or
2. *partial pooling*: for some $\hat{\theta} \in (\underline{\theta}, \bar{\theta})$, $q(\theta) = \tilde{q} < q^*(\theta)$ for all $\theta \in [\underline{\theta}, \hat{\theta}]$ and $q(\theta) < q^*(\theta)$ and is strictly decreasing for all $\theta \in (\hat{\theta}, \bar{\theta})$.

Thus, either quality is the same for all types, or it is the same for an interval of the lowest cost types and decreasing in type for higher cost types. As in the employment model of Section 3.1, quality is never above the efficient level $q^*(\theta)$ for any type.

The intuition for these results is as follows. If the relationship is sufficiently productive and the discount factor sufficiently close to 1, then (25) with $\theta = \underline{\theta}$ is not a binding constraint at efficient quality $q^*(\theta)$ for each θ . Because $q^*(\theta)$ is nonincreasing, it can then be implemented, and it is certainly optimal to do that. But when (25) with $\theta = \underline{\theta}$ is binding for $q(\theta) = q^*(\theta)$, it makes sense to reduce quality $q(\theta)$ below the efficient level $q^*(\theta)$ for all θ . It has to be below the efficient level for some θ , and reducing $q(\theta)$ marginally below $q^*(\theta)$ has only a second-order effect on joint surplus, whereas increasing $q(\theta)$ that is substantially below $q^*(\theta)$ has a first-order effect. Thus, rather than have $q(\theta') = q^*(\theta')$ and $q(\theta'') < q^*(\theta'')$ for some θ' and θ'' , it is better to reduce $q(\theta')$ marginally and increase $q(\theta'')$ marginally. Moreover, when (25) with $\theta = \underline{\theta}$ is binding, it must be the case that the requirement for $q(\theta)$ to be nonincreasing is also binding at $\theta = \underline{\theta}$. If that were not so, (25) with $\theta = \underline{\theta}$ would be relaxed by having $q(\theta)$ jump upward immediately above $\underline{\theta}$ to enable $c(q(\underline{\theta}), \underline{\theta})$ to be reduced, and (because that would affect output for only one of a continuum of values of θ that has no probability mass) it would certainly be optimal. Thus, if efficient quality is not achieved for all θ , there must be pooling for θ sufficiently close to $\underline{\theta}$. If the constraint (25) with $\theta = \underline{\theta}$ is sufficiently tight, this pooling will apply to all θ . But when it is less tight, the intuition for not pooling higher cost types before lower cost types arises from the limit on incentives. Starting from the minimum quality level, the bonus does not need to be increased much to raise quality uniformly. But at higher quality levels, it requires increasingly high bonuses to raise the quality supplied by lower θ types. Thus, it is optimal to focus incentives on the higher θ types.

Payment in this model depends only on the quality delivered. So an implication is that, if either the discount factor δ or the total gain from cooperation $S - \tilde{S}$ is sufficiently low for full pooling of types to be optimal, quality and payment will be independent of day-to-day changes in the supplier's cost. For higher values of $\delta(S - \tilde{S})$ such that partial pooling is optimal, there will be some variation in quality and payment, but only when day-to-day costs are particularly high. In practice, this might take the form of the purchaser paying less when delivered a batch of components with a particularly high proportion of defective items. Thus, one would expect to see quality more closely tailored to the supplier's cost conditions and greater payment variability in relationships in which the total gain from cooperation $S - \tilde{S}$ is greater and/or trade orders are more frequent, so that the discount factor δ relevant to the time between orders is higher.

Malcomson (2012b) analyzes the hidden information model in Levin (2003) with the additions that the value of quality to the purchaser changes from period to period without persistence and that the purchaser (but not the supplier) observes its value at the beginning of the period. There is thus private information about the purchaser's type, as well as about the supplier's, and efficient quality depends on both. The purchaser can signal her type to the supplier by making the payment p a function of that type and offering a bonus conditional on both it and the quality actually delivered. For those payments to be incentive compatible, the purchaser must expect an information rent when the value of quality is above its lowest level, which imposes restrictions on how p can vary with the purchaser's type. (It is an expected rent, because the purchaser does not know the supplier's type at the stage p is offered.) Pooling across both purchaser and supplier types is always an equilibrium (as is pooling across supplier types in Levin 2003). Efficient quality is increasing in the value of quality to the purchaser and decreasing in the cost of quality to the supplier but, as in Levin (2003), efficient quality may not be sustainable by a relational contract. When it is not, it turns out that if quality is increasing in its value to the purchaser for some purchaser types, it must actually be decreasing in its value to the purchaser for some other purchaser types. This property reinforces the advantages of pooling purchaser types and thus of making payment and quality independent of day-to-day changes in the purchaser's circumstances.

For the moral hazard case (the purchaser observes θ_t but not q_t), Levin (2003) uses two assumptions that also play a role in models discussed later.

Assumption 1 (MLRP) *The probability density function f corresponding to F satisfies the monotone likelihood ratio property that*

$$\frac{\partial f(y | q) / \partial q}{f(y | q)} \quad (26)$$

is increasing in y .

Assumption 2 (CDFC) *The distribution function F satisfies the convexity of the distribution function condition that $F(y | q = c^{-1}(x; \theta))$ is convex in x for any θ .*

Levin (2003) shows that, for the moral hazard case under these assumptions,

1. an optimal contract implements $q(\theta) \leq q^*(\theta)$ for all θ ; and
2. payments $P(\theta, y)$ are one-step in the sense that $P(\theta, y) = \underline{P}$ for all $y < \hat{y}(\theta)$ and $\bar{P} = \underline{P} + \frac{\delta}{1-\delta}(S - \tilde{S})$ for all $y \geq \hat{y}(\theta)$, where $\hat{y}(\theta)$ is the point at which the likelihood ratio $(f_q/f)(y | q(\theta))$ switches from negative to positive as a function of y .

The intuition is that, with a risk-neutral supplier, it makes sense to use the limited bonuses in the way that gives the strongest incentives, so the maximum incentive is given for outcomes that are more likely to arise with high quality. Thus, as in the employment model of Section 3.1, only one level of bonus is required.

Levin (2003) also considers the case in which the purchaser observes y_t but the supplier does not—the case of a subjective performance measure. This case adds a further complication

to contracting. Now not only does the purchaser, not observing one of q_t and θ_t , not know whether the supplier has breached an agreement $q(\theta)$ on quality but also the supplier, not observing y_t , does not know whether the purchaser has breached any agreement about how the bonus is to vary with y_t . So if the bonus agreement specifies that the amount of the bonus is to depend on y_t , the purchaser can make a short-term gain by claiming that y_t is at the level corresponding to the lowest bonus payment. Formally, suppose after privately observing y_t , the purchaser delivers a message m_t to the supplier with a bonus $b_t(m_t)$ attached. Then the purchaser will make distinct reports m' and m'' in response to distinct outcomes y' and y'' only if the two reports yield the same payoffs. With a stationary contract, this requires $b(m') = b(m'')$. But in a stationary environment with a stationary contract and hence a stationary future surplus S , this conflicts with providing incentives for the supplier, because the supplier's payoffs for outcomes y' and y'' will have to be the same. As an alternative to a stationary contract, Levin (2003) considers a termination contract with a cutoff threshold $\hat{y}$ such that, if $y_t < \hat{y}$, $P_t = p$ and the relationship terminates, whereas if $y_t \geq \hat{y}$, $P_t = p + b$ and the relationship continues. A termination contract is a special case of what Levin (2003) calls a "full review contract," defined as follows: given any history up to t and compensation offer at t , any two distinct outputs $y'_t \neq y''_t$ generate distinct reports $m'_t \neq m''_t$. The implication is that, in equilibrium, the purchaser maintains no private information from period to period. (This restriction can also be stated in terms of the equilibrium concept, namely, perfect public equilibria of the repeated game.) For the case in which q_t is not observed by the purchaser and θ is a fixed, known parameter, Levin (2003) shows that, if an optimal full review contract exists, a termination contract can achieve an optimum. Moreover, the termination contract preserves the property that there is just a single level of bonus, the one-step property. Because the stochastic term relating outcome to quality is iid, the gain from continuing the relationship at $t + 1$ is independent of the outcome at t , so termination is always inefficient. It can nevertheless occur in equilibrium, because the stochastic shock will sometimes result in $y_t < \hat{y}$. When that happens, the parties are effectively "burning money." This is a price that has to be paid to induce the purchaser to report the outcome truthfully while still providing incentives for the supplier to deliver a better expected outcome.

It is natural to ask whether there might be some way in which the inefficiency resulting from termination might be reduced. One possibility arises because the inefficiency is the result of the purchaser and supplier having different information about the outcome. So, if it were possible to use a mediator to narrow the information gap, that might reduce the probability of the relationship being terminated. Another possibility is to adopt the procedure suggested in Abreu et al. (1991) of lengthening the period between performance reviews and using the average outcome over the longer period to determine whether termination is triggered. This procedure enables the threat of later punishments to provide incentives in earlier periods and reduces the probability that termination occurs at a review date. Fuchs (2007), in a model with two potential output levels and two potential quality levels, shows that a contract with the properties that the supplier receives a fixed payment until the relationship is terminated, with the purchaser providing no feedback on observed output in the meantime, is optimal. To see why, consider a T -period review contract in which the purchaser waits T periods before considering terminating the relationship, even if output is consistently low. Increasing T reduces the expected loss from termination along an equilibrium path. But increasing T beyond a certain point results in

the limited penalty of termination providing insufficient incentives to the supplier in earlier periods. Fong and Li (2010b) consider the implications of the agent having limited liability in this setting. Fong and Li (2010a) show that garbling output signals intertemporally, with past outputs having an enduring effect on future signals, can increase the efficiency of contracting. Their model has two output levels. Incentive compatibility requires a bonus for the higher level. When higher output results in good outcome signals spread out over time, the same total reward for high output can be given with a lower bonus, thus relaxing the dynamic enforcement constraint (24).

MacLeod (2003) explores the case of a subjective performance measure when the supplier is risk averse, as in Pearce and Stacchetti (1998). While using a one-period employment model, and hence not formally a relational contract, he investigates limits on rewards similar to (24) that arise from a relational contract. In his model, as in the subjective information case in Levin (2003), the purchaser's information about performance is private and satisfies MLRP (Assumption 1). However, unlike in Levin (2003), the supplier receives a private signal about performance that is correlated with the purchaser's information. To allow for the possibility of "burning money" (which we know from Levin (2003) is essential when there is no objective performance measure) in the context of a single-period model, MacLeod (2003) introduces a third party to act as a budget breaker, that is, to enable the payment made by the purchaser to be different from that received by the supplier. He shows that, if the supplier's signal is perfectly correlated with the purchaser's, the optimal contract is the same as that if the purchaser's signal were verifiable. Moreover, the joint loss from imperfect correlation goes to zero as the correlation becomes perfect. In contrast, if the supplier's signal is uncorrelated with the purchaser's, the purchaser's payments are independent of his own signal but depend on the supplier's. Moreover, the supplier's compensation is the same for all signals of the purchaser except the worst, for which it is lower, because with MLRP (Assumption 1) the lowest signal is the most informative about whether effort is low. Thus, the one-step property applies not just to the risk-neutral supplier in the model in Levin (2003). Moreover, the supplier will normally (i.e., for most outcomes) receive the higher level and only occasionally, for the very worst performance, receive the lower. To get useful results for the case in which the supplier's signal is imperfectly correlated with the purchaser's, MacLeod (2003) uses the additional assumption that the supplier's signal is, with known probability, either the same as the purchaser's or completely uninformative. In that case, if the joint punishment to the purchaser and the supplier (i.e., the net payment to the third party) is bounded, the supplier's compensation increases with the signal up to a certain level but is the same for all signals above that level. There are also some results on the effect of the purchaser having biased perceptions of the supplier's performance. For further discussion of efficient contractual arrangements under these types of circumstances, see MacLeod (2007b).

Many of these models share a common characteristic. With relational contracts, the only thing that induces the parties not to breach their agreement is the potential gain from cooperation in the future. Because that potential gain is finite, the gap between the highest and the lowest future payoffs—and hence the maximum incentive that can be provided—is limited. When there is private information about nonpersistent types, and the potential gains from future cooperation are insufficient to sustain efficient quality for all types, more pooling across types typically results than when there is full information. This characteristic is encouraging for trying to understand supply relationships that, as documented by Carlton (1986), have

relatively rigid prices over time despite apparent short-term changes in production conditions. But there remains research to be done to assess the extent to which those rigidities can genuinely be attributed to pooling across types that are private information.

7. Private Information: Persistent Types

The Japanese manufacturers studied by Asanuma (1989) used information about past performance of suppliers to determine the terms for future trades. There is no gain in productive efficiency from this practice when suppliers' types are, as in the models in Section 6, iid draws in each period, though there may be strategic reasons for it (to punish a supplier who has breached a relational contract). It is different when types are persistent over time and have to be discovered by the other party.

In Bull (1987), it is the purchaser's type that is persistent but unknown to the supplier, rather than the other way around. The issue there is how a relational contract can be sustained between an infinitely lived purchaser and a supplier who operates for only a finite period of time that is known in advance. In the basic model of Section 3.1, the purchaser would not pay a bonus in the final period of the relationship. With no future of concern, the supplier would then set quality at the lowest level in that period, and so the relationship would be terminated in the final period, because there is no possibility of mutually beneficial trade. Given this behavior, the same argument can be repeated successively for each previous period to show that the relational contract never gets off the ground in the first place. But, if there is a succession of short-lived suppliers who observe how their predecessors have been treated, the relationship can be sustained in the way described by Crémer (1986). In Bull (1987), there are two types of purchasers, those who never pay a bonus in the final period and those who do if the reputation so acquired is sufficiently valuable. The latter are induced to pay, because they do not wish to be thought to be the former. In Mukherjee (2008), the supplier has an unchanging type unknown to both parties in advance and only a finite (two-period) lifetime. The purchaser can choose whether to make information about performance available to other potential purchasers, in which case career concerns of the type discussed by Holmström (1999) provide incentives for effort, or to retain this information and rely on a voluntary bonus to provide incentives. Depending on the precise specification, career concerns can be either substitutes or complements for relational incentives. There is now a substantial game-theoretic literature on models in which one long-lived player faces a succession of short-lived players (see Mailath and Samuelson 2006).

The focus in this chapter is on long-lived suppliers. Hörner (2002), in a model in which purchasers are consumers, allows for both noise and privately known persistent types but simplifies by having just two potential outcomes and suppliers of just two types. Types are not specific to a particular purchaser, so any information revealed publicly affects what other potential purchasers are prepared to pay that supplier. Bad types always choose low quality. Good types choose between high and low quality. Whichever quality is chosen, the outcome y_t to consumers may be good or bad, though there is a higher probability it is good when quality is high. As a result, type is not fully revealed in the first period. Consumers are indistinguishable to suppliers, so it is never incentive compatible for them to pay a bonus, and all payment is thus via p_t . Hörner

(2002) focuses on nonrevealing equilibria in which consumers leave a supplier as soon as they experience a bad outcome, all suppliers who have been supplying for the same length of time have the same price, and newly entering good suppliers earn zero expected profits. In such an equilibrium, the probability that a supplier is good increases with the time that supplier has been in the market, and hence so also does price. For newly entering good suppliers to have zero expected profits, price must start out negative. Yang (2012) analyzes a similar setup with a single purchaser. Halac (2012) considers a model in which the purchaser's payoff π_t , if not trading with the supplier, is private information. When the purchaser receives all the gain from continuing the relationship, there is an incentive for the purchaser to behave as if π_t were low, even when it is high (to induce the supplier to believe that a higher bonus is incentive compatible and accordingly supply high quality) but then to renege by taking the high outside option π_t and not paying the bonus. Conversely, when the supplier receives all the gain, the purchaser has an incentive to behave as if π_t were high, even when it is low (to induce the supplier to believe that there is less gain to appropriate).

The alternative to two types analyzed in the literature is a continuum of types. In MacLeod and Malcomson (1988), as in Hörner (2002), types are not specific to a particular purchaser. Formal differences from the employment model of Section 3.1 are that the environment is stationary, the cost of quality is $c(q)/\theta$ (where θ is the supplier's type, which is known to the supplier but not the purchaser), the probability ρ that breach is detected is 1, and there are no bonuses (so that the only payment is the fixed payment). Suppose the purchaser were to group supplier types into a set of ranks r (1 being the lowest), assumed observable to potential purchasers, with the following properties:

- payment is $p^r > p^{r-1}$,
- a minimum quality performance $q^r > q^{r-1}$ is required to stay in r , and
- those in rank r who deliver quality below q^r are demoted to $r - 1$ (or are dropped as a supplier and used by another purchaser in the equivalent of rank $r - 1$).

The expected utility from staying in rank r forever is then

$$U^r(\theta) = p^r - \frac{c(q^r)}{\theta} + \delta U^r(\theta), \quad \text{for all } r \geq 1, \quad \text{all } \theta, \quad (27)$$

which corresponds to (1) in the employment model of Section 3.1 with the bonus set to zero. Because other potential purchasers observe a supplier's rank, the price for rank r is determined by the zero-profit condition $p^r = y(q^r)$, so (27) can be solved to give

$$U^r(\theta) = \left[y(q^r) - \frac{c(q^r)}{\theta} \right] / (1 - \delta), \quad \text{for all } r \geq 1, \quad \text{all } \theta. \quad (28)$$

It is convenient to define $U^0(\theta)$ as the future payoff to type θ if dropped from the lowest rank (rank 1) permanently with payoff $U^0(\theta) = u / (1 - \delta)$.

Consider which types θ will deliver quality high enough to stay in rank r if they reach it. The incentive compatibility condition for type θ to do this, corresponding to (3) with no bonus, is

$$\delta \left[U^r(\theta) - U^{r-1}(\theta) \right] \geq \frac{c(q^r)}{\theta}, \quad \text{for all } r \geq 1, \text{ all } \theta. \quad (29)$$

Define θ^r as the lowest value of θ that satisfies this condition. Substitution from (28), use of the convention that $q^0 = 0$ and $c(q^0) = -u$, and rearrangement gives

$$\theta^r = \frac{1}{y(q^r) - y(q^{r-1})} \left[\frac{c(q^r)}{\delta} - c(q^{r-1}) \right], \quad \text{for all } r \geq 1. \quad (30)$$

An *equilibrium hierarchy* is a triple (q^r, p^r, θ^r) that satisfies condition (30) and the zero-profit requirement that $p^r = y(q^r)$ for each r . Competition among purchasers ensures that all supplier types who can be profitably employed will be. In particular, θ^1 must be the lowest value that is incentive compatible, so q^1 is determined to minimize the right-hand side of (30) for $r = 1$, given the conventions $q^0 = 0$ and $c(q^0) = -u$. This determines q^1 and θ^1 . Given q^1 and θ^1 , q^2 is determined to minimize the right-hand side of (30) for $r = 2$. This determines q^2 and θ^2 , and so on up to rank R such that $\theta^{R+1} > \bar{\theta}$, the highest type there is. This iterative process determines a unique equilibrium hierarchy.

In the description in Asanuma (1989: 14), purchasers “select a number of firms that have relatively good qualities from among those suppliers that have already been tried” for more responsible treatment. Suppose all supplier types start in rank 1 and are promoted to rank 2 if they deliver sufficiently high quality, then to rank 3 if they continue to perform sufficiently well, and so on. Can the purchaser set promotion criterion $\hat{q}^r$ from rank r to $r + 1$ such that supplier types eventually sort themselves into equilibrium ranks? To sort properly, it must be that types $\theta \geq \theta^{r+1}$ deliver sufficiently high quality for promotion. They will do that only if meeting the quality criterion $\hat{q}^r$ to gain promotion to rank $r + 1$ and then staying there has a higher payoff than staying in rank r ; that is, only if

$$p^r - \frac{c(\hat{q}^r)}{\theta} + \delta U^{r+1}(\theta) \geq U^r(\theta), \quad \text{for } \theta \geq \theta^{r+1}, r \geq 1.$$

But for selection to occur, it must also be that those of type $\theta < \theta^{r+1}$ do not find it worthwhile to deliver sufficiently high quality for promotion, so

$$p^r - \frac{c(\hat{q}^r)}{\theta} + \delta U^{r+1}(\theta) < U^r(\theta), \quad \text{for } \theta < \theta^{r+1}, r \geq 1.$$

With θ continuous, these two conditions imply the sorting condition

$$p^r - \frac{c(\hat{q}^r)}{\theta^{r+1}} + \delta U^{r+1}(\theta^{r+1}) = U^r(\theta^{r+1}), \quad \text{for all } r \geq 1. \quad (31)$$

Substitution for $U^r(\theta^{r+1})$ from (27) gives

$$\delta \left[U^{r+1}(\theta^{r+1}) - U^r(\theta^{r+1}) \right] = \frac{c(\hat{q}^r)}{\theta^{r+1}} - \frac{c(q^r)}{\theta^{r+1}}, \quad \text{for all } r \geq 1. \quad (32)$$

Because θ^{r+1} is, by definition, the lowest θ for which the incentive compatibility condition for the supplier (29) is satisfied for rank $r + 1$, it follows from (29) that

$$\delta \left[U^{r+1}(\theta^{r+1}) - U^r(\theta^{r+1}) \right] = \frac{c(q^{r+1})}{\theta^{r+1}}, \quad \text{for all } r \geq 1. \quad (33)$$

Equating the right-hand sides of (32) and (33) gives

$$c(\hat{q}^r) = c(q^{r+1}) + c(q^r), \quad \text{for all } r \geq 1,$$

which implies $\hat{q}^r > q^{r+1}$, for $r \geq 1$. So the quality required to be promoted from rank r to rank $r + 1$ is higher than that required to stay in rank $r + 1$ once there. This process, if implemented by the purchaser, eventually results in a supplier with θ between θ^r and θ^{r+1} being sorted into rank r . That is, all types reach the highest rank in which it is worthwhile for them to deliver the quality required to stay there. Moreover, implementing this promotion process is worthwhile for the purchaser. Those providing just sufficient quality to stay in a rank generate no profit for the purchaser. But those striving for promotion set quality higher while being paid the same, so it is clearly more profitable for the purchaser to set up the promotion system.

Malcomson (2012a) analyzes a development of the hidden information model in Levin (2003) in which the supplier's type is unknown to the purchaser, but instead of being iid, it is persistent over time. As in MacLeod and Malcomson (1988), there is a continuum of supplier types, with the outcome y_i a deterministic function of quality. But in contrast to MacLeod and Malcomson (1988), Malcomson (2012a) allows for bonuses. Moreover, the supplier's type is specific to the purchaser, which makes for a larger gain from continuing the relationship over alternative opportunities once information about type has been revealed. Provided the match is sufficiently productive, pooling of those supplier types who continue the relationship is always an equilibrium, as a result of which quality is not tailored to the supplier's type, and the purchaser does not learn about that type. When some separation of types is feasible, but efficient quality is not attainable, the parties can, however, do better in an equilibrium that initially partitions types into bands, followed by an optimal continuation equilibrium in which quality for those types in a band is at the highest level consistent with the commonly known information. That level is the highest that satisfies a condition corresponding to (16), with I (now an argument of only the supplier's cost function $c(q, I)$) denoting the highest cost type in the band. But with such a continuation equilibrium, separation may not be feasible, and full separation of types never is. These are also characteristics of the two-period ratchet effect model of Laffont and Tirole (1988) and thus seem robust in models with a continuum of privately known persistent types and the inability to commit to future contractual arrangements. Here, incentive compatibility for the purchaser restricts the spread of future rewards to different supplier types, which as in Levin (2003), limits the potential for separating them. But because here, unlike in Levin (2003),

types are persistent, a supplier can obtain an information rent for the indefinite future, not just the current period, by pretending to be a higher cost type. In contrast, by revealing type, the supplier loses that information rent in an optimal continuation equilibrium. The implication is that quality must jump by a discrete amount between adjacent bands of types even though type is continuous. Thus, the characteristic of MacLeod and Malcomson (1988) that, as described in Asanuma (1989), suppliers of different types are grouped into categories is preserved, despite the use of bonuses and despite supplier types being specific to the purchaser. In this model, however, among supplier types for which efficient quality is not sustainable, quality in the first period is strictly lower than in the continuation equilibrium for all but the least productive for which the relationship can be sustained. Unlike in the model of Laffont and Tirole (1988), quality in the first period never exceeds the efficient level. Thus, the purchaser learns about the supplier by cautiously building up the relationship with levels of quality lower than can eventually be sustained.

Although types are banded in both MacLeod and Malcomson (1988) and Malcomson (2012a), the differences in what the bands provide are differences in quality, not fundamental differences in tasks that might correspond to the differences between the “drawings supplied” and the “drawings approved” subcontractors discussed by Asanuma (1989). If it is efficient for different types of supplier to do different tasks, there is an additional dimension on which incentive compatibility can operate, because there is a gain to the purchaser in having a supplier do the task for which it is efficient, given its type. Suppose, for example, the purchaser commits to a fixed payment p_t for drawings-approved work that is higher than that for drawings-supplied work by more than the difference in the cost of supply. Then a high-type supplier has an additional incentive to reveal its type, because, if promoted to drawings-approved work, future profits will be greater. Moreover, the purchaser has an incentive to promote sufficiently high types, because it is more efficient to have such types do drawings-approved work. Gietzmann and Larsen (1998) have a formal model of this idea based on the promotion model in Fairburn and Malcomson (1994) and developed further in Fairburn and Malcomson (2001). Though not an infinite-horizon model, the underlying mechanism would seem to apply to the relational contract approach. Prendergast (1993) develops a model based on a similar underlying idea, though again not formally in a relational contract.⁴

8. Multiple Suppliers

In the models discussed so far, the purchaser treats each supplier independently. New issues arise when there are multiple suppliers. They can, for a start, be rewarded according to their performance relative to other suppliers. Che and Yoo (2001) investigate this possibility. As in Pearce and Stacchetti (1998), the outcome y_t for each supplier, which depends on both quality and a random shock, is verifiable, so the principal (who makes a take-it-or-leave-it contract offer) can commit to a contract conditioned on y_t for each supplier. The outcome and the quality

4. Chassang (2010) explores a model in which private information takes the form of the supplier knowing which of many actions are potentially productive to the purchaser and which are not, whereas the purchaser does not know this. Because the model does not permit payments between the parties (which puts it in a different category from most of the literature discussed here), the possibility of noncooperation for a while is the only way for the purchaser to influence the supplier's incentive to take costly action.

delivered are each assumed to take one of just two values, with the probability of each outcome strictly positive whatever quality is chosen. Unlike in Pearce and Stacchetti (1998), quality is not observed by the purchaser, and because either outcome can occur whatever quality is chosen, quality cannot be directly inferred from the outcome. Moreover, the suppliers are risk neutral and have limited liability that is assumed to rule out payments from them to the purchaser. The important addition is that the shock is common to the two suppliers. Thus, even when the outcome for one supplier is independent of the quality provided by the other, their outcomes are positively correlated. When the relationship can last at most one period, the optimal contract takes the form that a supplier is paid only when her outcome is better than that of the other supplier. That is, payment corresponds to an extreme form of relative performance evaluation. The intuition is that, because the shock is common to both suppliers, a high outcome is a stronger signal of high quality when the other supplier's outcome is low than when it is high. Thus, this payment scheme gives the biggest incentive to deliver high quality. In a repeated relationship, the contract itself does not depend on whether a deviation has occurred in the past, because the principal, who determines the contract, cannot observe deviations in quality and all payments are legally enforceable. When each supplier observes the quality delivered by the other in the past, the optimal payment scheme for a discount factor sufficiently close to one is joint performance evaluation (a supplier is paid more the better the other supplier's outcome). The intuition is that, with a suitably chosen contract, it is an optimal response to joint performance evaluation for a supplier to deliver low quality in the future if the other supplier delivers low quality. That provides both suppliers with the strongest incentive not to deviate by delivering low quality. Che and Yoo (2001) also consider the case in which a single task can be allocated to either one supplier or two suppliers, but in the latter case the purchaser observes only a joint outcome.

Kvaløy and Olsen (2006) extend the model in Che and Yoo (2001) to the case in which the outcomes are not verifiable, but there are no common shocks. In that case, as in the employment model discussed in Section 3.1, payments by the purchaser that are conditional on outcomes have to be made incentive compatible. As in Che and Yoo (2001), an advantage of joint performance evaluation in a repeated relationship is that it can make use of suppliers' abilities to monitor each other. But with the outcome unverifiable, an advantage of relative performance evaluation is that it reduces the purchaser's incentive to breach the relational contract, because higher payments to one supplier correspond to lower payments to the other. Kvaløy and Olsen (2006) show that, for given differences between the high and low outcomes and between costs of high and low quality, a higher discount factor favors joint performance evaluation, because the higher value of the future when the discount factor is high relaxes the incentive compatibility constraint for the purchaser. Conversely, a lower discount factor favors relative performance evaluation. This result contrasts with that of Che and Yoo (2001), in which joint performance evaluation is always preferable in a relational contract with verifiable output.

Levin (2002) considers n risk-neutral suppliers and continuous quality, not just two suppliers and two possible levels of quality as in Che and Yoo (2001) and Kvaløy and Olsen (2006). As in the latter papers, the quality $q_t^i \in [\underline{q}, \bar{q}]$ chosen by supplier i in period t at cost $c^i(q_t^i)$ is unverifiable but is observed by the purchaser and the other suppliers. Otherwise, the assumptions are as for a stationary version of the employment model of Section 3.1 with $\rho = 1$. Suppose the

outcome is additively separable across suppliers. In a bilateral relational contract in which each supplier ceases to perform only if individually cheated by the purchaser, the incentive compatibility constraint for each relationship i corresponding to (8) is then

$$\delta [S^i(q^i) - \tilde{S}^i] \geq c^i(q^i), \quad \text{for all } i, \quad (34)$$

where $\delta [S^i(q^i) - \tilde{S}^i]$ is the joint gain from continuing the relationship with supplier i . But with multiple agents, there can be a multilateral relational contract in which all suppliers cease to perform if the purchaser breaches on any one of them. Then the incentive constraints (34) can be pooled over suppliers to give the single constraint

$$\delta [S(q) - \tilde{S}] \geq \sum_{i=1}^n c^i(q^i), \quad (35)$$

where $\delta [S(q) - \tilde{S}]$ is the joint gain from continuing all n supplier relationships. The constraints (34) allow the gain from one relationship to be used to sustain only that relationship. Constraint (35) allows the gain from a relationship to be used in a cross-subsidizing way to sustain other relationships—in particular, those more productive at the margin. That can increase the total surplus sustainable. The mechanism is essentially the same as in the multimarket oligopoly model of Bernheim and Whinston (1990), where gains from collusion in one market can help sustain collusion in another. Levin (2002) also shows that if q_t^i is known only to i but generates an observable signal with error, an optimal multilateral contract is payment by relative performance (a tournament) with a fixed prize to at most one supplier. The underlying reason is the same as in Kvaløy and Olsen (2006).

There is, however, a potential downside to multilateral commitments: they are harder to back away from when outside circumstances change. Suppose production methods change in such a way that it is no longer efficient to use one of the suppliers. With bilateral relational contracting, the relationship with that supplier can be terminated without affecting the relationship with the other suppliers. With multilateral relational contracting, other suppliers may interpret termination with one supplier as the purchaser breaching the multilateral agreement. Suppose they do so with probability α . For concreteness, suppose there are just two suppliers, quality is a binary choice ($\underline{q}$ or $\bar{q}$), and supplier 2 becomes redundant with Poisson probability $1 - \gamma$. Then, with α chosen at the lowest level consistent with the purchaser's incentive compatibility, multilateral contracting improves on bilateral contracting if and only if

$$(1 - \delta) [S^2(\bar{q}) - \tilde{S}^2] \geq \frac{1 - \gamma}{\gamma} c^2(\bar{q}).$$

The same idea extends to more than two suppliers in a way that fits the distinction in Asanuma (1989: 17–18) between suppliers kept operating more or less continuously and those used as a capacity buffer. Levin (2002) shows that, if there are two groups of suppliers all of whom are to be

retained after a shock, the purchaser can always do at least as well by using a multilateral contract with them all. If there are two groups both containing suppliers to be dropped if requirements decrease, the purchaser will have to recontract with any suppliers in both groups who are to be retained in the event of an adverse shock. Again, the purchaser can do at least as well by combining the two groups. It follows that there will be an optimal arrangement with at most one group that includes suppliers to be released and (potentially, at least) another group that contains only suppliers to be retained. In this model (as in most models discussed in Section 7) there is, however, no reason for the two groups to be doing different tasks.

Other papers explore different avenues when there are multiple suppliers. Schöttner (2008) analyzes a model of task assignment with three tasks to be divided between two suppliers that is based on the formulation in Baker et al. (1994) and derives results on the characteristics that determine which tasks should be purchased from the same supplier. Board (2011) analyzes a model in which the purchaser must incur a specific investment each period to enable a supplier to produce, as a result of which the purchaser invests in at most one supplier in each period. The amount of specific investment required varies across time and across suppliers, so it is efficient to invest in different suppliers in different periods. There is, however, a benefit to having a set of preferred suppliers to whom the purchaser is loyal, in the sense of choosing only from this subset of possible suppliers. The underlying reason is that the higher the probability of future trades with a supplier, the weaker is the current period's incentive compatibility condition. Increasing that probability acts like increasing ρ in (8).

Finally, in Calzolari and Spagnolo (2010), as in Board (2011), the purchaser trades with only one supplier in each period. However, the fixed cost of each potential supplier is an iid random draw each period that is not observed by the purchaser. If quality were contractible, the purchaser could achieve efficient quality by inviting potential suppliers to bid in an auction. But with noncontractible quality, the purchaser has to induce the chosen supplier to deliver quality through the relational contract. In Calzolari and Spagnolo (2010), the purchaser holds auctions but may choose not to do so every period to avoid paying the fixed cost of organizing one and, when it does so, to restrict competition to a set of preferred suppliers for the same reason as in Board (2011). Reducing the number of competitors increases the expected informational rent to the winning supplier, so it reduces the purchaser's future gain from not cheating on the relational contract. Of course, it also increases the incumbent supplier's future gain by the same amount conditional on that supplier winning the next auction. So, conditional on the incumbent supplier winning the next auction, the joint future gains from not defaulting on the relational contract are unchanged. But reducing the number of competitors increases the probability that the incumbent supplier will win the next auction, so the net effect is to increase the joint gains from not defaulting, which is like increasing the left-hand side of (8) and so enabling higher quality to be sustained. Because the auction ensures that the purchaser gets the gains from increases in efficiency, there is a trade-off between increasing the number of competitors to obtain the lowest price and reducing it to increase quality. So if the number of potential competitors is sufficiently large, it is optimal to restrict the number entering the auction. Reducing the frequency of auctions can also increase sustainable quality. Calzolari and Spagnolo (2010) give conditions under which the purchaser actually does better by having suppliers collude in the auction process.

Underdeveloped in the relational contract context are the implications of the common agency situation in which multiple suppliers, each with private information about his own type, produce simultaneously. Martimort and Stole (2009) analyze common agency in the absence of relational contracts when the principal can choose which of a set of agents to contract with.

9. Partnerships

In all the models discussed so far, there are clearly identified suppliers whose decisions about quality affect the value of the output to a purchaser. In some contracts between firms, for example, joint ventures, the two parties are on a more symmetric footing in that the measurable output involves simultaneous inputs from both. In many models of such partnerships, the parties are, initially at least, entirely symmetric. To reflect the more neutral position, this section refers simply to “parties,” $i = 1, 2$. It is concerned only with partnerships involving relational contracts. Section 10 on organizational design considers issues arising from the existence of assets and who should own them.

For a basic model of partnerships, let q_t^i denote the quality chosen by party i at time t , $y(q_t^1, q_t^2)$ the value of the joint output, $b_t^i(q_t^1, q_t^2)$ the amount received by party i conditional on performance as long as the relational contract has not been breached, and $z_t^i(q_t^1, q_t^2)$ the amount received by party i if the relational contract has been breached. The functions $b^i(\cdot)$ are, like the voluntary bonuses in the models discussed in earlier sections, in general not legally enforceable. The sum over i of $b_t^i(\cdot)$ equals the joint output, as does that of $z_t^i(\cdot)$. There can also be fixed payments p_t^i made under the relational contract; the sum of these across i must be zero. Qualities are chosen simultaneously by both parties, with the choice of each subsequently observed by the other. A superscript i is attached to the previous notation to denote party i . If both parties stick to their relational contract, the payoff to party i , corresponding to that in (1) for the employment model, then becomes

$$U_t^i = p_t^i + b_t^i(q_t^1, q_t^2) - c^i(q_t^i) + \delta U_{t+1}^i, \quad i = 1, 2; \quad \text{for all } t \geq \tau. \quad (36)$$

Because the quality chosen by party i affects the payoff $z_t^i(q_t^1, q_t^2)$ that party i receives from breaching the agreement, optimal breach behavior is similar to that for the outsourcing model in Section 3.2. Specifically, if i were planning to breach the agreement about quality, it would be optimal to deliver quality

$$\tilde{q}_t^i = \arg \max_{q_t^i \geq \underline{q}} z_t^i(q_t^1, q_t^2) - c^i(q_t^i), \quad i = 1, 2; \quad \text{for all } t \geq \tau, \quad (37)$$

which corresponds to (10) for the outsourcing model. The payoff of party 1 from breaching, corresponding to (11) for the outsourcing model, would be no less than

$$p_t^1 + z_t^1(\tilde{q}_t^1, q_t^2) - c^1(\tilde{q}_t^1) + \delta \tilde{U}_{t+1}^1, \quad \text{for all } t \geq \tau. \quad (38)$$

The requirement that the payoff in (36) for party 1 exceed that in (38) gives the incentive compatibility condition corresponding to (12) for the outsourcing model:

$$\delta \left(U_{t+1}^1 - \tilde{U}_{t+1}^1 \right) \geq \left[c^1 \left(q_t^1 \right) - c^1 \left(\tilde{q}_t^1 \right) \right] + z_t^1 \left(\tilde{q}_t^1, q_t^2 \right) - b_t^1 \left(q_t^1, q_t^2 \right), \quad \text{for all } t \geq \tau. \quad (39)$$

A corresponding condition holds for party 2:

$$\delta \left(U_{t+1}^2 - \tilde{U}_{t+1}^2 \right) \geq \left[c^2 \left(q_t^2 \right) - c^2 \left(\tilde{q}_t^2 \right) \right] + z_t^2 \left(q_t^1, \tilde{q}_t^2 \right) - b_t^2 \left(q_t^1, q_t^2 \right), \quad \text{for all } t \geq \tau. \quad (40)$$

Recall that the sum over i of $b_t^i \left(q_t^1, q_t^2 \right)$ equals $y \left(q_t^1, q_t^2 \right)$. Thus, (39) and (40) can be added to give the pooled incentive compatibility condition

$$\begin{aligned} \delta \left(S_{t+1} - \tilde{S}_{t+1} \right) &\geq \sum_{i=1}^2 \left[c^i \left(q_t^i \right) - c^i \left(\tilde{q}_t^i \right) \right] - y \left(q_t^1, q_t^2 \right) + z_t^1 \left(\tilde{q}_t^1, q_t^2 \right) \\ &\quad + z_t^2 \left(q_t^1, \tilde{q}_t^2 \right), \quad \text{for all } t \geq \tau, \end{aligned} \quad (41)$$

where $\delta \left(S_{t+1} - \tilde{S}_{t+1} \right)$ is, as before, the joint gain from continuing the relationship at the end of period t . To this condition must be added the individual rationality conditions corresponding to (4) and (7) and conditions to ensure that it is incentive compatible for each party i to pay any negative $b_t^i \left(\cdot \right)$.

The functions $b_t^i \left(\cdot \right)$ do not appear in (41). How the parties divide the joint output under the relational contract is important only for individual incentive compatibility via (39) and (40) and for satisfying the individual rationality conditions corresponding to (4) and (7). This property resurfaces later in the discussion of organizational design in Section 10. If the parties have a choice of the functions $z_t^i \left(\cdot \right)$, it is advantageous to choose them to make (41) as weak as possible when due account is taken of the effect on the $\tilde{q}_t^i$ through (37). In general, the $z_t^i \left(\cdot \right)$ functions that do this depend on the $\left(q_t^1, q_t^2 \right)$ agreed under the relational contract, with a trade-off between increasing q_t^1 and increasing q_t^2 . It has become conventional in the literature on relational contracts to use, for comparison purposes, the efficient qualities $\left(q^{1*}, q^{2*} \right)$ defined by

$$q^{i*} = \arg \max_{q^i} y \left(q_t^1, q_t^2 \right) - c^i \left(q^i \right), \quad i = 1, 2. \quad (42)$$

Then, (41) with $q_t^i = q^{i*}$ for $i = 1, 2$ and all t becomes an incentive compatibility condition for achieving efficient qualities, and the value of the discount factor δ that makes it hold with equality is the lowest for which efficient qualities can be achieved for given $z_t^i \left(\cdot \right)$. The feasible $z_t^i \left(\cdot \right)$ that results in the lowest such δ is said to be relationally efficient.

Radner (1986) was concerned with how close the parties can get to a fully efficient outcome in a model of this type when (a) $b_t^i(\cdot)$ and $z_t^i(\cdot)$ are given exogenously, (b) there are no payments p_t^i , (c) there is no discounting ($\delta = 1$), and (d) stochastic terms that are imperfectly monitored enter the payoffs. Radner et al. (1986) give an example with discounting in which equilibria are bounded away from full efficiency even as the discount factor goes to one. Neither Radner (1986) nor Radner et al. (1986) considers a role for contracts to alter $b_t^i(\cdot)$ or $z_t^i(\cdot)$. Garvey (1995) does just that in a model with no stochastic elements by assuming joint output is verifiable, so that the parties can write a legally enforceable contract specifying $z_t^i(\cdot)$ as a function of $y(q_t^1, q_t^2)$. To simplify, he restricts contracts to constant shares of output and also imposes the restriction $b_t^i(\cdot) = z_t^i(\cdot)$. Because the $b_t^i(\cdot)$ then take only nonnegative values, (41) does not need to be supplemented by conditions that make it incentive compatible to pay negative ones. Garvey (1995) uses an example with (potentially different) quadratic cost of quality functions $c^i(q_t^i)$ and $y(q_t^1, q_t^2) = q_t^1 + q_t^2$ to show that the optimal shares are closer to one-half in a relational contract than in a spot market contract. Garvey relates these shares to ownership patterns, but that is not central to the analysis.

In McAdams (2011), the joint output at t is affected not only by the qualities (q_t^1, q_t^2) but also by a partnership-specific state of the world that is stochastic. The state is persistent, depending positively (in a first-order stochastic dominance sense) on the state and qualities delivered in the previous period. In his general model, monetary payments are unrestricted except that it must be incentive compatible for the partners to pay them. This structure yields potentially rich patterns of partnership development that McAdams (2011) describes in terms of transitions between (a) “dating” partnerships that last just one period with zero quality, because they are immediately seen to be unpromising; (b) “honeymoon” partnerships that survive the dating stage, which have higher current payoffs, because they are better matches and, as a result, induce higher quality; (c) “hard time” partnerships that yield low current payoffs, because the state is less propitious but may, nevertheless, be kept going because of the probability of improvement; and (d) “golden years” partnerships, in which the state has become so favorable, and the quality delivered so high, that the partnership ends only with the “death” of one of the partners.

In Doornik (2006), one party’s chosen quality is not observed by the other. Instead, there is for each i an observable (but not verifiable) stochastic individual performance measure x^i with iid probability density conditional on quality $f(x^i | q^i)$ that satisfies MLRP (Assumption 1). Party i receives return y_t^i , which is a deterministic function of both the realized performance measures (x_t^1, x_t^2) but is not verifiable, so there cannot be a legally enforceable contract to share these. The parties can, however, agree a relational contract involving voluntary bonuses. Both parties are risk neutral. Doornik (2006) shows that, if a relationship is feasible, there is always an optimal relational contract that is invariant, in the sense of being the same every period apart from possibly calling for termination after some outcomes, even if continuation is feasible and efficient. When CDFC (Assumption 2) holds and the two parties are identical, an optimal invariant contract has the following properties: (a) the parties terminate the relationship with probability 1 when both performance levels are below some thresholds; (b) otherwise, the bonus payment takes one of two levels, depending essentially on the likelihood ratios of the observable performance measures in a way that corresponds to the party with lower relative performance

paying the other. An optimal invariant contract does not necessarily require termination when continuation is feasible and efficient. An example is when each party's return is independent of the other's performance measure, so returns are separable. In that case, each party can act in the role of the purchaser in the moral hazard model in Levin (2003) with respect to the quality decision by the other. But, more generally, inefficient termination in some circumstances ("burning money") is required to keep the relationship incentive compatible, as in the moral hazard model in Levin (2003) with subjective performance measures. For some values of the discount factor, there is no fixed payment that is self-enforcing in the absence of bonuses, but efficient quality is implementable with an optimal relational contract. Thus, price (fixed payment plus bonus) varies with costs, as observed with Japanese automobile subcontracting. Price, however, varies less than if it were determined by period-by-period bargaining in the absence of a relational contract.

Rayo (2007) considers n risk-neutral parties choosing qualities $q_t = (q_t^1, \dots, q_t^n)$ whose joint output y is verifiable, as in Garvey (1995), but is a random variable with expected value $E[y | q]$. (There is also a party $n + 1$, who plays no role in production and serves merely to balance the payments between the parties, but whose payments still have to be incentive compatible.) In addition, there is a signal x^i of party i 's performance with density $f_i(x^i | q^i)$ that is independent across parties, is observed by all parties, but is not verifiable by outsiders. Denote by I the set of those who participate in a relational contract. Each participant receives a constant share $\alpha^i \geq 0$ of the realized output y_t , where the α^i are specified in a legally enforceable agreement and sum to one over all participants. Participants can also receive a legally enforceable fixed payment p_t^i and voluntary bonus payments $b_t^i(x_t)$ conditioned on the vector of realized signals x_t for all participants—by assumption, x_t is a sufficient statistic for (x_t, y_t) . Rayo (2007) assumes that each participant i 's net bonus plus discounted payoff in the continuation equilibrium at $t + 1$ conditional on x_t is additively separable in her own performance signal x_t^i and the performance signals of the other participants, denoted x_t^{-i} . Thus, it can be written as $V^i(x_t^i) + W^i(x_t^{-i})$ for some functions V^i and W^i . (Without that assumption, the optimal contract would take the form of a winner-take-all tournament, which, it is argued, would have practical problems of implementation.) He then shows that the constraints for no party to default on the required bonus payments can, as in Levin (2003), be pooled into the single aggregate dynamic enforcement constraint

$$\delta(S - \tilde{S}) \geq \sum_{i \in I} \left\{ \sup_{x_t^i} V^i(x_t^i) - \inf_{x_t^i} V^i(x_t^i) \right\}. \quad (43)$$

Rayo (2007) calls the term in braces with superscript i in this i 's "implicit incentive." It is the difference, under the relational contract and measured at the point bonuses are to be paid, between participant i 's payoffs with the best and the worst possible values of x_t^i . These implicit incentives arise from the gain from having the relationship continue in the future, so their total over all participants cannot exceed the total gain, which is what (43) requires. That condition is effectively an extension of (24) to the case of many participants with the continuation equilibrium depending on the stochastic signals. If the continuation equilibrium did not depend on

those signals, payoffs from $t + 1$ on would cancel on the right-hand side of (43), leaving only the bonus terms, as in (24).

Consider the implementation of some vector of qualities q with the vector of shares α . The share α^i provides an explicit incentive for participant i to deliver quality, but any additional incentive has to be provided by the implicit incentive, that is, by the term in braces with superscript i in (43). The minimum implicit incentive that will do this can be written $\Delta V^i(\alpha^i, q)$. Rayo (2007) first considers the case in which quality q_t^i is observed only by participant i and the $f_i(\cdot)$ satisfy MLRP and CDFC (Assumptions 1 and 2). Then, for implementing any optimal vector of qualities $\hat{q}$ that is less than fully efficient, there exists an optimal allocation of shares $\hat{\alpha}$ such that one participant, call her l , has $\hat{\alpha}^l$ sufficiently high that $\Delta V^l(\hat{\alpha}^l, \hat{q}) = 0$. Participant l is the participant i for whom $-\partial \Delta V^i(\hat{\alpha}^i, \hat{q}) / \partial \alpha^i$ is largest. The intuition is as follows. Condition (43) constrains the total implicit incentives that can be provided to all participants. Because incentives are in short supply when efficient qualities cannot be attained, it is optimal to use the legally enforceable shares for that participant i for whom they are most effective at reducing the implicit incentive required, that is, for whom $-\partial \Delta V^i(\hat{\alpha}^i, \hat{q}) / \partial \alpha^i$ is largest. Intuitively, l is a relatively productive participant whose quality is hard to assess by means of x^l . Rayo (2007) shows that participant l can be interpreted as an endogenously chosen principal who, in the spirit of Alchian and Demsetz (1972), receives the total gain from continuation of the relationship but whose role as principal is just to make all the payments to other participants, not to monitor how they perform.

The other main case considered by Rayo (2007) is that in which all qualities are observable by all suppliers, that is, $x_t^i = q_t^i$. Then, provided some participants receive implicit incentives under an optimal contract, all do ($\Delta V^i(\hat{\alpha}^i, \hat{q}) > 0$ for all i), and profit shares are dispersed ($\hat{\alpha}^i < 1$ for all i). Rayo explains the intuition as follows. Suppose participant i receives no implicit incentive, so all her incentives come from $\hat{\alpha}^i > 0$. When q^i is chosen optimally, by the Envelope Theorem, the change in i 's payoff from a small increase in q^i is of second order. Thus, the cost of inducing slightly higher quality from agent i with a small implicit incentive is essentially negligible and hence is always worthwhile. That $\hat{\alpha}^i < 1$ is shown by the following argument: if $\hat{\alpha}^i = 1$, i gets the full additional joint gain from additional quality and so would choose efficient quality without any implicit incentive. With an implicit incentive as well, i would choose quality above the efficient level, which cannot be optimal. Thus, given that there is some implicit incentive, it follows that $\hat{\alpha}^i < 1$.

The contrasting results for the two cases in Rayo (2007) illustrate the importance for incentive arrangements of the information quality of performance measures. When participants are able to monitor one another's performance only poorly, it is optimal to have one of them (one who is relatively productive but whose performance is particularly hard to assess) act as a principal who receives all the gain from continuation of the relationship and manages payments to all others. In contrast, when participants are able to monitor one another's performance well, a partnership in which they all receive shares of current output and also some of the gain from continuing the relationship in the future is optimal.⁵

5. Watson (1999, 2002) and Sobel (2006) consider partnerships in which partners contribute to a joint output but do not make direct payments to each other. From a modeling perspective, this means that the dynamic

10. Organizational Design

GM eventually took over Fisher Body, because, according to Klein (2000), efficiency requirements moved outside the zone of a self-enforcing relational contract. As the property rights literature stemming from Grossman and Hart (1986) and Hart and Moore (1988, 1990) has emphasized, however, a takeover does not remove the underlying incentive issues—it just moves them inside the integrated firm. The basic models discussed in Section 3 can be used to throw light on when it is more efficient to handle relational incentive issues within firms than between firms, hence making vertical integration worthwhile.

In Baker et al. (2002), nonintegrated supply corresponds to the outsourcing model and integrated supply to the employment model. The difference arises because ownership of the assets used in supply is taken to confer ownership of the goods produced by those assets. Then, when a supplier is taken over, its previous owner becomes a manager (as the Fisher brothers became when GM took over Fisher Body). This manager still has to be induced to provide appropriate quality but can no longer withhold supply for use as a bargaining chip for payment, because the output belongs to the downstream firm. In the event one party breaches a relational contract, the parties trade in the spot market thereafter (the so-called grim trigger strategies), but they renegotiate ownership of the asset to provide the most efficient spot market operation. In the basic models of Section 3, the implication is that $\tilde{U}_{t+1} + \tilde{\Pi}_{t+1}$ in (8) for the employment model is the same as $\tilde{U}_{t+1} + \tilde{\Pi}_{t+1}$ in (15) for the outsourcing model, because, whether or not the firms start out integrated, renegotiation leads to the same efficient spot market trading. Then, (8) with $\rho = 1$ is a weaker constraint than (15) for given q_t if $z_t(\tilde{q}_t) - c_t(\tilde{q}_t) > z_t(q_t)$, precisely the condition for use of a fixed-price contract to be advantageous in the model of Itoh and Morita (2011) discussed in Section 5. Notice that every term in this condition involves either the function $z_t(\cdot)$ or the quality $\tilde{q}_t$, both of which apply only when the relational contract is breached. It is only what happens in the event of breach that determines efficient organizational design. Halonen (2002) considers another form of organization, joint ownership, which is discussed further below.

Is this framework useful for discussing GM's takeover of Fisher Body? Suppose it were initially the case that $z_t(\tilde{q}_t) - c_t(\tilde{q}_t) < z_t(q_t)$, so that (15) is weaker than (8). Then a given q_t is sustainable at a lower discount factor δ_t when the supplier is a separate company, so the relationally efficient organization is outsourcing. For vertical integration to become efficient,

enforcement constraints of the partners cannot be pooled into a single constraint. From a practical perspective, it makes the models less appropriate for studying contracts between firms. (In Sobel (2006), the probability that cheating is detectable by the courts can, in addition, be increased by incurring an enforcement cost.) Thomas and Worrall (2010) allow for transfers between agents via the equilibrium outcomes of a Nash demand game played each period after output has been produced. This has the effect of imposing credit constraints that can result in rewards to one party being postponed (backloaded) until a time at which the other party is unconstrained. The formal structure of cooperation in repeated partnerships is related to that of collusion in repeated oligopoly, of which there are recent models in Sannikov and Skrzypacz (2007) and Athey and Bagwell (2008). The former makes the relationship explicit in an application of its result that collusion cannot be sustained when the parties' actions are perfect substitutes, new noisy information arrives continuously, and the parties are able to respond to that information quickly. But for reasons that are obvious in the context of illicit collusion, those models do not allow direct payments between the parties.

that inequality would have to be reversed. Transferring Buick body production to Flint was presumably jointly advantageous to GM and Fisher Body, because the savings on the costs of transporting completed bodies outweighed any increased costs of inputs. It is not, however, obvious that a reduction in transportation cost alone would have changed the relationally efficient organization. Suppose, for concreteness, the cost $c_t(q_t)$ at the body plant gate was unaffected by the change in location, the advantage being measured by an increase in $y_t(q_t)$ resulting from the savings in transportation cost of k per body for each of q_t bodies delivered. Under the split-the-difference bargaining outcome assumed by Baker et al. (2002), z_t is determined by the parties sharing equally the gain from the purchasing firm receiving the output over it being sold to a third party. Formally, with v_t the value for which the output can be sold to a third party,

$$z_t(q_t) = v_t(q_t) + \frac{1}{2} [y_t(q_t) - v_t(q_t)] = \frac{1}{2} [y_t(q_t) + v_t(q_t)]. \quad (44)$$

So if the cost of transporting bodies to an alternative automobile manufacturer increased by the same amount k per body, $z_t(q_t)$ would remain unchanged, and the relocation to Flint would leave the relationally efficient ownership unchanged. This example is, of course, intended only to illustrate use of the theory, not to provide a full analysis of the situation faced by GM and Fisher Body. Some careful research is still needed to see whether the model can really be applied to that case and, if so, how.

Baker et al. (2002) show that there is another effect to consider. Suppose, as in Levin (2003), the outcome y is stochastic given q_t and so is z , with both iid given q_t , so that the expected future payoff to the relationship does not depend on the current realization. Also as in Levin (2003), suppose the purchaser observes neither q_t nor the realization of the stochastic terms but does observe the realizations y_t and z_t . Then, in the notation of Section 6, the jointly observed outcome is $\phi_t = \{y_t, z_t\}$. Because the purchaser does not observe q_t (and so cannot punish directly breach of an agreement about quality), the incentive compatibility condition for the supplier to deliver quality becomes (in a stationary environment)

$$q_t \in \arg \max_q E_y [P(\phi) | q] - c(q). \quad (45)$$

This condition is just like (21) for the model in Levin (2003) except that there is no argument θ , because the agent can be of only one type. In the employment model, the incentive compatibility constraints (22) and (23) for the purchaser and the supplier, respectively, to pay agreed bonuses apply just as in Levin (2003) and hence so does the dynamic enforcement constraint (24). In the outsourcing model, (45) continues to apply, but, in line with (13) and (14) for the outsourcing model, (22) and (23) become

$$\delta (\Pi - \tilde{\Pi}) \geq \sup_{\phi} [b(\phi) - z] \quad (46)$$

$$\delta (U - \tilde{U}) \geq \inf_{\phi} [z - b(\phi)]. \quad (47)$$

Hence, the interaction between the variation in bonuses and whether the firms are integrated affects the incentives to breach a relational contract, so the variation in payoffs, not just their expected values, can be important in the choice between organizational forms. Baker et al. (2002) make use of specific functional forms to show that the relationally efficient organization does indeed depend on the variation in output for given q_t and also to derive further results.

Several papers consider developments of the model in Baker et al. (2002). Baker et al. (2001) extend it to allow supply to have some verifiable characteristics, as in the models in Section 5. Then the contractual payment p can be conditioned on those verifiable characteristics. The main result is that it is not possible to replicate the payoffs of spot outsourcing with a relational employment contract. Kvaløy (2007) considers an alternative to grim trigger strategies, specifically, that the parties trade in the spot market for one period only and then revert to their relational contract. That affects $\tilde{U}$ and $\tilde{\Pi}$ and hence the relational contracts that are sustainable. Ruzzier (2009) adopts a different specification of how z_t (.) is determined. Instead of assuming split-the-difference bargaining as in (44), he assumes v_t is an outside option that can be taken up by the supplier only once bargaining with the purchaser has been broken off, giving the bargaining outcome

$$z_t = \begin{cases} \frac{1}{2}y_t, & \text{if } \frac{1}{2}y_t \geq v_t \\ v_t, & \text{if } \frac{1}{2}y_t < v_t. \end{cases}$$

Then the distribution of v_t does not affect the choice between organizational forms if the top line applies (the case Ruzzier (2009) calls “high specificity”) and the distribution of y_t does not affect it if the bottom line applies (low specificity).

The underlying framework has also been extended to the case in which both parties take actions that contribute to the value of their joint output (the partnership models of Section 9). In Halonen (2002), both parties make their quality decisions simultaneously, these are observed by the other party, and either or both can be applied to an asset. If both are applied to the asset, the joint output is $y(q^1, q^2) = q^1 + q^2$; if only party i 's, party i 's output is λq^i , with $\lambda \in [0, 1)$, and party j 's output for $j \neq i$ is zero whatever q^j (λ is known, so there is no stochastic element). Neither quality nor output is verifiable, so no sharing contract is legally enforceable. In a one-period relationship, after one party has breached a relational contract, the parties still cooperate to apply both qualities to the asset, because doing so yields a higher total output. They share this output by bargaining that splits equally the difference between their joint output and what their individual outputs would be in the absence of cooperation. If the asset is owned by party i , these individual outputs are λq^i and 0. But the asset can also be owned jointly, in which case each party can prevent the other from using it, so both have individual outputs of zero. With ownership by party 1, the rewards in a one-period relationship that result from this bargaining are, in the notation of Section 9,

$$z^1(q^1, q^2) = \lambda q^1 + \frac{1}{2}[(1 - \lambda)q^1 + q^2] = \frac{1}{2}[(1 + \lambda)q^1 + q^2] \quad (48)$$

$$z^2(q^1, q^2) = \frac{1}{2}[(1 - \lambda)q^1 + q^2], \quad (49)$$

so the optimal qualities defined in (37) are

$$\tilde{q}^1 = \arg \max_{q^1 \geq \underline{q}} \frac{1}{2} \left[(1 + \lambda) q^1 + q^2 \right] - c(q^1) \quad (50)$$

$$\tilde{q}^2 = \arg \max_{q^2 \geq \underline{q}} \frac{1}{2} \left[(1 - \lambda) q^1 + q^2 \right] - c(q^2). \quad (51)$$

With joint ownership, both parties' individual outputs are zero, so the rewards in a one-period relationship are given by (48) and (49) with $\lambda = 0$. Thus, party 2 chooses the same quality $\tilde{q}^2$ under both forms of ownership and, provided $\lambda > 0$, party 1 chooses higher quality $\tilde{q}^1$ under single ownership (but it is still less than the efficient level, because $\lambda < 1$). Thus, in a one-period relationship, single ownership is better than joint ownership for $\lambda > 0$.

Under a relational contract, that is not necessarily the case. The formal analysis can be done by inserting the appropriate functional forms into (41). In contrast to Baker et al. (2002), Halonen (2002) considers primarily the assumption that ownership is not renegotiated in the event of breach by either party, which corresponds to making $\tilde{S}_{t+1}$ a function of λ . When $\lambda = 0$, single ownership and joint ownership are again equivalent. With joint ownership, nothing changes as λ changes (because λ is then irrelevant). However, with a single owner, $\tilde{S}_{t+1}$ is an increasing function of λ for $\lambda \in [0, 1)$, because from (50), $\tilde{q}^1$ is increasing in λ , and from (51), $\tilde{q}^2$ is independent of λ . So the long-term cost of breaching a relational contract for given (q^1, q^2) is decreasing in λ . The short-term gain from doing so is also decreasing in λ . Halonen (2002) shows that, for $c(q) = q^\gamma$ ($\gamma > 1$) and an optimal payoff structure when efficient qualities are achievable, these two effects exactly balance when $\gamma = 2$. For $\gamma < 2$, single ownership is relationally efficient; for $\gamma > 2$, joint ownership is relationally efficient. Halonen (2002) also considers the assumption that ownership is renegotiated in the event of default (so that $\tilde{S}_{t+1}$ is independent of λ) but only for a specific numerical example.⁶

In Bragelien (2007) too, both parties make quality decisions, but—as in Baker et al. (2002) and unlike in Halonen (2002)—output is an iid random variable for given quality, and quality decisions are unobserved by the other party. Neither output nor quality is verifiable. The benefit to each party if they subsequently cooperate is their own quality plus an additive stochastic term; it is noncontractible but is observed by both. If, after observing the benefit, either decides not to cooperate, their benefits are lower and, in addition to depending on what the benefits would have been had they cooperated, also depend on the ownership structure. If they cooperate, they share the gains from doing so. The form payments take under an optimal relational contract consists of each party receiving the payoff it would receive in the absence of cooperation, together with a fixed payment independent of the benefits from cooperation and a payment depending on the realized values of those benefits that takes one of just two values (a one-step payment schedule). With sufficient symmetry, the last of these payments depends on which agent has the higher realized gain from cooperation and so resembles a tournament. This result extends results in Levin (2003) for the case in which just one party decides quality to the case in which both do.

6. Applied to the model in Baker et al. (2002), joint ownership might be interpreted as implying that the supplier cannot sell the supply to a third party without the agreement of the purchaser. Then, in the formulation in (44), $v_t(q_t) = 0$ for all q_t , and hence $z_t(q_t) = y_t(q_t)/2$.

The main focus of Bragelien (2007) concerns the choice of organizational structure. Non-cooperation results in the parties operating as if in a spot market ever after. The paper considers both the case discussed by Halonen (2002), in which the parties are committed to the ownership structure forever once it has been determined, and that discussed by Baker et al. (2002), in which the parties can renegotiate their ownership structure if they move to a spot market relationship. For the first case, Bragelien (2007) gives conditions favoring an ownership structure that gives weaker (and, conversely, stronger) incentives in spot market interactions. They differ from those in Halonen (2002) because of the uncertainty. The generalization of Baker et al. (2002) is that the potential benefits are continuous, not just binary. For this case, the general result is that the ownership structure should never give worse incentives in the spot market for one party without giving better incentives for the other. ("Better" here may be stronger or weaker, depending on whether that party would otherwise choose quality below or above the efficient level.) There are also results for correlated performance measures. Bragelien (2007) illustrates the results with linear contracts, which may be optimal (if error terms are uniformly distributed and functions are linear) and for which explicit solutions can be derived.

Blonski and Spagnolo (2007) question whether, when modeled properly, there is actually a difference between the case in which ownership can be renegotiated following breach and the case in which it cannot. The essence of their argument, formalized in a model with both parties choosing quality but with no stochastic elements, is as follows. Trading in a spot market environment after one party breaches is inefficient, so the parties would gain by renegotiating back to continued cooperation. Doing so does not destroy incentive compatibility if the parties use restitution strategies, based on an idea in Farrell and Maskin (1989), in which the payoff to the breaching party in the continuation equilibrium played following breach is reduced to the level that party would have obtained by trading in the spot market ever after. (In the absence of wealth constraints, that can be achieved by a single monetary payment for restitution, but this is not the only possibility.) The reason restitution strategies do not upset incentive compatibility is that, if defaulting at t , the supplier still gets continuation payoff $\tilde{U}_{t+1}$, and if defaulting at t , the purchaser still gets continuation payoff $\tilde{\Pi}_{t+1}$ —it is only the continuation payoff of the nonbreaching party that is affected by the restitution. But if the parties were using the relationally efficient organization before breach, they will have no reason to renegotiate the organizational structure after breach. Thus, it makes no difference whether they can renegotiate that structure.

Baker et al. (2011) consider a different issue of organizational design: how to allocate decision rights in an organization in order to adapt decisions to changing circumstances. To illustrate, consider two parties and a single decision about quality q_t that can, in principle, be made by either of them. Which has the right to do so has to be determined before all uncertainty, represented by a random state of the world s , is resolved. The party given that right makes the decision in its own interest, once the uncertain state of the world has been revealed.⁷ So, in

7. Baker et al. (2011) contrast their approach with the incomplete contracts approach of Grossman-Hart-Moore in the following way. In the latter, a legally enforceable agreement about the decision to be made can always be negotiated between the parties after any uncertainty is resolved, no matter who has the formal right to make it. In the former, there is insufficient time to negotiate such an agreement, a situation referred to by Williamson (2000: 605) as "maladaptation in the contract execution interval."

a one-period relationship, it is optimal to give the decision right to whichever party's short-term self-interested decisions for each state s yield the highest expected joint payoff. But in an ongoing relationship in which actual decisions are observed by all parties, voluntary bonus payments and the payoffs in the continuation equilibrium can be conditioned on the state and on the decision made, so the decisionmaker can be induced to make decisions not solely in a short-term self-interested way. Then the party to whom the decision right is given becomes just like the supplier in the employment model of Section 3.1, except that there is uncertainty at the time the purchaser commits to p_t that is resolved by the time the supplier makes the decision q_t . (Baker et al. (2011) also allow for payments to be made between the state being revealed and the decision q_t being made.) Assume for simplicity that the state s is iid, and denote its realized value at t by s_t . Then in an obvious analogy with (1), we can write party 1's payoff conditional on being the decisionmaker in period t and on the relational contract continuing as

$$U_t^1(s_t) = p_t + b_t(q_t, s_t) - c_t^1(q_t, s_t) + \delta_t E_s [U_{t+1}^1(s)], \quad \text{for all } t \geq \tau, \quad (52)$$

where $c_t^1(q_t, s_t)$ is now to be interpreted as the net cost to party 1 of making decision q_t in state s_t instead of the decision that maximizes her short-term interest. One can make exactly the same notational changes to the purchaser's payoffs for the nondecisionmaking party 2 and so derive the incentive compatibility condition conditional on s_t , corresponding to (8) with $\rho = 1$:

$$\begin{aligned} \delta_t E_s [S_{t+1}(s) - \tilde{S}_{t+1}(s)] &\equiv \delta_t E_s [U_{t+1}^1(s) - \tilde{U}_{t+1}^1(s) + \Pi_{t+1}^2(s) - \tilde{\Pi}_{t+1}^2(s)] \\ &\geq c_t^1(q_t, s_t), \quad \text{for all } t \geq \tau. \end{aligned}$$

Because the decision right could, in principle, be allocated to different parties in successive periods, the joint future gain $E_s [S_{t+1}(s) - \tilde{S}_{t+1}(s)]$ is independent of who has the decision right in period t , as well as of the decision made at t . The parties can thus implement the decision rule $q_t(s)$ for all s with the decision allocated to party 1 in period t only if

$$\delta_t E_s [S_{t+1}(s) - \tilde{S}_{t+1}(s)] \geq \max_s c_t^1(q_t(s), s).$$

One can derive a similar condition for when the decision is allocated to party 2. The incentive compatibility requirement is obviously weaker if the decision right is allocated to the party i for which $\max_s c_t^i(q_t(s), s)$ is smaller. The decision rule $q_t(s)$ can thus be implemented for all s by some allocation of the decision right only if

$$\delta_t E_s [S_{t+1}(s) - \tilde{S}_{t+1}(s)] \geq \min_{i \in \{1, 2\}} \max_s c_t^i(q_t(s), s), \quad \text{for all } t \geq \tau.$$

This example illustrates the underlying idea. Baker et al. (2011) allow for richer structures with many parties and many decisions for which the right to decide can be allocated, not necessarily all to the same party. There are then many potential governance structures that specify who has the right to make which decision.

11. Rent and Relational Contracts

Crucial to sustaining a relational contract is that the sum of the future payoffs to the two parties from adhering to it is larger than the sum of their future payoffs from breaching it. If that is not the case, $S_{t+1} = \tilde{S}_{t+1}$ in (8), and no relational contract can be sustained. In other words, the parties must have a rent from continuing their relationship. The rent can go to either party—(8) is a condition on the total rent, not its distribution, and the payments p_t and b_t can be used to distribute that rent in any proportions. But that rent must exist. The same applies to all other models described in this chapter.

In much of the literature, the required rent comes from the assumption that, if one of the parties breaches the relational contract, they either trade in the spot market thereafter, or, if spot market trade cannot be sustained, they cease to trade completely. Even when, as in Blonski and Spagnolo (2007), they do not actually do that in the event of breach, the possibility of doing so is still important in ensuring that it is incentive compatible for the breaching party to pay restitution to the nonbreaching party. In practice, of course, each party may have other potential trading partners. This is not necessarily a problem if the potential partners observe which party has breached and treat the breaching party as a pariah, or even if other potential partners observe only that a relationship has come to an end and treat both parties to that relationship as pariahs (see MacLeod and Malcomson 1989). But in practice, there are many reasons other than breach for a relational contract to come to an end that third parties may not be able to distinguish from breach. As Bewley (1999: 298) emphasizes in the case of employment, many employers find it difficult to get information about potential employees from former employers. Dixit (2003) discusses market solutions, motivated by the Sicilian Mafia, in which intermediaries sell, at a profitable price, either information about the past behavior of potential partners or enforcement services. But a third party has no reason to pay that price unless it would reveal something inherent about the potential partner that is relevant to the productivity of a future relationship.

Without some way to generate the required rent despite outside markets, relational contracts will break down, as Bulow and Rogoff (1989) note in the case of sovereign debt. However, there are ways in which that rent can arise even if potential partners do not discriminate against those whose previous relationships have ended. Specific investments upfront are an obvious one. But in general, there is no reason why the efficient level of specific investment, even if positive, should be large enough to sustain a relational contract, let alone one that delivers efficient quality. An alternative widely discussed in the literature is the possibility that at least one party is not in a position to form another relationship straightaway. This may be because of exogenous market frictions due to search and matching, as in Kranton (1996b), Ramey and Watson (1997, 2001) and Sobel (2006). Or it may be generated endogenously through unemployment on one side of the market, as originally modeled in Shapiro and Stiglitz (1984) in the context of efficiency wages. In the latter case, it does not matter which party has difficulty rematching. It is an assumption of Shapiro and Stiglitz (1984) that the rent must go to employees in the form of efficiency wages, rather than to firms as the result of excess vacancies, as MacLeod and Malcomson (1989, 1998) show. But there must be a rent to one party or the other. For more on this issue in the context of employment, see Malcomson (1999).

Another possibility is explored by Kranton (1996a): starting the relationship with low quality, so that there is little to lose if the other party defaults, and having quality build up over time.

Recall that, in the basic employment model, (4), (7), and (8) are necessary and sufficient conditions for a quality sequence to be an equilibrium, and that these conditions are all inequalities. Moreover, only future gains (i.e., from the second period of the relationship $\tau + 1$ on) affect the left-hand side of (8), and lowering q_τ reduces the right-hand side. Thus, for any sequence of qualities $(q_\tau, q_{\tau+1}, \dots)$ that can be sustained as an equilibrium, a sequence $(q'_\tau, q_{\tau+1}, \dots)$ with $q'_\tau < q_\tau$ can also be sustained as an equilibrium, provided the individual rationality conditions (4) and (7) are still satisfied. As long as q_τ is not above the efficient level, it also yields less gain to starting a new relationship and hence less temptation to breach an existing one. Moreover, setting $q'_\tau < q_t$ creates some slack in (8) even if there were none before, so reducing $q_{\tau+1}$ (and hence the left-hand side of (8) for $t = \tau$) by a small amount will not upset incentive compatibility for period τ , creates some slack in the incentive compatibility constraint for $\tau + 1$, and does not affect incentive compatibility from $\tau + 2$ on. Thus, in the limit, one can always set $q_t = \underline{q}$ for as many periods after τ as needed to reduce U_τ to $\bar{U}_\tau$ and Π_τ to $\bar{\Pi}_\tau$, a way suggested by Murphy and Topel (1990) to remove the need for involuntary unemployment in the model of Shapiro and Stiglitz (1984). Watson (1999, 2002) and Sobel (2006) similarly explore starting relationships in a small or inefficient way.

Essentially, starting relationships small is a way of dissipating the potential gains from new relationships to make starting a new relationship less attractive than continuing an existing one. There are other ways this can be done. Klein and Leffler (1981) explore advertising. Carmichael and MacLeod (1997) explore gifts that cost the giver more than they are worth to the recipient. There are no doubt other possibilities.

12. Courts and Empirical Evidence

This chapter is primarily about theory. Empirical evidence on contracts between firms is discussed in Lafontaine and Slade (this volume), including the issues of rent and reputation that arise in relational contracts. But one issue of particular relevance to relational contracts is not covered there: the quality of the legal system.

Relational contracts are concerned with agreements that can be enforced without resort to courts. The spirit of much of the theory discussed here is that, although an effective legal system exists, important elements of the relationship cannot be enforced legally, because courts do not have the relevant information. However, relational contracts are also valuable for enforcing agreements that courts could in principle enforce but cannot in practice be relied on to do so. For example, the parties may be in different legal jurisdictions or courts may be too corrupt, cumbersome, or otherwise ineffective. Djankov et al. (2003) document how slow and ineffective courts can be, even in countries with highly developed legal systems, over such seemingly simple things as the collection of a check returned for nonpayment. Such circumstances provide good reason for parties to use relational contracts to avoid recourse to courts when they are effective substitutes, not just when crucial information is unverifiable (though the relational contracts may then not be able to rely on even noncontingent payments being legally enforceable). Greif (1994) documents the way in which eleventh-century Maghribi traders used reputations to enforce relational contracts when trading between countries. Fafchamps (1996) and Bigsten et al. (2000) document the widespread use of relational contracts among African businesses, and their less widespread use where legal institutions best support business. McMil-

lan and Woodruff (1999) find that private sector firms in Vietnam provide customers with more credit when alternative suppliers are hard to locate and when customers are identified through business networks, both of which may provide sources of sanction for default. Banerjee and Duflo (2000) demonstrate the importance of reputational effects for Indian software. But even though relational contracts can clearly act as a substitute for well-functioning courts, better formal institutions can also foster contracting, as Johnson et al. (2002) find in post-communist countries.

13. Conclusion

This chapter does not cover anything like all the literature on relational contracts. As noted in Section 1, it focuses on theory as applied to supply relationships between firms and does not consider applications to purely financial contracts, employment, or relationships involving sovereign bodies. The inability to commit that underlies relational contracts is inherent to relationships involving sovereign bodies, because there is nobody to enforce a contract on such a body, even when the relevant information is publicly available. Thus, relational contracts have been applied to issues of sovereign debt, to treaties between sovereign states, and to the relationships between rulers and ruled within states. Acemoglu (2003), for example, develops incentive compatibility conditions similar to those used here when analyzing taxation under dictatorship and democracy.

This chapter has, moreover, not discussed relational contracts concerned only with risk sharing. Indeed, for tractability, most of the literature surveyed here assumes all parties are risk neutral, though there are notable exceptions, such as Pearce and Stacchetti (1998) and MacLeod (2003). Issues of risk aversion perhaps deserve greater attention. So (in addition to other issues noted above) do issues of which of the multiple equilibria will be played in practice and of the implications of nonstationary environments.

There are also foundational issues that deserve greater attention. The findings of Macaulay (1963) provided an important motivation for economic research on relational contracts. However, models of the type presented here certainly do not capture all those findings. One role for relational contracts discussed by Macaulay (1963) is as a substitute for planning exchange relationships completely, a framework within which the relationship can be adjusted in the face of either unforeseen contingencies or inconsistent perceptions by the parties about what should happen in certain eventualities. That role is not a feature of the models discussed above. Formally, equilibria in those models are in terms of strategies that specify what actions the parties are to take for every history that can occur, and thus for every possible contingency. Moreover, equilibrium strategies are consistent in the sense that each party's strategy is a best response to the other's. Relational contracts in these models are a substitute for enforcement by courts, not a substitute for careful planning. There is certainly no modeling of unforeseen contingencies. As in so much of economics, incorporating unforeseen contingencies remains a major challenge. Kreps (1996) reflects on these issues and on possible ways forward.

Some earlier writers about relational contracts, such as Dore (1983), contrasted them with standard economic analysis and, in particular, with economists' perceptions of allocative efficiency. As Dore (1983: 472) put it: "Any economist, at least any economist worth his neo-classical salt, would be likely to scoff at the idea. Just think, he would say, of the market

imperfections, of the misallocation and loss of efficiency involved." That was, however, before most of the literature discussed in this chapter was written. It should be apparent from this survey that research by economists on relational contracts is precisely about how the parties may achieve more efficient outcomes by making use of relational contracts in circumstances in which courts cannot be relied on to enforce contractual agreements.

There remain important differences of interpretation, however, about the notion of trust. Trust is seen by many noneconomists as central to relational contracts. Some of the literature surveyed above interprets an equilibrium with quality above the level sustainable in a one-period relationship as involving trust, because at least one party leaves itself vulnerable to exploitation by the other. As MacLeod (2007b: 609) puts it: "in a relational contract, one party trusts the other when the value from future trade is greater than the one period gain from defection." In this spirit, Kvaløy and Olsen (2009) interpret an increase in the discount factor δ as an increase in trust, because it increases the stake that the parties are prepared to risk. That interpretation of trust is not, however, universally accepted. In the context of exchanges in which the gains from future dealings are sufficiently highly valued to induce cooperation, Sabel (1993: 1135) writes that "it would be wrong to associate cooperation with trust at all, because cooperation results from continuous calculation of self-interest rather than a mutually recognized suspension, however circumscribed, of such calculation." Sako (1992) develops different concepts of trust along these lines applicable to interfirm relations in Britain and Japan. These writers view relational contracts as being about more than self-interested cooperation.

Whether or not they capture all elements of relational contracts, however, the economic models discussed here have certainly been invaluable in illuminating important features of economic relationships. Further research will no doubt illuminate yet more.

Hybrid Modes of Organization

Alliances, Joint Ventures, Networks, and Other Strange Animals

Claude Ménéard

1. Introduction

The central message expressed throughout this chapter is that there is a whole class of economic organizations that contribute substantially to what Coase (1992: 713) called “the institutional structure of production.” These arrangements fall neither under pure market relationships nor within “firm boundaries.” They multiply because they are viewed as efficient in dealing with knowledge-based activities, solving hold-up problems, and reducing contractual hazards. They have properties of their own that deserve theoretical attention and empirical investigation.

Indeed, although the significance of these arrangements, hereafter identified as “hybrids,” remains difficult to quantify, they play a major role in developed market economies. Joint ventures, strategic alliances, sports leagues, franchises, and consortia provide rich examples. In a first approximation, hybrids can be defined as arrangements in which two or more partners pool strategic decision rights as well as some property rights¹ while simultaneously keeping distinct ownership over key assets, so that they require specific devices to coordinate their joint activities and arbitrate the allocation of payoffs (Ménéard 1997, 2004). Consequently, this chapter focuses on arrangements with joint mechanisms of governance.² It pays particular attention to multilateral agreements ($n > 2$), so as to build ideal types in which contracts are complemented by other means of coordination.

This chapter owes much to the participants in the National Bureau of Economic Research workshop on “Organizational Economics” as well as to participants in numerous seminars and conferences. I have also benefited from extensive exchanges with the volume editors, Robert Gibbons and John Roberts, and from fruitful questions raised by Claudine Desrieux, Anna Grandori, George Hendrikse, Geoffrey Hodgson, Chris Mantzavinos, Paolo Mariti, Mario Morroni, Joanne Oxley, Emmanuel Raynaud, Oliver Williamson, Josef Windsperger, and many others. The usual disclaimer applies.

1. This chapter follows Alchian (1987) in identifying property rights with the capacity to appropriate residual earnings.

2. Outsourcing illustrates the difficulty of delineating hybrids. Most outsourcing arrangements are of the arm’s length type, with no specific mechanisms of governance besides contracts. However, there are also outsourcing arrangements with coordinating devices going far beyond what is contractible (e.g., the “Toyota system”).

Efforts to capture the specificity of these arrangements within a coherent analytical framework remain underdeveloped. In economics, initial insights came from a coasian perspective, with hybrids viewed as challenging the boundaries of the firm. Richardson (1972) already emphasized the importance of modes of organization mixing cooperation and competition.³ In his pioneering essay on franchising, Rubin (1978: 223) introduced the term “hybrid” as a catchword, extending the trade-off between market transactions and integration to situations in which decisions are jointly agreed on among firms. This view concurred with the analysis developed simultaneously by Klein et al. (1978). Williamson also pointed out early the significance of these nonstandard agreements, although he initially considered them as unstable and transitory before fully integrating hybrids in his model (Williamson 1975, 1991; Ménard 2009). Meanwhile, a significant literature developed in sociology and managerial sciences, mostly about networks and alliances.

Nevertheless, hybrids remain theoretical orphans, as already noted by Borys and Jemison (1989), and this deficiency translates into “a rather messy situation marked by a cacophony of heterogeneous concepts, theories, and research results” (Oliver and Ebers 1998: 549). A rich empirical material has accumulated, while theory has focused on relatively narrow issues. As rightly emphasized by Baker et al. (2002: 71), economists rarely paid attention to these arrangements, and when they did, “the focus has typically been on asset ownership and other formal aspects of organizational structure.”

In this chapter I suggest that the time may have come for economic theory to harvest the abundant insights on hybrids. One obstacle is the diversity of arrangements, from forms close to market relationships to quasi-integrated organizations.⁴ However, I shall argue that structural characteristics underlie this diversity. In doing so, I focus on determinants of existence and conditions of stability of hybrids, with a particular attention to the underlying modalities of governance. Section 2 illustrates distinctive features of hybrids with a stylized case, thereafter substantiated by a visit to the richness of these arrangements. Section 3 discusses forces pushing to go hybrid, in the hope of outperforming markets as well as hierarchies. Section 4 examines challenges hybrids face and strategic choices they can make to overcome opportunism. Section 5 explores the governance mechanisms on which hybrids rely to reach stability and remain sustainable. Section 6 proposes a typology of hybrids based on the combination of the elements thus pinpointed. Section 7 concludes with remarks on unsolved problems and policy issues.

2. What Do Hybrids Look Like?

The fluctuating terminology for hybrids signals conceptual difficulties. Three competing terms prevail in the literature: “hybrids,” mostly used in economics, particularly in the Coase-Williamson tradition; “alliances,” a favorite in management journals; and “networks,” which dominates sociology.⁵ “Symbiotic arrangements,” “clans,” and other terms can also be found,

3. Almost simultaneously, Blois (1972) pointed out the empirical significance of quasi-vertical integration, although with no reference to Coase.

4. Cheung (1983) argued that there is a continuum in organizations and that contract should be the sole focus of attention. In this chapter I try to show why this approach can be misleading.

5. The term here refers to networks of firms, not to network industries.

although more sporadically. “Hybrid” benefits from covering the variety of interfirm agreements while rooted in theory and models explicitly derived from Coase (1937).⁶ I do not intend to emphasize definitional issues here. The fluttering terminology reflects the richness of relationships among businesses using means of coordination alternatives to the price mechanism without integrating. It also reflects the lack of a unified and satisfying theoretical explanation. To fix ideas, I start with an example that illustrates some key issues involved. The picture is then enriched by a visit to the variety of observable forms of hybrids.

2.1. A Stylized Example

In the late 1970s, faced with declining bread consumption and sharp competition from supermarkets using cheap flour and delivering mediocre products at low prices, a group of 35 French millers reacted by developing, successfully, high-quality products signaled by a brand name and supported by a complex organizational arrangement.⁷ This arrangement defines (1) a formal structure, (2) an allocation of rights, and (3) governing modalities that differ markedly from the polar cases of markets and hierarchies.

First, the millers created a legal entity to develop high-quality products, market them, and guarantee compliance to their standards by all partners. This entity—let us call it the “strategic center”—is governed by a board of administration, of which each miller is a member. Decisions by the board are made according to a “one person, one vote” rule, notwithstanding the uneven distribution of capital: at one end of the spectrum, one miller holds 62 shares while at the other end, another miller has 391 shares. The center legally owns the brand name, delegating its use to the millers. The brand is marketed through a network of franchised bakers—nowadays more than 3,000 bakers are affiliated—who commit to sell exclusively products using inputs delivered by the millers or certified by the center. Each miller has an incentive to recruit bakers, whose affiliation is conditional on acceptance and monitoring by the center. Policies regarding the brand are implemented by an executive committee of twelve millers, elected by their peers for 6 years, and a marketing committee of three members. In addition, an ethics committee of three elected millers is in charge of solving conflicts. In sum, the millers own a franchisor to which they delegate the right to monitor and discipline them as well as to supervise the franchised bakers.

Second, this arrangement proceeds through a complex allocation of rights. Each miller keeps control over key assets, that is, mill(s) and the logistics needed to collect inputs and deliver flour. Partners can use these assets for activities beyond the control of the joint entity, for example, producing and delivering flour to industrial bakeries not affiliated to the brand. However, the legally distinct strategic center holds property rights over the brand name and owns several facilities to do research, manage quality control, and train bakers, and it also develops new products. The strategic center thus creates new assets that it formally owns.

Decision rights are allocated accordingly. The millers remain fully responsible for their own resources and their strategies. The strategic center makes decisions regarding the evolution of

6. According to the *Oxford English Dictionary*, the term “hybrid” goes back to 1601 and designates the offspring of two different species.

7. This subsection draws on Ménard and Raynaud (2010).

the brand name (new processes, new products, quality standards, and marketing strategies) and of the governance structure (status of shareholders, contracts with bakers, allocation of social capital, and acceptance of new entrants or exclusion of partners). When it comes to payoffs, each miller remains the sole residual claimant for profits generated by his or her own assets, including benefits from the spillover effects of the brand name. However, royalties paid by the bakers are shared with the strategic center, which also bills services to the millers (e.g., quality control). In principle, profits from the strategic center are redistributed according to the number of shares, although in practice they have been systematically reinvested in the development of the brand.

Third, the governance by the strategic center is framed by contracts and by the above-mentioned ethics committee that operates as a private court.

There are two sets of contracts: contracts linking bakers to the network, which are typical franchise contracts,⁸ and contracts between the millers and the strategic center, which determine the core of the arrangement. Indeed, the millers, who are the shareholders, sign a contract with the strategic center that gives them the right to operate under the brand they formally own. The goal is to promote spillover effects by developing high-quality products, new techniques, and advertisement, while protecting parties against negative externalities, such as millers cheating on the quality of inputs delivered or adopting free-riding strategies to attract or capture franchisees (the bakers).⁹ These goals are embedded in contractual clauses codifying (1) the production process (control over equipment, determination after each crop of the required quality of flour, etc.); (2) marketing conditions; (3) conditions under which the center can ban a shareholder from the arrangement; (4) the right of the center to authorize other millers to supply bakers previously affiliated to a noncompliant partner. These clauses by themselves confer significant power to the center. They are complemented by internal rules and the role of the ethics committee.

Internal rules facilitate upstream and downstream control. Upstream, major decisions—such as changes in statutes, changes in the contracts between millers and the center, or exclusion—require two-thirds of the votes on the board. Rules preventing any miller to hold more than 15% of the rights and prohibiting the sale of shares to outsiders without board approval reinforce this control. Downstream, strict internal rules regulate relationships between millers and franchisees (the bakers): entry is filtered by the center, which also keeps an eye on newly affiliated bakers through a probation of 6 months. Once affiliated, technical and commercial assistance provided by the center facilitates control over the relationships between a miller and the bakers in his pool.

Last, the so-called “ethics” committee operates as a private court regulating intrabrand competition. Indeed, the reputation premium of the brand name (remarkably stable at about 10%) as well as competition among millers to attract new bakers or capture affiliated ones fuel incentives to free ride. The elected ethics committee is there to thwart these strategies thanks to significant discretionary power, particularly the possibility to impose penalties or recommend exclusion of repeatedly noncompliant millers. On all these issues, the board operates as a court of appeal. With formal contracts binding partners, it would be technically possible to turn to

8. See Lafontaine and Slade (2007).

9. The affiliation of bakers determines volume sold and hence, profits. A typical free-riding behavior for a miller is to capture a baker who has been prospected and possibly initiated by another miller of the group by offering advantageous conditions—because the free rider did not invest in the search and training process.

the legal system. However, this approach is viewed as disruptive and risky, incompleteness of contracts making the issue highly uncertain. After 30 years of implementation, partners have never resorted to courts.

To sum up, this case illustrates a mode of organization in which co-owners, who compete in their joint activities as well as in activities independent of their arrangement, delegate to a specific entity the right to monitor and discipline them. They do so because the arrangement can create new assets that generate extra profits while simultaneously producing positive externalities¹⁰ on their other activities. The complex allocation of rights that support the formal architecture involved as well as the mechanisms of governance needed for the success and durability of the arrangement is not specific to the millers' case.

2.2. A Brief Visit to the "Zoo"

Indeed, this stylized example captures only part of the richness of forms mixing cooperation and competition in interfirm relationships. From joint ventures to franchisee-owned franchisors, sports leagues, condominiums, consortia, or even cooperatives, "firms have invented far more ways to work together than organizational economics has so far expressed (not to mention evaluated)" (Baker et al. 2008: 146). In what follows, I focus on situations in which firms pass decision rights and even property rights across boundaries, so that some rights are no longer controlled by a single party. I illustrate the variety of solutions implemented by several different institutional structures dealing with shared control. This review is not intended to be exhaustive but rather points out properties analyzed thereafter.

In its usual form, *subcontracting* borders on standard market relationships, with parties sharing some decision rights while keeping assets and property rights distinct. For example, Toyota shares with its privileged subcontractors substantial decisions regarding the design of its cars. This arrangement often relies on the stability of the relationship. In a pioneering paper based on extensive interviews with 38 homebuilders in eastern Massachusetts, Eccles (1981: 339) discussed agreements between general contractors and subcontractors "over fairly long periods of time and only infrequently established through competitive bidding." Although most projects were short term, coordination requirements and the need for constant adaptation provided incentives to operate with the same partners. On average, relations persisted for more than 5 years (one persisted for 37 years), largely exceeding the duration of formal contracts. In more than 80% of the cases, subcontractors were selected through bilateral negotiations; less than 20% went through competitive bidding. This process does not discard the role of competition: the possibility of bidding maintains pressure. Other studies, particularly in the automobile industry, have shown the diversity of subcontracting, from arm's-length relationships to forms closer to supply-chain systems, up to quasi-integration (Helper and Levine 1992; Dyer 1997; Holmström and Roberts 1998). However, they all share at least two characteristics: key assets and decision rights remain distinct (as in the case of the millers), while one firm operates as the strategic center (which is distinct from the millers).

10. For example, the reputation gained through the brand has a positive impact on a miller's relationship with parties not dealing with the brand (e.g., industrial bakeries or restaurants).

Supplier parks, “a cluster of suppliers located adjacent to, or close to, a final assembly point” (Sako 2005: 3), share properties with subcontracting, although site interdependence usually imposes tighter coordination. The Volkswagen assembly line of trucks and buses in Resende, Brazil, is typical. Several firms operate under the same roof. They keep key property rights and decision rights distinct (several also supply competitors). However, specific assets and substantial decision rights are shared on the site (e.g., decisions regarding the physical distribution of equipment or the adjustments among partners along the assembly line imposed by the modular design of the subsystems). Supplier parks can also be partially virtual (e.g., Toshiba and its 200 direct partners and 600 “grandchild companies”) or almost entirely so, as with Dell.¹¹ In all cases, the allocation of rights and payoffs as well as coordination devices remain an issue.

Whether physically located or virtual, supplier parks mostly operate under the control of one firm. However, there are cases in which shared activities are monitored through different forms of joint agreements, with partners in a more or less symmetrical position. *Strategic alliances* have attracted a lot of attention in managerial sciences. They can be characterized as “the relatively enduring interfirm cooperative arrangements, involving flows and linkages that utilize resources and/or governance structures from autonomous organizations, for the joint accomplishment of individual goals linked to the corporate mission of each sponsoring firm” (Parkhe 1993: 795). Partners maintain distinct core assets and keep control over related property rights, thus departing from mergers and acquisitions. However, they jointly plan and monitor substantial activities, as in the airline industry, using contracts to coordinate and build relational trust, which particularly matters when duration imposes continuing adjustments, making spot or short-term agreements of the market type inappropriate (Jorde and Teece 1989; Gulati 1995b). Using a database of 12,500 contracts between biotech and pharmaceutical firms from 1973 to 2001, Baker et al. (2008) showed that the twelve top biotech firms and the twelve top pharmaceutical firms were directly involved in more than 32% of the alliances in the sector. Hence, a few firms form many alliances, defining a dense network of ties mostly related to research and development (R&D) projects (55% of the contracts). However, other studies show that R&D alliances can also be a one-shot game (Ryall and Sampson 2006). Holmström (1989) suggested that R&D projects may be prone to alliances because they are: (1) risky, (2) unpredictable, (3) long-term and multistage, (4) labor intensive, and (5) idiosyncratic. The resulting problems of observability, with related risks of opportunism, push toward constraining contractual clauses and cautiously delineated rights. However, R&D projects are not the only engine of alliances. Strategic alliances exist in many other activities, from wholesaling in the American hardware industry (Dwyer and Oh 1988) to the airline industry (Holmström and Roberts 1998) to alliances between equipment and component suppliers (Artz and Brush 2000). In all these arrangements, the relative symmetry among partners give contracts a key role as a coordinating tool.

Supply chain systems also rely on contracts, but they differ from strategic alliances with respect to the density and extension of shared rights. Based on complementary activities and/or competencies among autonomous partners, they require tight coordination across stages, usually from production to distribution. In a pioneering paper, Brown (1984) pinpointed the tight

11. Some integrated firms attempt to replicate traits of these external networks, for example, ABB and its 1,200 autonomous entities and 4,500 profit centers (Achrol 1997).

organization of transactions among independent parties in the dairy milk industry through administered channels that monitored quantities, controlled assortment, and guaranteed quality. Ménard (1996) exhibited similar arrangements in the poultry industry, with a complex set of contracts linking growers, slaughterhouses, integrators, and distributors. The design varies, according to whether the arrangement is monitored by a leading firm or a specific governing entity. Supply-chain systems benefit from powerful market incentives while providing tight control over key transactions, without the burden of integration. The analysis of these forms is a booming industry, in the agrifood sector, logistic, and so on.¹²

Supply chains almost always involve production, while *franchises* concern primarily distribution. However, boundaries between these forms are blurred, many franchisors having developed tight vertical coordination to control inputs as well as output, as illustrated by McDonald's. What differentiates franchising from most supply chains is the large number of partners abandoning part of their decision rights while pooling property rights to benefit from brand names and joint actions. Franchise systems also share characteristics of subcontracting because of the central role of the franchisor, whether it is a unique entity or a group, as in the millers' relation to bakers. The now-abundant literature on franchising almost entirely focuses on agency problems and financial constraints as explanations of their existence, with little concern so far for the various forms they take and the problems of governance they raise beyond incentive issues (but see Lafontaine and Slade 2007, this volume).

Joint ventures exhibit important characteristics of hybrids in a relatively pure form. Joint ventures "are simultaneously contractual agreements between two or more organizations and a separate legal (and usually organizational) entity with its own purpose" (Borys and Jemison 1989: 245; see also Hennart 1988: 361–362). Parent companies transfer some assets and property rights as well as some decision rights to a child company monitored by a specific governing body, while parents remain autonomous and often compete on other activities. This mix of global sovereignty and local cooperation involves forms of hierarchy that complement contracts. The motivation comes from expected gains, either from knowledge-based activities requiring competences that exceed separate capabilities (as in R&D projects) or from economies of scale (as when competing automakers jointly produce transmissions). However, joint ventures confront issues of governance (e.g., about rights they can claim over parents' resources), of loss of control (e.g., the irreversibility of transfer of knowledge), and of rent allocation (e.g., measuring the value added of scientists involved in joint activities). Such problems may explain the short lifespan of many joint ventures (Hennart 1988).

There are many other ways to organize interfaces among partners. *Partnership* is another nonstandard mode of organization, taking various forms, from law firms to the collective organization of salmon fishermen of the Pacific Northwest (Farrell and Scotchmer 1988). These arrangements often develop to deal with common pool resources. *Cooperatives* define another important category, almost a class of its own. The variety of their forms makes their characterization difficult, because they are spread over a wide spectrum, from quasi-integrated firms to marketlike arrangements. However, numerous cooperatives share characteristics of hybrids with respect to the joint allocation of rights and their mode of governance, dominated by the "one person, one vote" principle (see Hansmann 1988; Ménard 2007b).

12. See such journals as *Supply Chain Management* and *Journal of Chain and Network Sciences*.

In sociology and managerial sciences, hybrids are often described as *networks*.¹³ In a pioneering paper, Thorelli (1986: 37) characterized networks as long-term relationships between two or more organizations. Powell (1990) suggested a distinction between (1) networks structuring craft industries (e.g., construction or publishing), (2) networks shaping industrial districts (e.g., the Modena area or Silicon Valley), (3) networks framing vertical disaggregation (e.g., subcontracting in the automobile industry), and (4) networks organizing horizontal coordination (e.g., strategic alliances and partnership). The term then becomes a label more than a concept. A more specific approach, closer to Thorelli and to our concept of hybrids, identifies networks with durable collective action that requires specific governance. Early developments in the telephone industry illustrate the point (Barnett 1990; Barnett and Carroll 1993). The introduction of wire coils and new power technology at the beginning of the twentieth century allowed the expansion of long-distance calls, which required coordination among hundreds of companies (public and private), cooperatives, and “farmer lines” operated by groups of farmers.¹⁴ Coordination imposed technological standardization, while parties maintained differentiated services and distinct rights. Similarly, the development of automated teller machines substantially increased the volume of transactions and the variety of services but also required costly coordination and control among banks, with ambiguous organizational effects between incentives to integrate and incentives to outsource (Clemons and Row 1992). The notion of network is also often used, particularly in sociology, to tag minisocieties “of interdependent, reciprocal exchange relationships” (Achrol 1997: 68), shaped by “the density, multiplexity, and reciprocity of ties and a shared value system defining *membership* roles and social responsibilities” (Achrol 1997: 59). Aoki (2001: 366–370) described venture capitalists of Silicon Valley accordingly.

All these arrangements as well as others (condominiums, consortia, etc.) differ from integrated solutions (the “firm”), which rely on a center that keeps control over decision rights and owns assets in the last resort, with residual claimants well identified. They also differ from markets, at least as defined in the neoclassical tradition, because markets preclude central coordination, so that assets and related payoffs remain with separate owners, parties interacting exclusively through prices or through contracts that respect their autonomy of decision. However, hybrids can lean toward one or the other of these polar cases, depending on the intensity of the coordination required and the density of rights shared (see Section 6).

To contrast hybrids with hierarchies or markets, let us boil their properties down to their simplest content. Let us consider two firms, 1 and 2, and four assets $\{A, a; B, b\}$, with A and B related to the core activity of 1 and 2, respectively, and remaining within their boundaries, while a and b are assets valuable only if used jointly. Each firm holds full decision rights, D_A and D_B , while rights d_a and d_b require coordination, because they are linked to the joint usage of a and b . The resulting payoffs are therefore Π_A , Π_B , π_a , and π_b , with the last two generated if and only if the corresponding assets are jointly used (profits are zero otherwise). Last, we identify the

13. The term “cluster” is also used, although less often.

14. During 1910–1930, 707 companies were operating in Pennsylvania. Interestingly, public authorities facilitated coordination. Between 1904 and 1919, 34 states adopted laws mandating interconnection among proximate systems. At the federal level, the Kingsbury agreement obliged large American firms to accept connection all over the United States.

Figure 1. Modes of organization contrasted.

governing entity, if it exists and whatever form it takes, as the strategic center. Three resulting ideal types (markets, hierarchies, and hybrids) are summarized in Figure 1.

In markets, rights are allocated distinctly, and partners process transactions through the price system, without the interference of a joint strategic center. Cooperation that might be required to value some assets is monitored through contracts that do not encroach on the rights of the parties. In firms, divisions hold rights under delegation: in the last resort, they remain submitted to the control of the strategic center (the “headquarters”). In hybrids, key rights are in the hands of autonomous partners keeping title as residual claimants, while subsets of assets, rights, and associated payoffs are shared and monitored jointly. The following three sections explore further why parties prefer this last variety of arrangements, what makes them sustainable, and what governance mechanisms could allow them to outperform other modes of organization.

3. Why Go Hybrid?

Understanding why firms invest in projects that require loss of control over key rights raises important questions. Why do firms accept this loss of control? What forces push parties to go hybrid, rather than relying on pure market relationships or fully integrating?

As already noted by Rubin (1978: 223), these questions are very much in line with the problem raised by Coase (1937; see also Cheung 1983). Choosing alternatives to markets as well as to integration is motivated by expectations of improved allocation of resources: if hybrids exist and remain stable over time, it is likely because under certain conditions, they are better at handling transactions. However, the paucity of economic explanations of why hybrids develop is striking.¹⁵ In what follows, I briefly review theories, embedded in models exposed in other

15. Other disciplines were faster in taking into account hybrids. Grandori and Soda (1995) already provided a stimulating survey of organization studies on hybrids, while Oliver and Ebers (1998) reviewed a large set of contributions already available in sociology and managerial sciences.

chapters of this book, assessing the existence of hybrids. I then turn to a highly relevant empirical literature that relates only partially to these models to better understand forces favoring hybrids.

3.1. Theoretical Explanations

Any satisfactory explanation of hybrids must shed light on what motivates parties to pool strategic assets and share rights without integrating. It must also exhibit how these distinctive arrangements can provide adequate safeguards against risks of free riding while keeping incentives superior to alternative solutions. The conception of the firm as a production function and of markets as a price-formation device do not even account for the existence of hybrids. Economies of specialization (as in the construction industry), of scale (as with shared trademarks), or of scope (as in joint R&D projects) likely play a role in the decision to pool resources, but they do not explain why the optimal solution would not be merger or acquisition.

Only recently has economic theory addressed hybrids, with transaction cost economics playing a pioneering role. Agency theory and relational contract theory have also taken into account some hybrid forms, while less-developed approaches, such as the resource-based view, have provided useful insights. Because leading theories are presented in other chapters of this book, here I report only elements relevant to the analysis of hybrids.

3.1.1. *Transaction Cost Economics*

Transaction cost economics (TCE) deserves priority. The idea that there are alternative ways to organize transactions goes back to Coase (1937), followed by Williamson (1975). Both focused on the trade-off between markets and firms. However, in *Markets and Hierarchies*, Williamson (1975: 109) noted the existence of “intermediate forms of contracting,” but he expressed doubts about their stability and considered them as transitory. It is only in *The Economic Institutions of Capitalism* that he endorsed a more positive approach to arrangements later christened “hybrids,” going as far as considering them potentially “dominant” (Williamson 1985: 83). In 1991, he explicitly modeled them as a governance structure that could be an efficient alternative to markets and hierarchies, from which they differ with respect to (1) contract law, (2) adaptability, and (3) incentives and control (Williamson 1991). Hybrids would fit transactions requiring assets of intermediate specificity and facing moderate uncertainty, thus providing a middle-of-the-road solution. The resulting concept remained a bit fuzzy, with its reference to “semi-strong” governance captured essentially through “contract law.” This vagueness may explain why some Williamsonians questioned the possibility of a theory of hybrids (Masten 1996: 12), while critics challenged the idea that the attributes distinguishing hierarchies from markets (asset specificity, uncertainty, and frequency) provide adequate tools to understand the existence and properties of hybrids (Powell 1996; Hodgson 2002).¹⁶

Nevertheless, TCE has inspired a huge empirical literature (see Section 3.2), partly oriented toward enriching the heuristic model to substantiate the reasons that parties go hybrid. An illustration is provided by Artz and Brush (2000), who addressed the often rehearsed criticism,

16. From a different perspective, Holmström and Roberts (1998: 92) argue that “many of the hybrid organizations that are emerging are characterized by high degrees of uncertainty, frequency and asset specificity, yet they do not lead to integration.”

going back to Granovetter (1985), that TCE does not capture the social dimension supporting interfirm agreements. To include the role of interactions in the governance of hybrids, they introduced relational norms as a complementary attribute (see also Gulati et al. 2000).¹⁷ Using a different perspective, Ménard and Klein (2004) emphasized that the complexity of the transactions at stake might explain the decision to go hybrid, while Ménard (1996) noted that interdependent transactions may command such arrangements when parties want to avoid the drawbacks of integration, particularly bureaucratic costs and weak incentives. Notwithstanding their limits, these contributions and numerous others testify to the efforts of TCE to better capture the nature and strength of hybrids as alternatives to markets or hierarchies.

3.1.2. *Relational Contracts*

In partial continuity with TCE, the literature on *relational contracts* has shown a growing interest in hybrids (Klein et al. 1978; Klein and Murphy 1988; Baker et al. 2002; Malcomson, this volume). The initial inspiration comes from Macaulay (1963) and MacNeil (1974, 1978), who introduced the expression “relational” to emphasize the mix of contractible and noncontractible elements and the importance of the latter.¹⁸ According to Goldberg (1980; also Baker et al. 2002), parties establish tight bonds to limit the impact of (1) imperfect and costly information, (2) opportunistic behavior, and (3) difficulties for outsiders to enforce agreements plagued with nonverifiable elements. Hence, “the parties will be willing to absorb a lot of apparent static inefficiency in pursuit of their relational goals” (Goldberg 1980: 339).

Formalizing this approach in a model initially developed to account for labor relations within firms, Baker, Gibbons, and Murphy combined TCE and the new property rights theory to explain what forces push firms toward such solutions as joint ventures or strategic alliances (Baker et al. 2008). In this version, they differentiate governance structures according to how rights over assets and spillover payoffs are allocated. Even if relational contracts might help deal with noncontractibilities, they can also generate tensions and conflicts, and the magnitude of the resulting transaction costs depends on whether the coordinated use of assets complements or competes with the core activities of parties involved. The problem then becomes that of choosing a governance structure that allows parties to maximize their payoffs while facilitating adjustments. Hybrids provide alternative solutions, possibly optimal ones, when there are significant noncontractibilities.¹⁹

17. Using a survey of 400 firms specializing in industrial and machining equipment, electronic and electrical machinery, computer equipment, and transportation machinery, Artz and Brush (2000) approximated relational norms through three components (with associated proxies): collaboration, continuity in shared expectations, and communication strategy.

18. When referring to “relational contracts,” economists emphasize the rational behavior of parties expecting future exchanges, while sociologists, who also refer to “relational governance,” intend to capture norms and social ties emerging from prior exchanges (Poppo and Zenger 2002: 710). In the managerial literature, “relational” often refers to informal contracts as opposed to formal ones (Carson et al. 2006). In line with Goldberg (1980), Baker et al. (2002) or Malcomson (this volume) instead seek to incorporate noncontractible elements into the analysis.

19. This approach departs from the prevailing one in “the new property rights,” which focuses on who of A or B owns assets; joint ownership may be feasible but most of the time is considered to be suboptimal (see Holmström 1999, who emphasized that in that approach it never pays to have joint ownership, because either side can veto the use of assets). Halonen (2002) extended the Grossman-Hart-Moore model (see Hart and Moore 1990) to cases in which it could be optimal to share some rights, but it is not clear if we end up with a different governance structure or simply a distinct sharing rule.

A major characteristic and a limitation of this explanation is that rights ultimately remain in the hands of separate entities, while noncontractibilities make agreements unenforceable by courts, so that the outcome depends on (relational) reputation. As Macneil (this volume: Section 13) rightly emphasizes, “relational contracts in these models are a substitute for enforcement by courts, not a substitute for careful planning.”

In contrast to TCE, this approach so far remains an exercise in theory. Some empirical analyses relate to “the spirit” of relational contracts in that they try to capture ex post adaptations when some decisions are noncontractible. For example, referring explicitly to MacNeil (1978) and Baker et al. (2002), Poppo and Zenger (2002) use 152 reliable responses (out of 181) from randomly selected senior corporate managers of information services to show that relational governance complements formal contracts. “Relational governance” is here understood as social processes emerging from repeated interactions that facilitate adaptation.²⁰ However, such tests have limited relevance to the theory because of conceptual differences (e.g., between relational governance and relational contract).

3.1.3. Agency Theory

There are alternative explanations to the existence of hybrids. *Agency theory* inspired numerous research papers on franchising (Brickley and Dark 1987; Lafontaine and Slade 1997, 2007), with incentives and financial motivation viewed as the main issues. For example, Maness (1996) and Holmström and Roberts (1998) suggest that franchise dominates fast food but not supermarkets because franchising provides better incentives to local managers having to monitor multiple inputs simultaneously, while costs in supermarkets mostly come from inventory and warehousing, which can be handled through specialized functions within an integrated structure. However, Lafontaine and Slade (1997, 2007) demonstrated that franchise contracts do not deliver tailored incentives, and that financial motivation has a weak explanatory power, contrary to what the theory predicts. More generally, Lafontaine and Slade (2007) have shown that TCE prevails over agency theory when it comes to predictability, and that the latter hardly explains the existence and variety of franchise systems.

3.1.4. Resource-Based View

The *resource-based view* is another influential approach, particularly in organization studies and management sciences. In essence, it conceives of networks and other hybrids as ways to deal with uncertainties and change by sharing essential inputs, particularly competencies (Wernerfelt 1984; Nooteboom 1999: 8–42). A positive contribution of this view is to have attracted attention on the key role of learning and capabilities. However, it hardly explains why integration is not preferred to hybrids and why there are so many ways to face uncertainty.

To sum up, we still need a convincing theory telling us why hybrids exist and prosper and how they differ from alternative modes of organization. However, and notwithstanding their limitations, the contributions summarized above help frame the partial explanations dispersed in the empirical literature.

20. Relational governance is captured through four dimensions: open communication and sharing information; trust; dependence; and cooperation, with associated indicators focusing on relations between vendors and buyers.

3.2. Empirical Evidence

A substantial part of this literature can be related to the unsettling question raised by Simon (1951) and reactivated by Cheung (1983): why do autonomous economic entities abandon substantial rights without certainties about the payoff? More specifically, why are there arrangements that purposely avoid relying primarily on prices to coordinate without going as far as integration, in the hope of outperforming markets as well as hierarchies? Three determinants emerge from an abundant literature only partially grounded on the theories above: improved capacity to face uncertainty, the creation of value through mutually accepted dependence, and expected spillovers if adequate sharing rules are implemented.

3.2.1. *An Instrument to Deal with Uncertainty*

A possible motivation to go hybrid is that sharing rights and pooling resources improve capacities to face uncertainty. I understand uncertainty as contingencies difficult or impossible to predict that generate adaptation problems (John and Weitz 1988). As already pointed out by Eccles (1981) in his study on the construction industry, interfirm connections respond to a combination of the specificity and high variability of each project, making adaptability a key issue.

Uncertainty has always been viewed by TCE as a key attribute conditioning organizational choices *ex ante*. TCE also shares with the relational contract approach the idea that *ex post* non-contractibilities impose adaptation, determining the fitness of these choices. However, there are few tests in economics of the role of uncertainty in the decision to go hybrid,²¹ although uncertainty is viewed as a driving force in the sociological and managerial literature (Gulati and Gargiulo 1999). For example, Carson et al. (2006: 1059) proposed a distinction between volatility, defined as “the rate and unpredictability of change in an environment over time,” stemming from exogenous shocks, and ambiguity, understood as “the degree of uncertainty inherent in perceptions of the environment state irrespective of its change over time.” Using data from 125 informants on client-sponsored R&D relationships, they showed that formal contracts would be inefficient when volatility is high, while relational contracts fail when ambiguity is high.

This result suggests diversity in the types and sources of uncertainty, pushing parties to pool resources without integrating. It might partially explain the variety of hybrids. First, demand can be unstable or unpredictable. Using a survey of 183 responses collected in three Canadian industrial sectors (nonelectrical machinery, electrical and electronic machinery, and transportation equipment), Joshi and Stump (1999) showed that market turbulence plays a more significant role than competitive intensity in the decision to go hybrid. Second, technological change can promote hybrids as a mean to accelerate innovation or its adoption (Park 1996; Ghosh and John 1999; Powell 2003; Ryall and Sampson 2006). Superior technologies require a flexibility that the bureaucracy of integrated firms hardly provides, while hybrids would benefit from shared learning and resources (Anderson and Gatignon 2005). Third, variations in the quality of inputs and/or outputs may require tighter coordination than markets provide, as supply chain systems illustrate (Ménard and Valceschini 2005). Fourth, the risk of opportunism might encourage

21. There are some tests on the role of uncertainty in decisions to integrate, for example, Anderson (1985) and Saussier (2000), who estimated the role of uncertainty in the make-or-buy trade-off.

constraining agreements that mitigate hazards while preserving autonomy on key decisions. The role of opportunism in organizational choices (Williamson 1975: 26–30) underlies countless tests, starting with Anderson (1985).²² It provoked strong reactions, particularly among sociologists, who defend trust as a more likely response to uncertainty. In both cases, there is room for hybrids. Finally, unsecured environments (e.g., property rights poorly defined or not backed by adequate institutions) generate “appropriability hazards,” as in technology transfers, which hybrids could overcome without the disadvantages of full integration (Oxley 1999).

In developing joint strategies, sharing knowledge and risks, implementing common standards, and adopting adequate governance, hybrids might provide solutions not available to alternative arrangements (Robinson and Stuart 2007; Baker et al. 2008). This possibility could explain preferences for socially embedded relationships rather than arm’s-length relationships when uncertainty is high (Khanna 1998; Gulati 1998), when high adaptability is required (Uzzi 1997; Podolny and Page 1998), or when it is difficult to differentiate between poor performance and bad luck (Park 1996: 803). However, the exact impact of uncertainty on the choice and performance of hybrids remains underexplored, likely because of difficulties in finding adequate proxies and collecting appropriate data.

3.2.2. *Creating Value through Accepted Interdependence*

Partners in hybrids share some rights and assets, although often remaining competitors and being uncertain about possible payoffs, as illustrated by the millers’ case (see Section 2.1) or sports leagues. Why do they accept this mutual dependence on strategic segments of their activities, even when uncertainty is low?

An unambiguous answer is that they expect added value from their joint investments as well as from the spillover effects of these investments on assets and capabilities not pooled: they commit in the hope of creating value otherwise unattainable (Borys and Jemison 1989: 241). This strategic choice goes beyond cost minimization (Gulati 1998). As noted by Madhok and Tallman (1998: 336), “the flows of quasi-rents that stem from the dynamics among these relationships tend to hold the system together so long as the participant actors recognize that rents could well disappear with the alliance relationship, thus providing an economic incentive to avoid opportunistic actions.”²³

What are the sources of this added value?

Size is one possible determinant. When investments exceed the capacities of parties working solo (e.g., marketing products, promoting standards, and supporting R&D), firms might expect rents from bundled resources.²⁴ Joint assets might generate economies of scale and/or economies of scope (Park 1996). However, this explanation remains limited, notwithstanding advantages based on technology. First, if capital markets are efficient, why cannot firms find adequate support from banks or other lenders rather than taking the risk of pooling strategic

22. It is also a key argument used by Hansmann (this volume) to explain the existence of franchisee-owned franchisors.

23. See also Klein et al. (1978) and Klein (1996).

24. Powell (2003) argues the other way around: spin-offs would often be preferred to multidivisional structures by large corporations in order to benefit from financial advantages (e.g., obtaining federal grants, issuing stocks, and attracting new investors fascinated by the “new economy”) as well as from legal ones (e.g., limited liability).

resources? Second, if size matters, why not integrate? In a survey of 225 independently owned companies in the human biotechnology sector during 1990–1994, Powell et al. (1996: 120) showed that it is from building “a sea of informal relations” rather than from size that firms expect gains.²⁵

In that respect, complementarity might provide a powerful incentive to go hybrid. If it secures supply of existing resources, allows access to new resources, or facilitates diversification, mutual dependence becomes strategically valuable. In the same vein, separate firms may not have the resources to develop independent absorptive capacities (Cohen and Levinthal 1990), thus motivating strategic alliances, joint R&D projects, and the like. Complementarities between innovative firms and well-established ones when financial markets impose tight constraints may also encourage hybrid arrangements. Lerner et al. (2003) argue that the receptivity of financial markets to biotech is cyclical, so that when markets are cold, biotech firms turn to pharmaceutical and chemical firms. However, complementarities involve risk: innovation may fail, demand may change, and partners may behave opportunistically. Numerous studies emphasize the role of relational norms and social ties as buffers against these risks (e.g., Heide and John 1992; Artz and Brush 2000).

Learning effects provide another incentive to go hybrid, partially overlapping with complementarity. When markets cannot adequately bundle tacit knowledge and capabilities while firms need skills they cannot develop autonomously, incentives to join forces develop (Teece et al. 1997; Madhok and Tallman 1998; Ryall and Sampson 2006). Hybrids become portfolios of the skills they transfer and recombine, allowing novel syntheses (Powell et al. 1996; Stuart and Podolny 1996; Dyer and Singh 1998; Podolny and Page 1998; Powell 2003). However, joint learning effects remain difficult to capture and model, so that assessing their role is challenging.

These factors point out expected gains from pooled resources. However, sharing resources has drawbacks: it requires interfirm planning, which restricts individual decision rights and might generate costly negotiations and/or renegotiations. So why not prefer integration? Coase (1937) suggested limited managerial capacities as an explanation. Williamson (1996: 150) goes a step further, arguing that “selective intervention” that would allow integrated firms to replicate successful properties of alternative arrangements can hardly be achieved. Brickley and Dark (1987) argue that franchising develops because acquisitions may be too costly or too difficult to swallow, or resources needed to integrate may be too difficult to evaluate (see also Madhok and Tallman 1998; Brickley 1999). Baker et al. (2002) propose an alternative explanation. Upstream ownership decreases downstream parties’ temptation to renege but creates temptation for the upstream party to renege. If the first consideration dominates, integration is optimal; otherwise, sharing rights through nonintegrative arrangements could offer the appropriate solution.

3.2.3. Sharing Rent while Checking Opportunism

Williamson (1991) argued that when markets do not provide adequate coordination, hybrids might be the first best, because they maintain higher incentives than do integrated firms. Incentives in hybrids are three dimensional: (1) each firm remains a residual claimant on payoffs provided by its own assets; (2) each partner can claim a share of the rent generated by jointly used assets; and (3) all partners may cash rents from activities unrelated to the arrangement,

25. “We argue that when knowledge is broadly distributed and brings a competitive advantage, the locus of innovation is found in a network of interorganizational relationships” (Powell et al. 1996: 119).

thanks to spillover effects of their joint reputation. In sum, parties accept mutual dependence because they expect increased ex post surplus, which improves ex ante incentives to join and invest.²⁶

In that context, allocation of asset ownership becomes a key issue, because “[it] provides levers that influence bargaining outcomes and hence incentives” (Holmström and Roberts 1998: 79). However, this reasoning presumes the possibility of an unambiguous distribution of rights, while in many hybrids payoffs of types (2) and (3) are not contractible, or only partially so. Going hybrid and relying on relational contracts might then be an efficient solution when costs of integration would be too high and contributions from interdependent assets are difficult to assess. This approach is consistent with Hansmann (this volume), who emphasizes the trade-off between costs of ownership and those of contracting when choosing a mode of organization. Although there are cases of returns strictly proportional to equity shares, as in many joint ventures, most hybrids rely on incomplete agreements. This reliance comes about because standard contracts perform poorly or because of measurement problems, as in joint R&D, so that “organizing a satisfactory split of the gains becomes non trivial” (Ghosh and John 1999: 133).²⁷ Inadequate allocation of rents could challenge the comparative advantages of hybrids, with partners (1) scaling back investments, (2) adapting less, or (3) forgoing activities that raise hazardous measurement problems. This explains why hybrids are often considered suboptimal (Rey and Tirole 2001).

If we keep in mind this strategic significance of rent sharing rules in hybrids, we would expect an abundant literature on this issue. It is not so. Contributions remain scarce and focus essentially on two mechanisms, royalties and tournaments, which both presume well-defined rights. Royalty rules have been explored extensively for franchise systems. They typically have a linear form, such as

$$\text{Fees} = F + \beta y,$$

where F is a lump sum; y is the total sales; and β is the royalty rate, in most cases in the 4–8% range (Lafontaine 1993; Lafontaine and Slade 1997). This standardized rule challenges the idea that contracts vary incentives to match specific conditions across sectors, regions, or the like. Ménard (1996) reached a similar conclusion in his analysis of producers’ groups in the certified agrifood sector, and Rubin (1978: 227) already wondered why franchisees accept such rigid rules.²⁸

26. In the parlance of game theory, partners cooperate because they expect a net positive value. Parkhe (1993) compares strategic alliances to a stag hunt, with hunters pooling their skills in hope of capturing stags rather than free riding in hope for some of them to bag a rabbit. Cooperation then dominates alternative strategies.

27. Referring to 42 R&D alliance contracts, Ryall and Sampson (2006) noticed that in most cases property rights were allocated according to who the primary developer is. This approach does not solve problems that emerge when anteriority is unclear or when input contributions are difficult to identify, which is often the case with hybrids.

28. Rubin’s answer was that parties prefer this arrangement rather than relying on capital markets because it would better motivate franchisors. “The most plausible explanation seems to be that the franchisee has some incentive to motivate the franchisor to be efficient—that is, just as the franchisor desires the franchisee to run the operation efficiently, so the franchisee desires to give the franchisor an incentive to be efficient in those aspects of the relationship which require an ongoing performance by the franchisor” (Rubin 1978: 227).

A variation of this rent sharing rule, and a more flexible one when factors determining contributions are difficult to assess, is to rank parties according to specific variables, with the possibility of integrating qualitative factors. Using data from contracts among growers and integrators in the poultry industry, Knoeber (1989) showed that ranking growers allows the parties to (1) adapt cheaply to changing productivity without renegotiating; (2) bind growers to integrators when the former provide their own assets; (3) induce self-selection of high-quality growers;²⁹ and (4) facilitate truthful revelation.³⁰

However, tournaments depend on the capacity to rank contributions and match them with contributors, which is hardly the universal case in hybrids. As argued by Ménard (2004; see also Oudot and Ménard 2010), when transactions become complex and contributions are not verifiable, as in R&D projects, noncontractible rules, such as fairness (Grandori and Soda 1995: 196) or perceived equity (Fehr and Schmidt 1999) and ex post bargaining tend to prevail.

These insights remain limited. Many discussions on sharing rules in hybrids focus on specific devices based on the allocation of risks, for example, (1) fixed prices in chain systems in which suppliers support all risks, (2) target prices with shared risks, and (3) cost-plus formulas in which the buyers support all risks. These solutions apply to situations with rights unambiguously identified. When it comes to noncontractibles, the literature remains elusive. Because finding ways to share rents while preventing free riding is so crucial to hybrids, this paucity of analyses is striking. It may be due to the neglect of hybrids by economic theory but also to the difficulty of capturing how rents are allocated without well-defined, contractible rights.

4. How to Face Opportunism: Sustainability of Hybrids

The difficulties that hybrids face in finding appropriate sharing rules to cash positive externalities from their interaction while simultaneously confronting competitive pressure from partners as well as from outsiders are a source of tension and impose hard choices.³¹ Solutions condition the possibility for hybrids to outperform markets as well as hierarchies. The survival and stability of hybrids depend on their capacity to find the right partners, to circumscribe risks of opportunistic strategies, and to implement procedures for arbitrating conflicts and reducing tensions among parties.

4.1. Challenges to Stability

Hybrids combine joint efforts and competing goals, which continuously create tensions among partners who intend to maintain a fruitful cooperation while valuing their own assets. Richardson (1972) already emphasized variations in tensions among partners to interfirm agreements,

29. Contracts can be canceled if a grower's performance is consistently below average.

30. Other references to tournament rules among partners in agrifood chains are Tsoulouhas and Vukina (2001) and Wu and Roe (2006). A reference to sports is Ehrenberg and Bognanno (1990), which deals with golf—a limited example, however, because performance can be easily associated with individual golfers.

31. Sako (2005) illustrates some of these dilemmas using the example of supplier parks. Should firms favor: (1) Modularity or outsourcing? (2) Voice (commitment) or exit (flexibility)? (3) Diversified employment governance or a unified one? (4) Suppliers' roles as assemblers or as partners?

depending on whether they share physical assets while competing or build joint resources to benefit from complementarities without competing.

First, there is the strategic decision about what resources to pool. Partners might (1) develop a subset of resources from which each one can draw, as in many R&D projects; (2) share resources sequentially, as with logistics in supply chain systems; or (3) build and maintain joint assets, as in collective trademarks. Pooling financial resources is a classical example: it is a leading explanation to the existence of franchising,³² in that it allows expanding into markets otherwise hardly accessible (Brickley and Dark 1987; Oxley 1999). It also tightens bonds among partners in networks (Aoki 1988: 102).³³ Pooling physical assets might also support mixed strategies, as with laboratories jointly built and monitored by partners in the biotechnology industry (Powell 1996). Similarly, sharing human assets may allow spillover effects in competencies and know-how. However, pooling resources challenges the competitive advantage that each partner could expect from developing its own specific assets. Hence, partners confront the need to commit versus the risk of capture.

Second, the combination of separate and shared rights makes monitoring and disciplining parties particularly challenging and is used as an argument to qualify hybrids as second best (Rey and Tirole 2001; Baker et al. 2008). Mixing cooperation and competition, christened “coope-tition” by Nalebuff and Brandenburger (1998), might not be exclusive to hybrids: employees or divisions compete within firms, notwithstanding the expectation of cooperation.³⁴ What distinguishes hybrids is the need to stabilize cooperation among otherwise competing partners without relying on hierarchy and with limited control over strategic rights.

On the one hand, accepted interdependence imposes constraints on the usage of pooled resources from which common returns as well as private benefits are expected (Gulati et al. 2000; Baker et al. 2008).³⁵ These benefits differ from those coming from the industry level (e.g., market structures or technological innovation) or from heterogeneity among firms (Dyer and Singh 1998). On the other hand, partners remain competitors. Hergert and Morris (1988) noticed that 71% of strategic alliances concern parties competing in the same market. Ménard (1996) exhibited similar results among networks in the poultry industry, and so did Park (1996) in a study of 204 equity-based interfirm linkages in the electronics industry and Robinson and Stuart (2007) in the biotechnology and pharmaceutical industries.

The challenge of stability versus autonomy that coopetition faces might help explain observable gaps between duration of formal contracts and duration of contractual relationships in hybrids. Hakansson (1989; see also Hakansson and Johansson 1993) documented the stability of networks among small and medium enterprises in Sweden, notwithstanding the short duration of formal contracts, with two-thirds of the partnerships lasting for more than 4 years and an average duration of 13 years. This confirms similar observations in the construction industry (Eccles 1981), among French small and medium manufacturing firms

32. This explanation has been seriously challenged (Lafontaine and Slade 1997, 2007).

33. Cross-financial participation among top shareholders may end up with control in the hands of the network, which raises the issue of its adequate governance, as pointed out by Aoki in the case of *keiretsu*.

34. Tirole (1986: 212) defined firms as a “network of coalitions and contracts that interplay.”

35. Powell (1996: 211) noted the following about high-tech sectors: “membership in a common technological/intellectual community creates strong and visible mechanisms for peer-based governance.”

(Paché and Paraponaris 1993), in the agrifood sector (Ménard 1996), and so on. However, tensions over usage of pooled resources or rent sharing also carry risks of instability, including the breach of contracts. For example, the mortality rate in horizontal alliances is higher than in vertical ones, stemming from competition (Bleeke and Ernst 1993). Sampson (2005) also found a high rate of dissatisfaction and alliance termination in 464 R&D alliances in the telecommunications industry during 1991–1993, while Khanna (1998) noted the risk that “racing” strategies among partners increases instability, particularly when mutual learning is at stake. Ambiguities about residual rights and difficulties in implementing clear sharing rules push hybrids to search for adequate mechanisms of governance (Park 1996; Ménard 2004). Finding stability without challenging the autonomy of partners remains a key issue for hybrids.

4.2. Finding the Right Partners

In that respect, selecting the right partners becomes crucial. Two dimensions of selection have particularly attracted attention. First, antecedents signal the reliability of potential partners and provide insights into the compatibility of management systems and decision processes (Lorenzoni and Baden-Fuller 1995). In a series of papers on strategic alliances and networks, Gulati (1995b), Gulati and Gargiulo (1999), and Gulati et al. (2000) showed that repeated interaction among parties is a key component in the selection process. Using data from 1980 to 1989 on 166 organizations located throughout the United States (54), Europe (46), and Japan (66) and operating in three industrial sectors (new materials, industrial automation, and automotive products), Gulati and Gargiulo (1999: 1447), quoting Granovetter (1985: 490), showed the importance of “trusted informants” and/or “information from one’s own past dealings with this person” in choosing partners and reducing uncertainties when forming alliances. In line with Granovetter (1985; see also Dyer and Singh, 1998: 666 et seq.), they emphasized (1) past cooperation (“relational”), (2) indirect ties through third parties (“structural”), and (3) the role of potential partners in preexisting alliances (“positional”) as factors framing selection. The analysis of the role of centrality and proximity in Robinson and Stuart (2007) supports this observation. However, Poppo and Zenger (2002) and Ryall and Sampson (2006) showed some puzzling effects of antecedents: prior alliances develop trust, signaling the high value of a relationship and encouraging informal governance, but repeated interactions also improve information and the capacity to write detailed contracts, making highly formal relationships easier to implement.

Second, the imposition of restrictions on potential partners operates as a screening device. Selection means barriers to entry. Hybrids have a more or less open architecture. Powell (1996) emphasized cross-traffic between universities and firms and among firms in the biotech industry as facilitating the development of co-specialized assets. However, Ménard (1996) displayed the tight restrictions imposed on partners in the French “label” system, and Baker et al. (2008) found a similar pattern in biotechnology and pharmaceutical alliances, dominated by a hard core of 12 firms. In addition, Grandori and Soda (1995: 196) argued that the broader the scope of cooperation, the stricter are the rules of access. According to Dyer and Singh (1998), variability in openness depends on (1) the level of ambiguities about sources of rents; (2) the degree of replicability of resources generating rents; (3) the degree of imitability of resources to be pooled;

(4) the availability of partners of the same type; (5) the accessibility to capabilities they offer; and (6) specificities of the institutional environment.

All in all, hybrids' permeability remains limited by provisions determining resources to be pooled, delineating decisions to be shared, and fixing rules of governance. The resulting contractual constraints—for example, nonlinear pricing, royalties, minimum prices, quotas, exclusive territories, exclusive distribution, and packages—and other commitments are integral components in selecting and monitoring partners. They also severely challenge competition policies (Rey and Tirole 1986; Ménard 1996, 2007a).

4.3. Straightening Ties to Reduce Opportunism

Beyond selection, the “willingness of trading partners to exert effort on behalf of the relationship” (Mohr and Spekman 1994: 137) is central to maintaining a stable arrangement while keeping opportunism in check. Shared goals and common expectations legitimize coordination, facilitate joint decisions, and prevent free riding. In an extensive analysis of 166 alliances, Gulati (1995b) showed that firms prefer to deal with partners already interacting with others, thus benefiting from informational advantages and mitigating control concerns. Among many others, Powell et al. (1996) or Robinson and Stuart (2007) on biotechnology, Baker et al. (2008) on alliances between biotech and pharmaceutical firms, and Aoki (2001: 347–375) on the role of venture capitalists in building networks in Silicon Valley confirm that “the social dimensions of interorganizational relationship play a crucial role in controlling and coordinating behavior in transactions” (Bradach 1997: 294).

This importance of informal relationships was already emphasized by Macaulay in 1963. In the 1980s, several contributions focused on the role of social ties in “nonstandard” modes of organization. Ouchi (1980) introduced the notion of clans as homogeneous networks minimizing goal incongruence while tolerating high ambiguity about outcomes, thanks to shared values. Ben-Porath (1980) pointed out the role of social ties in overcoming high uncertainty (e.g., about quality, or when obligations are spread over time). Granovetter (1985; see also Zucker 1986; Adler 2001) extended the idea to interfirm relations in an influential critique of standard economic assumptions as well as of Williamson's (1985) emphasis on opportunism. Social ties became a leading theme in the sociology of networks.

It also permeated managerial sciences, through the analysis of trust. Thorelli (1986: 40) defined trust as “an assumption or reliance on the part of A that if either A or B encounters a problem in the fulfillment of his implicit or explicit transactional obligations, B may be counted on to do what A would do if B's resources would be at A's disposal.” Trust could emerge from prior history, from expectations of continuity, or from the interdependence of these two factors.³⁶ It would operate through (1) the convergence of expectations among partners with different goals; (2) the development of idiosyncratic language for carrying routines and

36. Sako and Helper (1998) identified three sources of trust: contractual (confidence that the other party will carry out the agreement); competence (confidence that the other party will be capable of doing what it promises to do); and goodwill (confidence that the other party will take initiatives mutually beneficial while restraining from taking unfair advantage). Their test, based on data collected from 3,000 suppliers in the automotive industry, exhibited that Japanese networks of suppliers are significantly more trusting than the competing U.S. suppliers.

information; (3) the transformation of tacit rules in common knowledge through shared norms; and (4) adaptation to unforeseen contingencies with reduced transaction costs (Jones et al. 1997: 929; Sako and Helper 1998: 388).

Williamson (1996: 250–275) challenged the role of trust, reducing it to calculative strategies. The resulting controversy, still going on, exhibited the complex role of trust in facilitating flexibility and solving conflicts (Achrol 1997: 65 et seq.). Using an example from Uzzi (1997: 55) about a manufacturer in the New York garment industry who moved his production to China after having notified his American partners ahead of time to let them adjust while he did not notify contractors with whom he had arm's-length relationships, Podolny and Page (1998: 61) concluded: "Cooperation does not arise as a route to future gains."

Economists and organization theorists interpret trust as a reputational issue (MacLeod 2007). *Reputation* relies on various supports (Farrell and Scotchmer 1988; Parkhe 1993; Gulati 1995b; Adler 2001; Poppo and Zenger 2002). It can grow out of (1) recurrent transactions among partners, a central explanation in game theory; (2) familiarity among partners sharing a common background, due to social similarities, geographic proximity, or devices purposely designed for that goal (e.g., training sessions, managerial seminars); (3) information about past agreements with third parties; or (4) institutional roots, as when partners belong to professional associations that implement behavioral norms or technical standards.

More generally, the density of ties likely plays an important role in the decision to go hybrid but also in the choice of a specific form. In their survey of more than 3,854 strategic alliances in biotechnology from 1976 to 1998, Robinson and Stuart (2007) showed that parties involved in a dense network (measured by the centrality and proximity of partners) are (1) less likely to rely on equity participation and (2) more likely to rely on extra contractual enforcement mechanisms to prevent hold-up. However, there might be "a potential dark side of overembedded ties," which could sustain relationships that are no longer fruitful (Poppo et al. 2008: 52; see also Anderson and Jap 2005).

4.4. Implementing Control

Ties help build a reputation that generates trust, facilitate selection of partners, influence the choice of the mode of governance, and smooth adaptation. However, hybrids often need more drastic means to control and discipline partners.³⁷ These "different safeguards are likely to have different set-up costs and result in different transaction costs over different time horizons" (Dyer 1997: 537).

The threat to expel underperforming partners or free riders is such a tool. Threat works if the expected losses from being ousted exceed the gains of free riding (Klein 1996) and if the mode of governance adopted allows such radical sanctions. The implementation of a private court to control and penalize noncompliant millers (see Section 2.1) illustrates the complex devices that

37. This could signal a difference between relational contracts among firms and within firms: in hybrids, reneging threatens the very existence of the agreement; within firms, hierarchy provides means for dealing with the situation. See the comparison between reneging temptations in outsourcing and in employment relationships in Baker et al. (2002).

may be needed to make threat effective.³⁸ Ostracism in the film industry or the destruction of traps of interlopers and noncompliers in the Maine lobster industry provide other examples (Jones et al. 1997). Greif (1993, 2005) similarly showed the power and complexity of threats that rely on collective sanctions in the network of the Maghribi traders.³⁹

However, threat remains an ambiguous tool. First, it is often a one-shot game. Second, it signals conflicts and difficulties in solving problems, which might tarnish reputation and challenge future partnerships. Third, ousting noncompliers challenges hybrids, because they cannot rely on a central entrepreneur to do so.⁴⁰ Contracts may help discipline free riders (e.g., imposing penalties or defining conditions under which a noncompliant can be expelled). However, they cannot control for all situations. In an extensive study of more than 1,500 alliances, Gulati (1998) demonstrated that when making decisions to cooperate, partners are less concerned by contractual hazards than by the expected costs of governing their relationships. Brickley and Dark (1987) and Bradach (1997) reached a similar conclusion about franchising and identified various control devices that (1) limit the discretion of agents, (2) reduce opportunistic temptation by restricting residual claims, (3) establish benchmarks through company-owned outlets, and (4) discipline franchisees through consultants in charge of persuading them to remedy violations of standards. Achrol (1997: 64 et seq.) suggested that control is exercised through expertise, reputation, and influence (which he calls “referential”), while Mohr and Spekman (1994) had already pinpointed several techniques implemented by hybrids to avoid relying on threat: joint problem-solving devices (e.g., a specific committee), persuasion, smoothing over differences, domination, harsh words, and arbitration.

The central lesson of these studies (and several others) is that checking free riders exceeds the capacity of contracts and pushes toward implementing specific control mechanisms, ultimately resulting in a governing body. In the long run, the search for stability and the need to fight opportunism might well drag hybrids away from quasi-market relationships and toward quasi-integration.

To sum up, the coexistence of pooled resources, autonomous rights, and distinct assets is a source of tensions that make devices to sustain hybrids both vulnerable and essential. Multitask models (Holmström and Milgrom 1991) might help frame the difficulty. Partners jointly owning some assets while keeping distinct rights on others must choose simultaneously joint actions and autonomous or even competing actions that can nevertheless benefit from spillover effects. How can parties limit the risks that some partners might divert their attention from joint actions or even endorse choices harmful to joint activities? In exploring answers to this question, the similarities with decisionmaking in teams and committees are limited. Economic theory does not yet have adequate models to capture

38. Raynaud (1997) emphasizes the limits to the threat of expulsion stemming from the internal conflicts that could result among remaining partners. In contrast, Bradach (1997), referring to the example of defranchising of restaurants in the United States, displays the limits coming out of a mix of institutional constraints and the risk of disrupting the network.

39. See also the role of “merchants’ laws” (Milgrom et al. 1989).

40. This is precisely the *raison d’être* of entrepreneurs according to Alchian and Demsetz (1972).

how partially pooled resources and imperfectly contractible outcomes affect the decision process.⁴¹

5. Governance of Hybrids: A Variety of Answers

To monitor joint assets and create new ones, partners take the risk of exposing shared rights to opportunistic behavior, to the point of negative spillover effects.⁴² The need to control and discipline partners to make hybrids sustainable encourages governance endowed with authority, the intensity of which varies according to the specificity of assets pooled, the allocation of rights, and the incentives at stake. The stability of a hybrid depends on its governance and on its ability to deal with the challenges it faces.

By governance, I mean devices that instill order in joint activities through the allocation of assets and rights, so as to mitigate conflicts while allowing benefits from mutual gains (Williamson 1996: 12). The specificity of governance in hybrids comes from the need for parties to coordinate while “partner sovereignty provides a constant strain” (Borys and Jemison 1989: 242).

As evidence from previous sections suggests, there are different ways of “encompassing the initiation, termination and ongoing relationship maintenance between a set of parties” (Heide 1994: 72). If autonomy characterizes parties operating on markets while administrative coordination prevails in hierarchies, hybrids mix autonomy and cooperation. This mix takes various forms, from tight coordination by a strategic center to looser ties relying on shared information. In what follows, I focus on three structural components of governance and the underlying role of relational contracts. Although these components are found in combination most of the time, I shall argue in Section 6 that the dominance of one of these components determines the type of hybrid.⁴³

5.1. Coordinating through a Strategic Center

Ongoing competition among partners and the simultaneous quest for stability push toward tighter coordination when shared assets and rights become significant. Risks of opportunistic behavior need to be circumscribed when strategic decisions must be made jointly among otherwise sovereign partners. This might explain the key role of strong coordinators (strategic centers) in most stable hybrids.⁴⁴

41. A stimulating approach to decisionmaking in complex organizations is proposed by Visser and Swank (2007). There are also similarities between decisionmaking in hybrids and choices in politics, with the key role of median voters. However, a nonnegligible difference is that in many hybrids, “voters” do not have the same weight. There are exceptions, though, as with the millers or in cooperatives using the “one person, one vote” rule, which is also a source of problems (Cook and Iliopoulos 2000; Hendrikse 2004; Ménard 2007b).

42. For example, in food franchising systems, spoiled food delivered by a single franchisee might spill destructive externalities over the entire network.

43. See also Hendrikse (2004). Bradach and Eccles (1989) argued early on that three basic control mechanisms govern transactions within and among firms: price, authority, and trust. The difference among modes of organization then depends on the prevalence of one mechanism over the others.

44. I retroactively discovered that Lorenzoni and Baden-Fuller (1995) also referred to “strategic centers” as coordinating devices.

Strategic centers can be understood as a shorthand expression for institutional entities under which transactions are initiated, negotiated, monitored, adopted, enforced, and terminated.⁴⁵ The specificity of hybrids is that such centers exert authority on a limited subset of rights. They can constrain partners by (1) adjusting collective action or joint decision rights, (2) designing enforcement mechanisms to discipline parties, (3) framing bargaining processes over quasi-rents, and (4) deciding dispute-resolution procedures. The millers' board, assemblies ruling condominiums (Klein et al. 1978), groups of producers (Sauvée 2002), and boards monitoring joint ventures provide examples.

First, strategic centers shape collective actions by monitoring joint decision rights. Thorelli (1986: 38) referred to "power," understood as "the ability to influence the decisions or actions of others." Ménard (1996, 1997, 2004) developed the concept of authority to capture the delegation of subsets of decision rights to an entity that is formally (and most of the time legally) distinct, with the power to discipline parties when it comes to joint actions. Authority differs from hierarchy in that it relies on consent rather than command, maintaining some symmetry among the holders of rights. In hybrids, authority is built through (1) control over the allocation of pooled resources, (2) development of shared competences, (3) provision of expertise, (4) creation of a sense of common purpose, and (5) legitimization through social acceptance.

Second, authority requires enforcement. Interpreting Williamson (1985), Park (1996) suggested that enforcement differs depending on whether it is operating in bilateral or trilateral arrangements. In the former, parties enforce decisions through negotiations, because in the last resort decisions remain in the hands of parent firms, as in joint ventures. When actions become more intertwined and/or the network becomes extensive, rendering internal transactions and joint decisions to monitor and enforce increasingly complex, coordination would require trilateral governance, with enforcement transferred to a well-defined entity (e.g., a professional staff or a central management that can select collective actions, evaluate performance, and penalize noncompliants).⁴⁶ Professional sports leagues or the millers discussed in Section 2.1 illustrate the point.

Third, authority allows strategic centers to frame the bargaining process. Ménard (1996) examined how a group of producers in the poultry industry implemented a central entity in charge of organizing negotiations among partners as well as regulating the bargaining process with distributors. Analyzing the success of Saveol, a network of producers of high-quality vegetables, Sauvée (2002) analyzed an arrangement in which small owners delegate substantial decision rights to two distinct cooperatives that themselves delegate rights to two joint ventures in charge of controlling inputs, developing products, and marketing them. However, delegation of rights over a limited subset of assets raises a difficult trade-off for hybrids: how to keep the arrangement adaptable through the transfer of adequate authority while keeping holders of this authority under control. This difficulty may explain why so many interfirm agreements place a "high premium on personnel with long memories, sound hearts, and a penchant for looking both ways before crossing the street" (Palay 1985: 164).

45. This definition is adapted from Palay (1984: 265).

46. "The central management has decision-making power over members and it monitors the members' cooperation activities and imposes sanctions, if necessary" (Park 1996: 812).

Fourth, the existence of multiple sources of tensions (see Section 4.1) encourages the adoption of formalized mechanisms to solve disputes within the strategic center or between the center and its constituencies. In their study of the U.S. hardware industry, Dwyer and Oh (1988) suggested that formal procedures might prevail over centralization and participation in differentiating modes of organization.⁴⁷ The development of routines that codify links among partners and serialize the decisionmaking process helps reduce disputes and/or facilitates their resolution. The implementation of transmission channels that facilitates control (e.g., automated management information systems) can similarly help formalize relationships. Detailed technical appendixes to contracts also frame disputes and renegotiations among partners. Policing devices, such as “mystery shoppers” in franchises or field audits and internal inspections in the millers’ case, similarly ease identifying and redressing noncompliant behaviors. Enforcement procedures might go even further, implementing private courts to judge and discipline noncompliant partners (see Section 2.1 on the millers, or the now classical analysis of merchant laws in the Champagne fairs in Milgrom et al. 1989).

Numerous empirical studies (e.g., Brown 1984; Lorenzoni and Baden-Fuller 1995; Ménard 1996, 2004; Ménard and Raynaud 2010) confirm this role of authority delegated to and implemented by a strategic center.⁴⁸ They are in line with what TCE predicts: the more strategic the rights and assets shared, the more formal the governance becomes.

5.2. Third Parties as Ordering Forces

Strategic centers shape decisions from within, ideally making agreements self-sustainable. In the last resort they remain offshoots of parent companies. Because they get their authority from delegation, they depend on the commitment of their constituencies and remain directly exposed to risks of opportunism. To confront these difficulties, hybrids might turn to exogenous entities to facilitate coordination and discipline partners, either because shared rights are not sufficiently strategic to justify joint authority or because the impulse to cooperate comes from parties external to the relationship (e.g., public policies). These ordering forces can be public or private.

Public authorities can interfere directly in the development of hybrids through agencies, regulations, and the like. In the French poultry industry, a quality certification system initiated by small producers was later formalized, on their demand, with the legal creation of certifying organizations governed by representatives from the government, the sector, independent experts, and it was key to the success of “red label” products (Ménard 1996). Another example is R&D projects that depend on subsidies conditional on interfirm agreements, as with the European Galileo project, which intends to build a system that competes with the Global Positioning System. In addition, public authorities can provide indirect incentives to cooperate, as when they ease access to scientific centers or technology parks to firms willing to interact.

47. Formalization has become a standard variable differentiating arrangement in organization theory.

48. From a different perspective, Bradach (1997) noted that franchise systems also develop forms of strategic control to overcome agency problems, for example, combining a large monolithic hierarchy (company-owned units) and a federation of semi-autonomous hierarchies (e.g., KFC, in which 17 actors owned half of all franchises in 1989).

External monitoring of hybrids can also depend on private entities. Formal procedures can be embedded in the arrangement to facilitate adaptation, as when adjustments are delegated to identifiable arbitrators (often lawyers or experts) or to professional associations. In the French beef industry, networks privately initiated turned early on to professional unions for solving conflicts and enforcing agreements (Mazé and Ménard 2010). However, partners often prefer less-formal devices and refer to mediators for adapting their relationships (Rubin 2005). Ryall and Sampson (2006) go even further, showing how partners may plan penalties for those who become confrontational. One problem that researchers must deal with when identifying these devices is the difficulty of collecting information on private monitoring of adaptation and conflicts.⁴⁹

In addition, numerous hybrids find support in mixed entities, in which private agents and public representatives jointly make decisions. Under pressure from the competition authorities of the European Union, who considered the initial arrangement as collusive, the certifying organizations mentioned above are now autonomous entities, in many cases with representatives from the private and public sectors, while others are entirely private (Ménard and Valceschini 2005; Raynaud et al. 2009).

However, monitoring hybrids through external agents faces severe limitations. It confronts problems of verifiability by third parties, a serious constraint in arrangements that reserve substantial rights for separate parties and/or organize complex transactions. Implementing decisions from exogenous entities might also have dissuasive costs, involve unacceptable delays, or require controls that are barely tolerable. Several studies suggest that these obstacles are better overcome through informal safeguards, which lower transaction costs and are hard for competitors to imitate (Gulati 1995a; Dyer and Singh 1998; Robinson and Stuart 2007).

5.3. Shared Information

Asymmetric information is a major source of opportunism in hybrids. Of course, information problems plague all modes of organization. They are amplified in hybrids, because existing assets and rights are partly shared, while new assets and rights are created that can hardly be attributed to specific contributions. Moreover, the autonomy of partners prevents hierarchical solutions, and overlapping assets and rights require more information than market prices can offer.

Relevant information might be collected through repeated transactions (Gulati 1995b); or through appropriate information systems, such as integrated logistics, shared transportation facilities, common buying procedures, and joint collection of data on customers (Clemons and Row 1992; Ménard 1996, 2003). Using their dataset from alliances between biotechnology and pharmaceutical firms, Robinson and Stuart (2007) refer to networks as platforms disseminating information, thus reducing uncertainty and benefiting from shared capabilities. New information technologies might help, although data are inconclusive about whether they favor interfirm agreements or integration (e.g., in the trucking industry). Following Arrow (1974), Heiman and

49. Lumineau and Oxley (2012) provide a rare analysis of private resolution of conflicts through arbitration, mediation, or negotiated settlement. They examined 102 contractual conflicts from 1991 to 2005 in which lawyers intervened, involving 178 firms operating in manufacturing and retail sectors. They showed that 41 conflicts were solved this way, while the remaining 61 ended up in courts.

Nickerson (2002) emphasize the role of physical channels linking partners. High-bandwidth channels (e.g., co-location) would allow rich interfaces among partners, facilitating coordination but also raising problems of delineation and enforcement of rights over tacit knowledge; low-bandwidth channels (e.g., e-mails or faxes) would reduce contractual hazards but restrict the transfer of information.

In all cases, information devices are intended to make partnership sustainable by reducing the risk of opportunism, facilitating mutual control, and lowering transaction costs. Shared information can help reach these goals through (1) modularity and replicability of know-how, which allows implementation of joint routines; (2) open standards, which make communication easier while increasing transparency of transactions; (3) implementation of devices that allow conversion and translation of protocols and interfaces at low cost; and (4) development of intuitive interfaces (Clemons and Row 1992; Paché and Paraponaris 1993; Langlois 2002; Anderson and Gatignon 2005).

The literature on the role of information in the governance of hybrids and how it might differentiate them from other modes of organization remains surprisingly sparse. Powell (1990; see also Powell et al. 1996), using data from the biotechnology sector, suggested that information in networks is “thicker” and “freer” than in hierarchies, while it requires reciprocity that does not fit arm’s-length relationships of the market type. This remains an interesting intuition to be explored further.

5.4. Underlying It All: Contracts

In most hybrids, governance is at least partially framed by contracts. This framework provides a strong argument to examine hybrids through contractual lenses. Contracts are powerful tools, facilitating coordination as well as control. However, their role should not be overemphasized. Macaulay (1963) already noted that they primarily supply frameworks within which other devices prosper. Because the analysis of contracts plays an important role in this book, I hereafter focus solely on issues of particular relevance for the analysis of hybrids.⁵⁰

Ideally, partners would rely on self-enforcing contracts embedded in formal safeguards that keep calculative parties within the range delineated by the agreement or in social norms pervasive enough to discipline them (Ouchi 1980; Artz and Brush 2000). As argued by Klein (1996; see also Baker et al. 2002: 40; Mazé and Ménard 2010), even when outcomes are not verifiable by a third party and are prohibitively costly to specify *ex ante*, no party may wish to renege if the expected value of the future relationship is sufficiently large.

However, theoretical insights on the importance of noncontractible elements as well as empirical studies on contractual flaws exhibit the limited role of contracts. The complex overlapping of autonomy and cooperation in hybrids typically makes contracts relational.⁵¹ Changing

50. For a detailed review of contracts in interfirm relations, see Lafontaine and Slade (this volume) and Malcomson (this volume: Sections 8 and 9). Hansmann (this volume) also discusses related issues.

51. See Rey and Tirole (2001: 25–26):

There is little point writing a detailed contract that protects the partners by reducing potential externalities and specific covenants restricting the set of possible actions. Partners are already protected by their control rights; and such contractual features, which are pervasive under undivided control, only serve to reduce incentives

market conditions, uncertainties surrounding the outcome of joint projects, measurement problems, ill-defined property rights and/or weak institutions making enforcement dubious are factors motivating flexibility and the potentially positive effects of renegotiations.⁵² These problems are not exclusive to hybrids. What make contracts in hybrids distinct are the amplitude of adjustments variables and the room left for relational adaptation, a point already noticed by Borys and Jemison (1989: 243) and emphasized by Robinson and Stuart (2007) in their examination of alliances in biotechnology. Ryall and Sampson (2006) exhibit how the resulting heterogeneity in contractual clauses coagulates in boilerplate terms motivated by the need to facilitate adjustments when hybrids face knowledge leakages or inefficiencies in dispute-resolution devices.⁵³

Noncontractibilities translate into out-of-contract adjustments. Brown (1984: 266) already noted that in networks “the contract itself is more a formalization of an understanding than it is a legally-enforceable obligation. Breaches of contracts are rarely taken to court, even in the litigious US. This means that the contract can be renegotiated (or ignored) if need arises and the contingent claims problems are thereby avoided.” Almost simultaneously, Palay (1984) showed in a detailed study of 51 transactions between rail freight carriers and shippers that if adhering to clauses or adjusting only at the margins prevailed in nonspecific transactions, adjustments exceeding the terms of contracts dominated idiosyncratic transactions. Similar observations have been made about franchises, in which contractual provisions define only a framework (Bradach 1997), or in strategic alliances, in which contracts operate primarily as facilitating devices. Grandori and Cacciatori (2006; see also Grandori and Furlotti 2006) showed in a survey of innovation-motivated alliances that contracts are typically simple and short (7–8 pages), with clauses focused on a few core issues, mainly the assignment of property rights, whereas decisions on tasks and process are left aside. In their study of 42 R&D alliances in the telecommunications equipment manufacturing and microelectronics industry, Ryall and Samson (2006) substantiate the role of contracts as blueprints helping to plan collaboration, define partner expectations, and reduce misunderstanding and costly missteps. Moreover, similar contracts might carry different meaning according to their environment. In a survey of carmaker suppliers in Japan and the United States, Sako and Helper (1998) show that American suppliers use long-term contracts as a protection against opportunism from their customers, whereas Japanese suppliers view long-term contracts as signaling opportunistic customers!

In sum, the governance of hybrids relies on a set of devices, of which contracts are only one element, although a very important one. The combination of these devices likely explains the variety of hybrids; the prevalence of one of them determines the subset to which a given empirical form belongs.

without improving efficiency. Joint ventures may also want to shut down the partners' otherwise desirable outside opportunities in order to foster their commitment to the joint venture.

52. The idea that contracts are deliberately left open goes back to Simon (1951), but still meets resistance (see Tirole 1999). For the potentially positive role of renegotiation, see Estache and Quesada (2002).

53. These regularities concern provisions on confidentiality; the right to terminate on bankruptcy or changes in key management; limitations of liability; and arbitration provisions. Numerous contracts explicitly waive firm rights to bring disputes before the courts or other administrative bodies (Ryall and Sampson 2006) or restrict the temptation to go to arbitration (e.g., clauses specifying that arbitration should be in the language and country of the partner not bringing the dispute).

6. Toward a Typology of Hybrids

Many economists are doubtful about the relevance of establishing a typology of organizations, although lessons from the history of science tell otherwise.⁵⁴ Having described hybrids as a class of their own, Rubin (1978: 232) nevertheless concluded that “the franchisee is in fact closer to being an employee of the franchisor than to being an independent entrepreneur.” Cheung (1983: 1) went a step farther, arguing that firms and other arrangements are simply shorthand descriptions of ways to organize activities through contracts. Williamson (1975: 109) initially considered these intermediate forms as unstable and transitory, while as late as 1996, Masten (1996: 12) argued that “their form must be assessed on a case-by-case basis.” True, the variety of observable forms suggests a continuum of arrangements between markets and hierarchies. However, when we examine, say, joint ventures, we are aware of looking at something different from franchising or supply chain systems. Is a classification of hybrids possible without flattening their characteristics?⁵⁵

6.1. Alternative Approaches

Numerous studies have answered this question positively, using criteria derived from organization theory, with an emphasis on (1) the coordination mechanisms involved, (2) the degree of centralization, and (3) the formalization of decisionmaking. Other studies use the perspective of TCE to give a positive answer, with a key role for the specificity of investments involved and, to a lesser degree, the uncertainty surrounding transactions at stake.

Putting coordination at the forefront, Grandori and Soda (1995) classified interfirm networks as (1) social networks, relying on personalized relationships (e.g., industrial districts); (2) bureaucratic networks, obeying formal rules (e.g., franchises); and (3) proprietary networks, based on cross-holding property rights (e.g., joint ventures).⁵⁶ Sauvé (2002) categorized hybrids according to whether allocation of decision rights requires horizontal or vertical coordination. Park (1996) differentiated forms according to their degree of centralization, with alliances, and voluntary and mandatory trilateral agreements as the main categories. More recently, Carson et al. (2006) argued that uncertainty should be the key variable for classifying interfirm contracts as formal or relational.⁵⁷

Endorsing a transaction cost perspective, Oxley (1997) identified three types of hybrid arrangements according to how they deal with contractual hazards and appropriability: *unilateral*

54. Developing appropriate classifications played a major role in, for example, the natural sciences (the Linnaean taxonomic system), chemistry (Mendeleev’s periodic table), and medical sciences (nosology).

55. Biology provides a useful analogy here: the discovery that all living organisms share common characteristics (e.g., cells) did not destroy the usefulness of identifying distinct species. At the end of the day, what matters are losses and gains in reducing the spectrum of organizational forms to discrete “bands.” In my view, the exercise plays a positive role in (1) boiling down properties of classes and subclasses to a small number of determinants and (2) helping identify flaws and black holes in our theories of organizations.

56. Their typology also differentiates subclasses depending on whether relationships are symmetric or asymmetric.

57. Ranging between markets adapted to weakly specific assets and hierarchies prevailing when specificity is high, arrangements would vary according to the type of uncertainty, with formal contracts more efficient when the ambiguity related to measurement problems is high, while relational contracts are more efficient when volatility is high.

contracts (e.g., licensing), close to markets although poorly adapted to high hazards; *bilateral contracts* (e.g., technology sharing agreements), with more committed parties who are nevertheless exposed to ex post haggling or third-party adjudicative costs in solving conflicts; and quasi-integrated *equity-based alliances*, in which partners share resources, organizational routines, and communication methods but must deal with costly monitoring and control. Gulati and Singh (1998) argued that anticipated coordination costs—not appropriation—determine organizational choices, because they delineate the authority acceptable by autonomous partners and the role of trust in alleviating costs.⁵⁸ Using a dataset on alliances, they differentiated (1) *contractual alliances*, with no shared ownership but joint activities coordinated through negotiations (e.g., distribution agreements); (2) *minority alliances*, in which one or several partners take minority equity, so that (weak) hierarchical relationships develop (e.g., participation in a board); and (3) *joint ventures*, with an independent command structure that internalizes pricing, operating procedures, and dispute resolution. More recently, Baker et al. (2008) characterized the variety of governance structures according to the allocation of asset ownership, decision rights, and payoffs. Their typology runs from mergers and acquisitions to total divestitures, with intermediate agreements (e.g., licensing, alliances, franchising) when some decision rights and/or payoffs rights are contracted and parties abandon part of their autonomy in exchange for expected spillovers.

6.2. A Governance Perspective

Building on these contributions and based on the variables examined in the previous sections, I propose a typology that encapsulates these variables as instruments shaping the outcome of hybrid form, that is, the prevailing mode of governance. The underlying logic is that forces pushing to “go hybrid” on the one hand and strategic choices commanding the degree of centralization needed to provide sustainability on the other hand result in various governance structures.

If we contrast hybrids with the two standard polar cases of pure markets (with autonomy of strategic resources and rights and decentralized coordination as key characteristics) and pure hierarchy (with strategic assets and rights unified under a centralized entity in charge of their allocation and control in the last resort), we can substantiate our simplified Figure 1.

Facing uncertainty and complexity through arrangements that allow the creation of extra value requires sharing rules that maintain cohesiveness. The intensity of these forces that push to endorse specific modes of governance translates to the variable density of pooled strategic rights and resources (horizontal axis in Figure 2). In contrast, the sustainability of an arrangement requires instruments for checking on partners eager to preserve their autonomy, with various solutions determining the degree of control or coordination needed (vertical axis in Figure 2). The outcome is the variety of arrangements summarized in Figure 2, in which the outer frontier along the two axes captures what would be termed “pure” modes of governance.

58. “By coordination costs, we mean the anticipated organizational complexity of decomposing tasks among partners along with ongoing coordination of activities to be completed jointly or individually across organizational boundaries and the related extent of communication and decisions that would be necessary” (Gulati and Singh 1998: 782). They tested their hypothesis with a multinomial logistic regression on a sample of 1,570 alliances involving U.S., European, and Japanese firms from 1970 to 1989 in three sectors (biopharmaceuticals, new materials, and automobile manufacturing).

Figure 2. Typology of hybrids. The lens-shaped shaded area delineates the tolerance or acceptance zone.

The perspective adopted builds on the Coase-Williamson tradition, with hybrids located between spot markets (in which autonomous parties cash benefits from their own actions, so that deliberate coordination is at a low) and hierarchies (which capitalize on coordination and control over common resources and rights, considerably reducing the autonomy of insiders and their capacity to privately appropriate surplus). In the hybrid zone, we find the variety of answers to governance issues, according to the prevalence of one of the devices identified in Section 5. The more partners expect from pooling resources, the more autonomy they will be ready to sacrifice with respect to their decision and property rights, up to the point where rights are fully integrated. Likewise, the more coordination is needed to maintain the stability of an arrangement, the more centralized will be the monitoring and control of that arrangement.

On the left of the spectrum, close to spot markets, *information-based networks* rely essentially on information platforms to coordinate; ownership over assets and decision rights remain distinct, so that payoffs are closely linked to the actions of separate parties. Porous frontiers and continuous exchanges among biotech firms in the Boston area or among information technology firms in Silicon Valley, as well as forms of consumers' associations, provide illustrations.⁵⁹ At the other end of the spectrum, partners rely on tight coordination by means of strategic centers empowered with formal authority and contractual clauses constraining members who pool

59. Recent studies suggest that networks can be more formal than expected. In their study on the biotechnology sector, Robinson and Stuart (2007) show that centrality in the web and proximity to potential partners give powerful means to some firms, facilitating control and reducing the need to hold property rights.

significant rights; appropriation of residual gains becomes a key issue. Joint ventures in R&D projects or the millers' case (see Section 2) illustrate the point. In between we find arrangements in which partners keep control over the hard core of their assets, although they develop non-negligible relationship-specific investments. Such arrangements tend to rely on third parties to monitor tensions and coordinate efforts, whether the third party is a public entity (e.g., agencies monitoring part of the label system in the French agribusiness) or a private arbitrating entity jointly agreed upon and in charge of filling blanks in contracts (as in many strategic alliances).

However, as argued in this chapter, we are rarely on the optimal frontier. Because noncontractible rights are so significant most of the time, while the autonomy of parties and their rights impose constraints on the arrangement, relational contracts are at the core of hybrids. The lens-shaped area in Figure 2 captures the idea of a tolerance or acceptance zone that allows adjustment and adaptation among partners. The lower bound delineates the inferior limit of what is acceptable to parties. Hence, the shaded area is where modes of governance operate most of the time.

Most hybrids fall into one of the three types identified in the figure, according to the governing device that prevails. However, devices often overlap, thus mixing pure types. The light rays radiating from the origin and separating types of hybrids suggest this permeability. Indeed, one advantage of this typology is to help understand why and how arrangements often grouped under the same umbrella (e.g., franchises or cooperatives) actually take many different forms according to the activities they coordinate or the strategies they pursue, notwithstanding similarities in the transactions they organize. This richness results from (1) the complex forces that explain the existence of hybrids and delineate the acceptance zone within which they operate and (2) the trade-offs hybrids continuously face in organizing transactions along nonstandard procedures intended to maintain cohesion and stability in the partnership.

7. Conclusion

The central lesson of this chapter is that "there is an increasing sense that the networks of relationship in which particular exchanges are embedded have properties that are greater than the sum of its parts and outcomes that cannot be explained by studying its parts alone" (Achrol 1997: 63). Hybrids are institutional structures with characteristics of their own. They resort to specific governing devices developed to deal with (1) property rights that ultimately remain distinct, although significant assets are pooled; (2) decision rights that keep partners independent, although shared rights restrict their autonomy; and (3) the need to design adequate incentives in a context in which frontiers among residual claimants are blurred. Hybrids proliferate because they can take advantage of coordination and cooperation that overcome gains associated with market competition, while partners remain autonomous, thus providing more flexibility and better incentives than what an integrated structure could offer.

The existence and characteristics of hybrids are substantiated by an abundant empirical literature. However, explanatory theories remain underdeveloped. Models are needed that would capture the role and richness of these arrangements in market economies. We also lack adequate data for estimating the weight and dynamics of these forms in modern capitalism. Five unsolved problems deserve a particular attention in my view. First, we need to understand why hybrids often co-exist with integrated firms. Second, we still remain in the dark with respect to the exact significance of these arrangements in the production and distribution of goods and services.

Third, we do not clearly understand the role of technological changes (e.g., information and communication technologies) in the evolution of their governance. Fourth, the interaction of hybrids with their institutional environment (e.g., rules governing property rights) requires in-depth studies. Finally, several characteristics of hybrids challenge competition policies, which remain largely grounded in theories built on the simplistic trade-off between markets and firms, so that substantial revision of these policies is likely required.

These issues only define part of the rich research agenda opened by the acknowledgment that in modern market economies, hybrid arrangements may be the normal and prevailing way of doing business.

Corruption

Abhijit Banerjee, Rema Hanna, and Sendhil Mullainathan

1. Introduction

Corruption is rampant in many poor countries. As such, anticorruption policies continue to be a central component of development strategies. For example, since 1996, the World Bank alone has supported more than 600 anticorruption programs.

Unfortunately, this is one area where research has lagged policy. Research on corruption faces two important obstacles—one empirical and one theoretical. On the empirical side, the primary challenge is measurement. Corruption, by its very nature, is illicit and secretive. How does one study something that is defined in part by the fact that individuals go to great lengths to hide it? How does one deal with the fact that attempts to measure corruption may cause the actors involved to either reduce their illicit behaviors during the periods of measurement or find new ways to obscure their behavior? If we cannot accurately measure corruption, how can we test among different theories, measure its impacts, or even produce suggestive correlations?

In recent years, some progress has been made to deal with these challenges. In particular, while the previous generation of corruption measures were mainly based on the perception of corruption by participants (with various assorted problems in interpreting these measures), the current generation of studies have focused on collecting and reporting objective information, obtained either from direct measurement or from other information.

The theoretical challenge comes in part from the need to go beyond thinking of corruption as a generic form of moral hazard in organizations to the point where we can map different manifestations of corruption to different underlying environments. Here the word “environment” is interpreted to cover both the usual focus of the corruption literature (the nature of the monitoring and the punishments) as well as the intrinsic motivation of the bureaucrats (e.g., how corruption fits into their moral compass)—and what is less emphasized, the nature of the particular economic decision that the bureaucrats are participating in. This expansion is important for two reasons. First, from the point of view of empirical research, differences in the nature of corruption in different economic settings is an important source of testable predictions. Second,

for policy design, it is vital that we are able to think of how changing the environment might be an effective substitute for simply adjusting the punishment (which may not be feasible).

An example might clarify the second point. Bandiera et al. (2009) study waste in government procurement in Italy, a country that is often rated as one of the most corrupt in Europe. Using detailed data, they show that different branches of government pay very different prices for the same product (down to the brand and color). These price discrepancies can differ by 50% or more. In fact, they estimate that the government could save up to 2% of GDP if most purchase officers paid the same price as that obtained by the most frugal officers.

They also show, however, that the price differences are a function of where the purchase officers buy. They can either obtain their supplies from the market or from an approved supplier, Consip. Consip charges a publicly announced price, which leaves no scope for kickbacks. Going to the market, in contrast, potentially allows the buyer to negotiate his own deal, which might include something extra for himself. If buyers go to the market to get kickbacks, we would expect the least-corrupt officers (i.e., those who were previously paying the lowest prices) to be the ones who switch to the Consip option when it becomes available. In fact, the data suggest the opposite. When a new item is added to Consip's list of available items, the bureaucrats paying the highest prices turn to Consip. Moreover, these purchasing officers are also the ones that were, by all accounts, the best monitored—members of the centralized bureaucracies rather than the more autonomous hospitals and universities. These observations suggest a different narrative. These officers pay much higher prices than others not only because of kickbacks. The issue is also one of justifiability. Buying from the official supplier requires no justification—and no effort. Bandiera et al. (2009) argue that a major source of the waste here is the fear of being prosecuted for corruption. Bureaucrats pay high prices to avoid any taint of corruption. Notice that under this logic, changing the bureaucratic rules to give the bureaucrat a fixed procurement budget but full discretion—so that she can even pocket any money she saves, may generate both less waste and less corruption. She might even pocket more money, but that would be perfectly legal, and being free to keep the money may give her a strong reason to avoid waste.

This argument does not imply that full discretion is always a good idea. Think of the allocation of hospital beds. If need is not related to ability to pay, giving a bureaucrat full discretion about how to allocate beds may lead to a large proportion of them going to those who do not really need them. Making stringent rules about how the bureaucrat is supposed to allocate the beds will generate corruption, as the greediest bureaucrats will bend the rules to make more money, but also, potentially, a better allocation, because the more honest bureaucrats will adhere to the rules.

The more general point is that corruption is the result of the task that the bureaucrat is assigned to carry out. We can usually get rid of it by setting the appropriate task (giving discretion), but that is not always desirable from society's point of view. The optimal response to the possibility of corruption may often be to change the nature of the task. Note that the change in the task may not always reduce corruption: it might just address the misallocation or degradation of services that corruption often causes (e.g., that hospital beds were going to the rich or that the wait for a bed was unacceptably long).

Starting from the premise that the corruption we observe may be the result of the task assigned to the bureaucrat gives us a way to generate testable implications. In particular, we will then be able to map the specific problem the government is trying to solve into a vector of

outcomes (e.g., bribes, lines, or misallocation of beds). The questions we seek to answer are of the form: Are the waits likely to be longer when the government is trying to target hospital beds to the very poor rather than to the less poor? Are bribes likely to be greater when trying to target hospital beds to the very poor?

This repositioning of the corruption literature away from a purely crime-and-punishment approach toward a more task-focused approach connects it more closely to the literature on the internal economics of organizations that has emerged over the past two decades. This literature explicitly recognizes that most organizations use bureaucratic mechanisms similar to the ones associated with government bureaucrats for many of their internal decisions, which creates scope for corruption (Tirole 1986). However, there is much to be gained from focusing on the specific characteristics of the kinds of settings in which governments work. For example, one source of corruption in government is that governments are expected to deliver goods and services to those who cannot pay for their full value. This issue is less important in for-profit organizations. We return to the relationship between corruption in government and similar issues in private firms in Section 3.5.

This chapter highlights the progress made in the corruption literature over the past decade or so, with a focus on the doors this progress opens for future research. In this way it aims to be more forward than backward looking, less of a comprehensive review of corruption research and more of a guide to where it appears to be headed.¹ It provides a theoretical framework to illustrate the tasks approach and an overview of the tools now available for empirically analyzing corruption. It then lays out the open questions we think are both interesting and within reach.

We start with a discussion of what we mean by “corruption” in Section 2. The key point is that corruption involves breaking rules, not just doing something that is unethical or against the collective interest. This approach leads us naturally to think of the task that the bureaucrat has been assigned (which includes the rules). This is the subject of Section 3, where we develop a simple theoretical framework for thinking about corruption and its many manifestations. We then discuss strategies for measuring corruption in Section 4. Section 5 discusses a recent empirical study that provides a clear test of the model, and Section 6 reviews the growing literature on how to combat corruption. We conclude with a discussion of the main areas we think important for future research (Section 7).

2. Defining Corruption

We define corruption as the breaking of a rule by a bureaucrat (or an elected official) for private gain. This definition includes the most obvious type of corruption—a bureaucrat taking an overt monetary bribe to bend a rule, thereby providing a service to someone that he was not supposed to. However, it would also encompass more nuanced forms of bureaucratic corruption. For example, it would include nepotism, such as if a bureaucrat provided a government contract to a firm owned by her nephew rather than to a firm that ought to win a competitive, open

1. Summarizing a literature as large and multidisciplinary as corruption poses unique challenges. In this chapter, we have erred on the side of being forward looking, trying to paint a picture of where this literature is headed. Though we have aimed to cover all important existing literature, some gaps are an unfortunate necessity to keep this chapter manageable in length: our apologies to authors whose work we could not cover in much detail.

procurement process. This definition would also cover the case of a bureaucrat who “steals time”: she may, for example, not show up to work, but still collect her paycheck.²

Under this definition, the rules define what is corrupt. As a result, the same act can be classified as corruption in one setting but not in another. For example, in many countries (the United States, India, etc.) a citizen can obtain passport services more quickly if he pays a fee. While this act would not be considered corruption in these countries, it would be in others, where no such provision in the law exists. In contrast, many important political economy issues may not necessarily be considered corruption under this definition. For example, a government official providing patronage to supporters may have important ethical and allocative implications, but this act would not necessarily be corruption if no formal rule is technically broken.³

The definition of corruption used in this chapter is similar to those used by others in the literature, but there are important distinctions. For example, our definition is quite similar to that discussed by Svensson (2005: 20)—“the misuse of public office for private gain”—and to Shleifer and Vishny (1993: 599), who define corruption “as the sale by government officials of government property for personal gain.” All three definitions imply that the official gains personally from her particular position. Moreover, as Shleifer and Vishny (1993) define property quite loosely to include both physical assets (e.g., land) and assets that have an option value (e.g., a business license), their definition encompasses many of the same acts of corruption discussed in this chapter and in Svensson (2005). However, there are slight differences in what qualifies as corruption across the definitions. For example, suppose we assume that a government official has the final say over whom to allocate a government contract to. He may choose to sell it to his nephew, and gain great personal happiness from doing so. Thus, this may be considered corruption under Svensson (2005) and Shleifer and Vishny (1993). However, if the official has the final say, and has not broken any official rules, this would not be considered corruption under our definition, despite being morally questionable.

We have chosen to use this definition for a combination of pragmatic and conceptual reasons. Pragmatically, the emphasis on breaking formal rules (as opposed to moral or ethical ones) sidesteps the need to make subjective ethical judgments and thereby avoids the need to have a deeper discussion of cultural differences.⁴ The emphasis on all kinds of gain rather than just monetary sidesteps a measurement problem: bribes by their very nature are hard to measure, whereas rule breaking is easier to measure. Conceptually, these distinctions are also in line with the framework we describe in the next section.

3. A Formal Framework for Understanding Corruption

The challenge of modeling corruption comes from the very definition of corruption. As stated in Section 2, corruption is when the bureaucrat (or elected official) breaks a rule for private gain. This immediately raises some questions, because the rules themselves are chosen by the

2. Quite often, we see the same forms of corruption in the nonprofit sector, where a social good is being provided, and the private and social value may not necessarily coincide. The models presented in this chapter would naturally extend to the nonprofit sector.

3. For a deeper discussion of political corruption, see Pande (2007).

4. Of course, culture is discussed explaining corruption, simply not when defining it.

government. Specifically, why have these rules, which we know are going to be violated, been put in place? Why not change the rules so that there is no incentive to violate them? This idea leads to an ancillary question: can you change the rules costlessly and eliminate corruption without affecting anything else that you care about?

To understand these issues, we begin by thinking about the underlying task. Our model of tasks is simple, and yet it captures many of the tasks bureaucrats (and also those in the private sector) typically carry out. We focus on an assignment problem. A bureaucrat must assign a limited number of slots to applicants. The applicants differ in their social valuation of a slot, their private valuation of it, and also their capacity to pay for it. This simple setup captures many important cases. Consider a profit-maximizing firm selling a good. In this case, the slot is the good, and private and social values coincide perfectly. Next, consider the case of a credit officer assigning loans at a government bank. Here, the private ability to pay may be the lowest precisely among those who have the highest social returns from the loan. This potential for divergence between private and social returns is not incidental—it may be the reason the government was involved in providing the loans in the first place. However, it is also the reason there is corruption.

The bureaucrat's task here goes beyond just allocating the slots: she may also face rules about what prices she can charge for them and whether she can engage in “testing” to determine an agent's type. The government sets both these rules and the incentives facing the bureaucrat.

Although this framework does encompass many models of bureaucratic misbehavior in the literature, we make no claims of generality for it. We make a large number of modeling choices that are pointed out as we develop the model. These are made mostly in the interests of simplicity and clarity, but many of them can also have substantive implications.

3.1. Setup

We analyze the problem of a government allocating slots through a bureaucrat who implements the allocation process. There is a continuum of slots of size 1 that need to be allocated to a population of size $N > 1$. Agents (i.e., citizens) have differing private and social values for slots. Specifically, there are two types of agents: H and L with mass N_H and N_L , such that $N_H + N_L > 1$. The social value of giving a slot to type H is H and L for type L . We assume that $H > L$. Private benefits can be different, with each group valuing their slots at h and l . Agents' types are private information and unknown by either the government or the bureaucrat, though the bureaucrat has a technology for learning about type that is called “testing,” which we describe below. Agents also differ in their ability to pay for a slot, which we denote by y_h and y_l ; because of credit constraints, agents may not be able to pay full private value, so $y_h \leq h$ and $y_l \leq l$.

There is a generic testing technology to detect agent types that the bureaucrat can use. If used on someone of type L (who is trying to pass the test) for a period of time t , the probability that he will fail the test (i.e., get an outcome F) is $\phi_L(t)$, $\phi'_L(t) \geq 0$. The corresponding probability for a type H who wants to pass is 0; he always passes if he wants to (i.e., gets the outcome S). Either type can always opt to deliberately fail. The cost of testing for t hours is νt for the bureaucrat. The cost of being tested for the person for t hours is δt . A simple example of testing would be a driving exam to verify that one can drive.

Testing is the only costly action taken by the bureaucrat in our model. We assume that the bureaucrat does not put in any effort to give out the slots. We capture much of what is relevant about bureaucrat shirking through this device, but there are no doubt some nuances that the model misses.

3.1.1. Possible Mechanisms

The basic problem for the bureaucrat is the choice of a mechanism. The bureaucrat announces a direct mechanism that she can commit to ex ante.⁵ Each mechanism constitutes a vector $R = (t_x, p_{xr}, \pi_{xr})$, where t_x is the amount of testing for each announced type $x = H, L$; π_{xr} is the probability that someone acquires a slot conditional on announcing type $x = H, L$ and achieving result $r = F, S$; and p_{xr} is the price this individual will pay in the corresponding condition. We restrict this discussion to winner-pay mechanisms here (mechanisms where the applicant does not pay when he does not receive a slot). For analysis of the more general case where a nonrefundable fee is required to enter the bidding, see, for example, Banerjee (1997).

Because the bureaucrat only chooses direct mechanisms, any R is supposed to satisfy the incentive constraints:

$$\pi_{HS}(h - p_{HS}) - \delta t_H \geq \pi_{LS}(h - p_{LS}) - \delta t_L$$

and

$$\begin{aligned} & \pi_{LS}(l - p_{LS})(1 - \phi_L(t_L)) + \pi_{LF}(l - p_{LF})\phi_L(t_L) - \delta t_L \\ & \geq \pi_{HS}(l - p_{HS})(1 - \phi_H(t_H)) + \pi_{HF}(l - p_{HF})\phi_H(t_H) - \delta t_H \end{aligned}$$

Moreover, the clients are allowed to walk away. This is captured by the participation constraints:

$$\begin{aligned} & \pi_{HS}(h - p_{HS}) - \delta t_H \geq 0 \\ & \pi_{LS}(l - p_{LS})(1 - \phi_L(t_L)) + \pi_{LF}(l - p_{LF})\phi_L(t_L) - \delta t_L \geq 0. \end{aligned}$$

There is also a total slot constraint:

$$N_H \pi_{HS} + N_L \pi_{LS}(1 - \phi_L(t_L)) + N_L \pi_{LF} \phi_L(t_L) \leq 1.$$

Finally, there is affordability: agents cannot pay more than they have:

$$\begin{aligned} & p_{Hr} \leq y_H, r = F, P \\ & p_{Lr} \leq y_L, r = F, P. \end{aligned}$$

Define $\mathbf{R}$ to be the set of values of R that satisfy these conditions.

3.1.2. Rules

The government chooses a set of rules for the bureaucrat that take the form $\mathcal{R} = (T_x, P_{xr}, \Pi_{xr})$, where T_x is the set of permitted values for amount of testing (t_x), P_{xr} is the set of permitted

5. We recognize that the actual mechanism used will often be very different from the direct mechanism. We discuss some of the issues this raises in Section 3.6.

prices, and Π_{xr} is the set of permitted values for the probability that someone acquires a slot (π_{xr}) for $x = H, L$ and $r = F, S$. Although we assume that the government does not observe every individual's type, we do allow P_{xr} and Π_{xr} to depend on the buyer's type. The idea is that if there is a gross misallocation of slots or large-scale bribery by one type, there may be some way for the government to find out (the press might publish a story stating that the hospital beds were all being occupied by cosmetic surgery patients who are paying high prices, or the government might sample a few people who received slots). However, we do not assume that being able to observe violations of P_{xr} automatically implies being able to observe violations of Π_{xr} : it may be easy to find out that some people are being charged more than the permitted prices without learning anything more generally about how the slots are being allocated.

We assume that $\mathcal{R}$ is feasible in the sense that there exists at least one $R = (t_x, p_{xr}, \pi_{xr}) \in \mathbf{R}$ such that $t_x \in T_x$, $p_{xr} \in P_{xr}$, and $\pi_{xr} \in \Pi_{xr}$. If $\mathcal{R}$ is not a singleton, then the bureaucrat has discretion.

The government also chooses p , which is the price that the bureaucrat has to pay to the government for each slot he gives out. Assume that this is strictly enforced, so that the price is always paid. This assumption can be relaxed easily, but the result offers no new insights.

In specific examples, we make specific assumptions about what the government can contract on, which will give structure to $\mathcal{R}$. For example, if t_x is not contractible, then the rules will not address it—in other words, T_x will be $[0, \infty] \times [0, \infty]$.

3.1.3. The Bureaucrat's Choice

For each mechanism $R \in \mathbf{R} \cap \mathcal{R}$, the bureaucrat's payoff is

$$\begin{aligned} & N_H \pi_{HS} (p_{HS} - p) + N_L \pi_{LS} (p_{LS} - p) (1 - \phi_L(t_L)) \\ & + N_L \pi_{LF} (p_{LF} - p) \phi_L(t_L) - v N_H t_H - v N_L t_L. \end{aligned}$$

However, if R is in $\mathbf{R} \cap \mathcal{R}^c$, we assume that a bureaucrat pays a cost for breaking the rules, which is γ . Hence, the bureaucrat's payoff for any R in $\mathbf{R} \cap \mathcal{R}^c$ is

$$\begin{aligned} & N_H \pi_{HS} (p_{HS} - p) + N_L \pi_{LS} (p_{LS} - p) (1 - \phi_L(t_L)) \\ & + N_L \pi_{LF} (p_{LF} - p) \phi_L(t_L) - v N_H t_H - v N_L t_L - \gamma. \end{aligned} \quad (1)$$

We assume that the cost γ is unknown to the government when setting rules, though it knows that it is drawn from a distribution $G(\gamma)$. A corruptible bureaucrat is one for whom γ is finite.⁶ As a result, we write $R(\mathcal{R}, \gamma)$ as the mechanism chosen by a bureaucrat with cost of corruption γ when the rule is $\mathcal{R}$.⁷

3.1.4. The Government's Choice

We assume that the bureaucrat is the agent of what we call the “government” (but what others have called the “constitution maker”), a principal whose preference is to maximize the social welfare generated by the allocation of the slots. This assumption is partly an artifact of the way

6. This formulation is quite specific, and the cost of violating the rules is independent of the extent of violation.

7. We assume that when indifferent, the bureaucrat chooses what the government wants.

we model things. What is key is that the bureaucrat has a boss whose objectives are different from hers and who is in a position to punish her. Otherwise, she would never have to break any rules, because she, in effect, would make her own rules. The assumption that her boss cares only about social welfare is convenient but not necessary. Much of what we have to say would pertain if the principal cares less about the bureaucrat's welfare and more about that of the other beneficiaries, which may be true even if one thinks of the principal as the standard issue, partly venal, politician. After all, the politician cares about staying in power, and making the bureaucrat happy may not be the best way to do so. Of course, it is possible that the bureaucrat is the one who cares about beneficiaries and is trying to protect them from her boss. This is an interesting and perhaps important possibility that we do not investigate here. More generally, a setup like ours deliberately rules out the more interesting strategic possibilities that arise in models of political economy, to focus on the implementation issues that arise even without them.⁸ The government therefore maximizes

$$\int [N_H \pi_{HS}(R(\mathcal{R}, \gamma))H + N_L \pi_{LS}(R(\mathcal{R}, \gamma))(1 - \phi_L(t_L(R(\mathcal{R}, \gamma))))L \\ + N_L \pi_{LF} \phi_L(t_L(R(\mathcal{R}, \gamma)))L - (v + \delta)N_H t_H(R(\mathcal{R}, \gamma)) - (v + \delta)N_L t_L(v)] dG(\gamma)$$

by choosing $\mathcal{R}$.

3.1.5. Interpretation

We intend for this model to be the simplest one that can illustrate all features of interest. Specifically, it allows the bureaucrat to have multiple dimensions of malfeasance:

- *Corruption.* The bureaucrat breaks the rules.
- *Bribe taking.* The bureaucrat charges higher prices than those mandated.
- *Shirking.* The bureaucrat fails to implement mandated testing.
- *Red tape.* The bureaucrat implements more than the mandated amount of testing.
- *Allocative inefficiency.* The wrong people obtain the slots (according to the rules), or some slots remain unallocated when the rules require that all slots be given out.

There is corruption in equilibrium because the government does not observe the cost γ . If the government knew the particular bureaucrat's γ , it would know what the bureaucrat would choose, given the rules that are set; hence, the government would be able to set rules that would not be broken. However, when γ can take different values, the government has to choose between rules that give the bureaucrat a great deal of discretion (so that they will almost never be broken) and rules that are more rigid (to induce the bureaucrat to act in the social interest) and therefore will be broken by some bureaucrats (precisely because they are more stringent).

8. It is also worth making clear that the assumption of welfare maximization, although standard, is quite particular. The government could care, for example, about the distribution of welfare between the bureaucrats and the potential beneficiaries. In this case the government may prefer an inefficient outcome, because it achieves distributional outcomes better and may therefore create a more complex set of trade-offs than are permitted here. We return to this issue in Section 3.6.

This straightforward problem goes beyond the standard resource allocation problem under asymmetric information in two important ways. First, we do not assume that the private benefit to the person who obtains the slot is necessarily the social benefit. Such a divergence is characteristic of many situations involving the government. For example, society wants to give licenses to good drivers ($H > 0$) and not to bad ones ($L < 0$), but the private benefits of getting a license are probably positive for both types. Or suppose the slot is avoiding a jail sentence. H types are innocent. L types are not. $H > 0$ is the social benefit of not sending an innocent to jail. $L < 0$ is the social benefit of not sending a criminal to jail. However, the private benefits are positive for both types: $h \leq l$ but $h, l > 0$. Second, we allow the potential beneficiaries to have an ability to pay that is less than their private benefits (or willingness to pay) ($l > y_L$ or $h > y_H$). This condition is conventionally treated as being equivalent to the beneficiary being credit constrained, but it is worth emphasizing that it covers a range of situations (including the credit-constraint case). For example, consider the person who wants to take his child to the hospital to be treated, but his permanent income does not cover the cost. He would, however, be willing to pay his entire income (less survival needs, say) to save his child's life and also would be willing to additionally stand in line for 4 hours a day every morning. In this case, his total willingness to pay (in money and time) is clearly greater than his ability to pay. Clearly, if he could freely buy and sell labor, this case would reduce to the standard credit-constraint case, but given the many institutional features that govern labor markets, this would be an extreme assumption.⁹

However, the formulation embodies a number of important simplifying assumptions. We impose, for example, that rule breaking of any type has the same cost, which obviously need not be the case. For example, when a bureaucrat and an agent collude in such a way that the agent is better off than under the official rules, there will probably be less chance of being caught than when the bureaucrat attempts to make the agent worse off. We also do not deal with distributional issues: the government is indifferent to who—between the bureaucrat and his various types of clients—gets to keep how much money. We return to why this issue may be important later in the chapter.

3.2. A Useful Typology

Before jumping into the analysis of this model, it is helpful to underline some of the different possibilities that can arise in our framework (Table 1). The following typology will prove to be particularly handy. The labels of the cases should be self-explanatory, but more explanation emerges as we analyze each case.¹⁰

9. Another example that exploits a different rigidity in labor markets is the following. There is a woman who is not allowed by her family to work, but she is willing to walk 3 miles every day to make sure that her child gets an education. Her ability to pay (assume that the rest of the family does not care about education) is clearly less than her willingness to pay.

10. That we have only four cases is an artifact of the assumption that all H types are identical in their willingness and ability to pay and likewise for L types. However, the basic distinction we are trying to make here is between the case where H types are willing and/or able to pay more and the case where they may not be (captured by $h \leq l$ and $y_H \leq y_L$). The situation where a large fraction of L types are willing and/or able to pay more than a large fraction of H types is qualitatively very similar to the case where all L types are able/willing to pay more than all H types.

Table 1. Possibilities arising from the corruption model

Agent's valuation of slot	Agent's relative ability to pay	
	$y_H > y_L$	$y_H \leq y_L$
$h > l$	Case I: alignment	Case III: inability to pay
$h \leq l$	Case II: unwillingness to pay	Case IV: misalignment

3.2.1. Examples of Case I: Bids Aligned with Value

In this case, social and private value rankings align. Although the pure market case, $H = h = y_H$, $L = l = y_L$, belongs to this category, this case is ultimately broader than that, because even though the rankings may align, the actual ability to pay may not match social value. Some other examples that fall into this case include:

1. *Choosing efficient contractors for road construction.* Type H are the more efficient contractors. For the same contract, they make more money ($h > l$): Within our framework, contractors asking a lower price for their work is the same thing as them paying more up front to secure a contract that will eventually pay them a fixed amount. Because the contractors will be paid for their work, the price that they pay to obtain the contract can be seen as just a discount on how much they will eventually be paid rather than viewed as an out-of-pocket expense. It is plausible therefore that $y_H = h$ and $y_L = l$.
2. *Allocating licenses to import goods to those who will make the socially optimal use of them.* In an otherwise undistorted economy, the private benefits should be the same as the social benefits, as in the road construction example, but in this example, there may be credit constraints, because the license is first paid for and the profits come later. However, it is plausible that type H agents should be able to raise more money than type L agents. Thus, $y_H < h = H > L = l > y_L$, and $y_L < y_H$.

3.2.2. Examples of Case II: Unwillingness to Pay

This case is the least likely of the four cases, and so we do not spend much time on it. However, one possible example is a merit good, such as subsidized condoms for protection against HIV infection: H are high-risk types. They like taking risks. Hence, $h < l$. However, they may also be richer than type L (e.g., because they can afford to buy sex): $y_H > y_L$.

3.2.3. Examples of Case III: Inability to Pay

In this case, there is alignment of values: the high type values the good more than does the low type, but there is an inability to pay.

1. How to allocate hospital beds? The H types more urgently need the hospital beds (e.g., compared to those who just want cosmetic surgery). The social valuation probably should be the private valuation in this case: $H = h > L = l > 0$. However, there is no reason to assume that the H types can afford to pay more. We capture this situation by assuming $y_H = y_L = y$.
2. How to allocate subsidized foodgrains targeted to the poor? Presumably, the H types are the poor who benefit more from subsidized foodgrains, and the social benefit is plausibly

just the private benefit ($H = h > L = l > 0$). However, the poor may not be able to pay as much for the grain as can the nonpoor: $y_H < y_L$.

3. How to allocate government jobs to the best candidates? The private gains from landing the job may be higher for the H types (because the jobs offer so much more rents than the next-best alternative, and the better candidate may get more out of the job). However, everyone is constrained by how much they can pay for the job up front ($y_H = y_L = y$).

3.2.4. Examples of Case IV: Values Misaligned

In this case, there is simple misalignment between social and private valuation: those to whom the government would like to give the slot value it the least:

1. *Law enforcement.* We have already mentioned this example, where the slot is avoiding jail time: $H > 0 > L$, $y_H = y_L = y$, $h = l > 0$.
2. *Driver's licenses.* We discussed the setup of this example previously. However, this example would fall under Case IV if bad drivers value the license more, because they are more likely to be picked up by the police: $H > 0 > L$, $y_H = y_L = y$, $h < l$.
3. *Procurement.* The government wants to procure a fixed number of widgets and has a fixed budget for them (e.g., Bandiera et al. 2009). Suppose there are high-quality firms and low-quality firms. It is socially efficient to procure widgets from the high-quality firm, even though these firms have higher costs. In this case the slot is the contract, which needs to be allocated among firms. The gains from getting the contract are obviously higher for the low-quality firm, which has lower costs. So $l > h$. As long as these firms are not credit constrained, that would also mean that $y_H = h$ and $y_L = l$.

3.3. Analyzing the Model

This very simple model nevertheless allows for a rich variety of possibilities and situations. Here we confine ourselves to some illustrative examples of the kind of incentive issues that can arise in this framework, the corresponding patterns of rules chosen, and the violations of the rules. Specifically, we focus on a set of special instances of Cases I, III, and IV, which yield many of the insights we are looking for. We then briefly discuss the other cases.

3.3.1. Analysis of Case I

In this case, private and social rankings are aligned. Assume in addition that $N_H < 1$, but $L > 0$, so that it is optimal to give the leftover slots to L types. To solve the government's problem, we start with the mechanism design problem. Consider the following candidate solution (we drop the success or failure subscripts when a particular type is not being tested):

$$p_H = y_L + \epsilon, \quad p_L = y_L$$

$$\pi_H = 1, \quad \pi_L = \frac{1 - N_H}{N_L}$$

$$t_H = t_L = 0.$$

Notice that the low types would not want to pretend to be high types. They cannot pay p_H . What about the high types? If they pretend to be the low types, they could pay ϵ less, but they would receive the slot with probability less than 1. As long as

$$h - (y_L + \epsilon) \geq \frac{1 - N_H}{N_L}(h - y_L),$$

the high types would prefer to pay the price and be guaranteed a slot. We can always set ϵ low enough to ensure that this is the case. Therefore, the mechanism is incentive compatible for small enough ϵ . Because both types receive positive expected benefits, the participation constraints are also satisfied. The solution is feasible, because the ratio $\frac{1 - N_H}{N_L}$ was chosen precisely to exhaust the total number of slots. Finally, it is affordable, as long as ϵ is small enough, because $y_H > y_L$ in this case. Define E to be the set of ϵ such that this mechanism is in $\mathcal{R}$.

This solution is also social-welfare maximizing, because every H type receives a slot, every slot is taken, and no one is tested. The key question is whether the bureaucrat will want to choose this mechanism for some $\epsilon \in E$: if he will choose it, then the government's problem is solved. However, it is possible that he might prefer an alternative mechanism.

Given our assumption that there is a fixed cost of breaking the rules, if the bureaucrat is corruptible and chooses to break the rules, he will choose the mechanism that maximizes his payoff given by (1). Therefore, he will want to maximize the amount of revenue he can extract. The mechanism already allows him to extract all possible revenues from type L . To maximize his payoff (in this class of mechanisms), he will set ϵ to its maximal value in E . That is, he will set

$$p_H = p_H^* = \min \left\{ y_H, y_L + (h - y_L) \frac{N - 1}{N_L} \right\}.$$

Let us, with some abuse of terms, call the following the “auction mechanism”:

$$\begin{aligned} p_H &= p_H^*, \quad p_L = y_L \\ \pi_H &= 1, \quad \pi_L = \frac{1 - N_H}{N_L} \\ t_H &= t_L = 0. \end{aligned}$$

However, in this scenario, he is not extracting all the rents from type H , because p_H might be lower than y_H . What are the other mechanisms that could potentially give him higher payoffs?

One is the class of monopoly mechanisms. Set

$$\begin{aligned} p_H &= \widetilde{p}_H \leq y_H, \quad p_L = y_L \\ \pi_H &= 1, \quad \pi_L = \min \left\{ \frac{(h - \widetilde{p}_H)}{(h - y_L)}, \frac{1 - N_H}{N_L} \right\} \\ t_H &= t_L = 0. \end{aligned}$$

These mechanisms are constructed so that the probability of getting the slot as an L type is low enough that no H type will want to pretend to be an L type. No L type can afford the

slot at the H type's price, so that incentive constraint also does not bind. By construction, these mechanisms also satisfy the slot constraint, as well as the participation and affordability constraints. However, they generate an inefficient outcome, as some slots are wasted.

Obviously, this class of mechanisms will only interest the bureaucrat if $(h - y_L) \frac{N-1}{N_L} + y_L < \widetilde{p}_H \leq y_H$. The condition that it makes more money than the auction mechanism is that the expression

$$N_H(\widetilde{p}_H - p) + N_L \frac{(h - \widetilde{p}_H)}{(h - y_L)}(y_L - p)$$

is increasing in $\widetilde{p}_H$, because for $\widetilde{p}_H = (h - y_L) \frac{N-1}{N_L} + y_L$, this is exactly the payoff from the auction mechanism. The relevant condition is therefore

$$N_H > N_L \frac{(y_L - p)}{(h - y_L)}.$$

If this condition holds, the monopoly mechanism that maximizes the bureaucrat's earnings will have $\widetilde{p}_H = y_H$. Otherwise, the auction mechanism dominates.

Finally, the last alternative we consider is the testing mechanism:

$$p_H = \min \left\{ y_H, h - (h - l) \frac{1 - N_H}{N_L} \right\}, \quad p_{LS} = p_{LF} = y_L$$

$$\pi_H = 1, \quad \pi_{LS} = \pi_{LF} = \frac{1 - N_H}{N_L}$$

$$t_H = 0, \quad t_L = \max \left\{ 0, \frac{1}{\delta} \min \left\{ (h - y_L) \frac{1 - N_H}{N_L} - (h - y_H), (l - y_L) \frac{1 - N_H}{N_L} \right\} \right\}.$$

The exact construction of this mechanism is less obvious, so let us look at it in a bit more detail. The idea of this mechanism is to use testing just to reduce the rents of the self-declared L types, so that H types would not want to pretend to be L types. It is inefficient, because testing is wasteful. Because H types are more likely to pass a test than L types are, it would be counterproductive to reward "passing": the goal is to discourage H types from pretending to be L types. To reward failing the test also does not work: H types can always fail on purpose. Therefore, there is no advantage to conditioning on test outcomes.

To see that testing relaxes type H 's incentive constraint, note that now it becomes

$$(h - p_H) \geq (h - y_L) \frac{1 - N_H}{N_L} - \delta t_L.$$

Clearly, p_H can go up when t_L increases, which is why the bureaucrat might want it to. However, there is obviously no point in driving t_L past the point where $p_H = y_H$. This defines one limit on how large t_L should be:

$$(h - y_H) - (h - y_L) \frac{1 - N_H}{N_L} \geq \delta t_L.$$

Another limit comes from the fact that, by imposing testing, the L type is made worse off. So t_L must satisfy IR_L :

$$(l - y_L) \frac{1 - N_H}{N_L} \geq \delta t_L.$$

As long as IR_L is not binding, raising t_L always pays off in terms of allowing p_H to be raised. Once it binds, it is possible to continue to increase t_L by reducing p_L below y_L . However, this will never pay off, because reducing p_L also forces the bureaucrat to reduce p_H . Setting $\delta t_L = (l - y_L) \frac{1 - N_H}{N_L}$ and plugging this into type H 's incentive constraint gives us the limit on how high we can drive p_H by testing L types:

$$p_H \leq h - (h - l) \frac{1 - N_H}{N_L}.$$

Putting these observations together explains why we construct the testing mechanism in this way.

It is also worth observing that $t_L = 0$ when $y_L = l$. This result occurs because when IR_L is binding, red tape will never be used. Thus, the fact that the bureaucrat's clients are unable to pay the full value of what they are getting is key for the result that there is red tape (that is why they pay in "testing" rather than money).

These three mechanisms do not exhaust the class of feasible mechanisms. For example, it may be possible to combine the testing and monopoly mechanisms. However, it is easy to think of situations where each of them may be chosen by some bureaucrats, depending on the rules that the government sets and other parameters. The trade-offs that this model generates are mainly what we need to understand.

Scenario 1 Suppose that $(h - y_L) \frac{N-1}{N_L} + y_L \geq y_H$. Then, the auction mechanism extracts as much rent as possible. The government can give the bureaucrat full discretion (no rules) and expect the optimal outcome. It can then set p to appropriately divide the surplus between itself and the bureaucrat. The bureaucrat chooses the auction mechanism.

Scenario 2 Suppose that $(h - y_L) \frac{N-1}{N_L} + y_L < y_H$. Assume that π_{xT} , p_{xT} , and t_x are contractible. The rules do not impose any restrictions on the choice of t_x . Also, assume that the bureaucrat has no cost of testing ($v = 0$) and that it is possible to extract maximal rents from type H by testing the type L , which will be true when¹¹

$$y_H \leq h - (h - l) \frac{1 - N_H}{N_L}.$$

Suppose first that the government sets no rules. Because the bureaucrat pays no cost for testing and testing allows her to extract maximal rents, she will choose the testing mechanism described above as a way to create artificial scarcity.

11. As long as $y_L < l$, this condition is consistent with the condition $(h - y_L) \frac{N-1}{N_L} + y_L < y_H$ imposed above.

One alternative for the government is to set the rules so that the maximum price the bureaucrat can charge is $(h - y_L) \frac{N-1}{N_L} + y_L$, and all testing is forbidden. For those bureaucrats not prepared to break the rules, the optimal mechanism in this case will be the auction mechanism (because they were deviating from it precisely to charge the H type a higher price, which is now not allowed).

However, those bureaucrats who have a low cost of breaking the rules (low γ) will deviate from the auction mechanism and choose the testing or the monopoly mechanism.¹² The testing mechanism tends to extract less money from each L type (because they also pay the cost of being tested), but more L types get slots. Which of the two will be chosen depends on the parameter values. For example, an increase in $y_H - y_L$, keeping $1 - y_L$ fixed, makes the monopoly mechanism relatively more attractive (intuitively, when the H type can pay relatively more, the cost of including the L type increases). If the monopoly mechanism is chosen, there will be no red tape, but large bribes (price above the maximum allowed price) will occur. If the testing mechanism is chosen, we will observe both bribery (price above the maximum allowed price) and red tape. Nevertheless, from the social welfare point of view, this outcome is strictly better than the no-rules outcome, because a fraction of the bureaucrats (those with high γ) choose the auction mechanism. What is particularly interesting here, though, is that the rules themselves are now affected by the potential for corruption. A different set of rules make sense when the bureaucrats are more corruptible.

Scenario 3 Suppose that $(h - y_L) \frac{N-1}{N_L} + y_L < y_H$. Assume p_{xr} and t_x are contractible, but π_{xr} is not.¹³ However, let v be very high, so that the bureaucrat is not prepared to use red tape.

In the absence of any rules, the bureaucrat will either choose the auction or the monopoly mechanism. We already generated the condition under which the monopoly mechanism makes more money:

$$N_H > N_L \frac{(y_L - p)}{(h - y_L)}.$$

Interestingly, this condition is less likely to hold if p is lower—the government may be better off not charging the bureaucrats for the slots. However, even with $p = 0$, it is possible that the above condition holds (especially if y_L is very low), and the bureaucrat, unconstrained, would choose the monopoly mechanism. Suppose that this is the case. Then the no-rules outcome will leave many slots unallocated.

The government may prefer to set a rule where the prices that can be charged are capped by $(h - y_L) \frac{N-1}{N_L} + y_L$. Then the bureaucrats who have high γ will choose the auction mechanism, while the low- γ bureaucrats will choose the monopoly mechanism. There will be bribery, because the monopoly price is higher than the price cap.

12. It is true that in our model we would get the same result with either a rule on testing or a cap on the price, but this reflects our extreme assumption that breaking one rule is the same as breaking them all. An epsilon extra cost of breaking two rules instead of one would make it strictly optimal to have both rules.

13. In our model, because the bureaucrat always pays the government for the slots, the government actually knows how many slots he has used and therefore should be able to contract on π_x . However, it is easy to think of an extension of the model to a state of the world where the demand for slots is lower and the government does not observe this state.

3.3.2. *Analysis of Case III*

Let us focus on one special case: $L > 0$, $N_H < 1$, $h > l$, $y_H = y_L$ (which are the assumptions under which this case is analyzed in Banerjee 1997). To limit the number of cases, let $y_H = y_L = y < l$ and $\phi_L(t) = 0$; that is, no one ever fails the test. In this case, once again there is an auction mechanism:

$$\begin{aligned} p_H &= y, \quad p_L = p_L^* \\ \pi_H &= 1, \quad \pi_L = \frac{1 - N_H}{N_L} \\ t_H &= t_L = 0, \end{aligned}$$

where p_L^* is such that¹⁴

$$l - y = \frac{(1 - N_H)}{N_L}(l - p_L^*).$$

This mechanism implements the efficient outcome, because the high types, though they cannot pay more, value the slot more ($h > l$) and hence would rather pay the high price (all they can afford) and ensure a slot rather than risk not getting one at the low price. The logic of auctions still works.

However, now consider an alternative testing mechanism:

$$\begin{aligned} p_H &= y, \quad p_L = y \\ \pi_H &= 1, \quad \pi_L = \frac{1 - N_H}{N_L} \\ t_H &= t_H^*, \quad t_L = 0, \end{aligned}$$

where t_H^* is given by

$$l - y - \delta t_H^* = \frac{1 - N_H}{N_L}(y - l).$$

As in Scenario 2, testing only happens when $l - y > 0$.

A third is a lottery mechanism, given by

$$\begin{aligned} p_H &= y, \quad p_L = y \\ \pi_H &= \pi_L = \frac{1}{N} \\ t_H &= 0, \quad t_L = 0. \end{aligned}$$

The bureaucrat charges everyone y and simply holds a lottery to allocate the slots.

14. This only works if y is high enough. Otherwise, p_L might have to be negative.

Scenario 4 Suppose that π_{x_F} , p_{x_F} , and t_x are all contractible, and $v = 0$.

What would happen if the government set no rules? The bureaucrat would always prefer the lottery, with a very significant misallocation of slots.

Now, suppose the government sets the rules so that the bureaucrat is required to choose

$$\pi_H = 1, \quad \pi_L = \frac{1 - N_H}{N_L},$$

but there is no rule for what prices he can charge or the amount of testing. Every bureaucrat will choose the testing mechanism, because it gives them the same payoff as the lottery without breaking any rules.

Suppose the government wants to stop this unnecessary testing. Then it can set rules so that the bureaucrat is required to set the auction mechanism:

$$\begin{aligned} p_H &= y, \quad p_L = p_L^* \\ \pi_H &= 1, \quad \pi_L = \frac{1 - N_H}{N_L} \\ t_H &= t_L = 0. \end{aligned}$$

This mechanism will be chosen by those bureaucrats who have high enough γ . However, the low- γ bureaucrats will choose the testing mechanism, and there will be both bribery and red tape.¹⁵

Alternatively, the government could choose the lottery as the rule. All bureaucrats would then choose it and there would be no corruption and no red tape, but the outcome that everyone chooses would involve misallocation. However, because there is no testing, this outcome might be better than that from testing, if the cost of being tested, δ , is high enough. Moreover, the testing mechanism is only better because it makes the high- γ bureaucrats choose the optimal mechanism. Therefore, if most bureaucrats face a low value of γ , representing a government that cannot enforce the rules very well, then the lottery mechanism is likely to dominate.

3.3.3. Analysis of Case IV

Let us restrict our attention to the specific situation $N_H > 1$, $y_L = l > h = y_H$, and $L < 0$. The goods are scarce, but the private valuation of the high types is lower than that of low types. The low types should ideally not obtain the slots.¹⁶ The analysis in this section draws on Guriev (2004). Consider the following testing + auction mechanism:

$$\begin{aligned} p_{HS} &= p_H^*, \quad p_{HF} = p_L = l \\ \pi_{HS} &= 1/N_H, \quad \pi_{HF} = \pi_L = 0 \\ t_H &= t_H^*, \quad t_L = 0, \end{aligned}$$

15. Once again we assume that the bureaucrat (at least weakly) prefers to break one rule rather than two.

16. For examples, see Laffont and Tirole (1993).

where t_H^* and p_H^* solve the two equations¹⁷

$$h - \delta t_H^* - p_H^* = 0 \quad (2)$$

$$(1 - \phi_L(t_H))(l - p_H^*) - \delta t_H^* = 0. \quad (3)$$

It is easy to check that this mechanism satisfies all the constraints. Of particular interest are type L 's truth-telling constraint:

$$(1 - \phi_L(t_H))(l - p_H^*) - \delta t_H^* \leq 0,$$

which states that type L individual voters weakly prefer not getting the slot to pretending to be a type H and getting it with some probability. It is clear that for this condition to hold, $t_H^* > 0$, because without testing, the L types always want the slot if the H types do. Testing is necessary in this case.

This mechanism also implements the optimal allocation (only H types get the slots) with the least amount of testing.

However, the bureaucrat may consider other mechanisms. One possibility is a straight auction:

$$p_H = p_L = l$$

$$\pi_H = 0, \quad \pi_L = 1/N_L$$

$$t_H = 0, \quad t_L = 0.$$

Another is a lottery. No one is tested, but the allocation is all wrong—only L types receive the slots:

$$p_H = p_L = h$$

$$\pi_H = 1/N, \quad \pi_L = 1/N$$

$$t_H = 0, \quad t_L = 0.$$

Scenario 5 Suppose that π_{xr} , p_{xr} , and t_x are contractible, and $v > 0$. Consider what would happen without any rules. The auction mechanism maximizes the bureaucrat's earnings without any testing and will be chosen. Now suppose the government sets rules about t_x , π_{xr} , and p_{xr} exactly at the level given by the testing + auction mechanism. Bureaucrats who do not want to break the rules will then choose the testing + auction mechanism. The ones who are prepared to break the rules will choose the auction mechanism. There is bribe taking, shirking, and misallocation of resources (similar to Bandiera et al. 2009).

However, the government could also give up on trying to implement the ideal testing + auction mechanism. It could set the rules corresponding to the lottery mechanism. The advantage of this mechanism is that the bureaucrats are making more money from the slots, because $h > p_H^*$, and spending less effort on testing; hence, the gains from deviating are smaller. The disadvantage is that some slots go to the L types, even if the bureaucrat is not corrupt. However, fewer of them deviate from the rules and give all slots to the L types.

17. We assume that a solution with $p_H^* \geq 0$ exists, which is true when $l - h$ is not too large.

3.4. Interpretation of Results

The above analysis makes clear the essence of our approach. Governments are interested in setting rules when the *laissez-faire* outcome does not maximize social welfare. Put simply: in this model, governments only interfere to improve an inefficient situation. Corruption, however, results when these rules do not extract maximum surplus for the bureaucrat. Sometimes the rules allow the bureaucrat to extract surplus exactly as she wants (e.g., Case I in Section 3.3.1), but in many other cases they may not. The task assigned to the bureaucrat and the rules are chosen by a government cognizant of the possibility for corruption. In several of the cases, it is clear that the presence of corruptible bureaucrats changes the rules and tasks. The government chooses those rules, and the task is assigned to the bureaucrat, recognizing that the rules will sometimes be broken. The overall outcome is still improved by setting those rules. This is the essence of the tasks approach.

However, the model also offers other, more specific, insights. The first observation is that red tape goes hand in hand with bribery. Given that testing is costly, there is no reason to overuse it, unless there is extra money to be made. However, there are two distinct reasons for using it. When the willingness to pay is aligned with ability to pay and social valuation (Case I; specifically, Scenario 2), red tape is faced by L types, that is, those who have a low probability of obtaining the good, and is designed to create some artificial scarcity and extract more rents for the bureaucrat (along the lines suggested by Shleifer and Vishny 1994). In other words, the purpose of the red tape is to screen in the types with a high willingness to pay. When ability to pay is not related to the willingness to pay (Case 3, Scenario 4), then red tape emerges, because even corrupt bureaucrats prefer to generate as efficient an allocation as possible, conditional on not making less money. The red tape is then placed on the H type, and the purpose is to screen out the types with a low willingness to pay.

The second point is that red tape only emerges when $y_L < l$. Moreover, it is easy to check that in both cases, red tape increases in the gap between the willingness to pay and the ability to pay. The intuition is simple. It is precisely because this gap exists that it is possible to impose red tape. If there were no such gap, the client would simply walk away if faced with a great deal of red tape. This reasoning makes it clear why people do not have to endure red tape when they try to buy most marketed goods (i.e., goods for which $l = y_L$). Governments are associated with red tape, in this view, because governments often supply goods to people whose ability to pay is less than their willingness to pay. For that reason, this problem is particularly acute for governments serving the poor.

A third point, which is related to the first, is that red tape does not have to result from scarcity. Scarcity may have a positive or a negative effect on red tape, depending on whether we are trying to discourage the H type from pretending to be an L type (Scenario 2, where scarcity reduces red tape) or the opposite (Scenario 4, where scarcity increases red tape).

A fourth point comes from thinking about the correlation between red tape and bribery. This correlation is emphasized by La Porta et al. (1999), who, looking at cross-country data, argue that the positive correlation of testing with bribery is evidence that much testing is unnecessary and hence is red tape. As already observed, red tape only occurs when there is bribery. However, we cannot assume that there is always more red tape when there is more bribery—that depends on what is the underlying source of variation as well as the underlying economic problem. For example, both in Scenarios 2 and 4, the incentive to move away from the auction outcome

toward the testing outcome is always stronger when $l - y_L$ is larger. Therefore, there will be more red tape and corruption when y_L is lower, as long as the government sets rules that correspond to the socially efficient mechanism. In contrast, when $y_H - y_L$ goes up, keeping $l - y_L$ fixed, corrupt bureaucrats will switch from testing to monopoly (see Scenario 2). There is an increase in the size of bribes and a fall in red tape.¹⁸

A fifth point follows from Scenario 5. Bribery can be associated with red tape, but it is also associated with shirking, which, in a sense, is the opposite of red tape.

A sixth point follows from the observation in Scenario 4 that a rightward shift in the distribution of γ will lead the government to switch from rules that correspond to the lottery mechanism to those that correspond to the testing mechanism. This switch leads to greater bribery and more red tape but to less misallocation and is therefore worthwhile. In other words, greater state capacity might be associated with more red tape and bribery. Conversely, a lack of bribery cannot be interpreted as evidence that all is well.

A seventh observation is that corruption might force the government to give up on trying to maximize its revenues from the sale of slots. In Scenarios 1 and 3, we saw that the government should set the price of the slots to the bureaucrat as low as possible to reduce corruption.

Finally, it is clear that the government often faces a choice between more desirable mechanisms that are more subject to corruption and less desirable ones that are less so. This is exactly the choice in Scenario 4 but also in Scenario 5. Corruption is therefore an outcome of this choice.

3.5. Firms and Governments: A Digression

The broad framework developed above would apply, *mutatis mutandis*, to any situation where the principal cares about the assignment of slots to the right people but not how much money he makes from the slots, but the slot allocation is implemented by an agent who does not care about who gets the slots but is concerned about how much money she makes. The first assumption comes directly from our framework.

However, much of what is interesting here also relies on two additional assumptions. First, the private valuation of those who receive the slots is not necessarily equal to the value the principal puts on giving them the slots. Second, the private valuation may not be the same as the ability to pay.

These assumptions are quite natural in the context of thinking about governments and similar organizations, such as nonprofit organizations. However, in the conventional way of

18. A negative correlation would also result if we were prepared to go outside the world of the model and assume that the government has other unmodeled reasons for setting a price cap that do not have to do with promoting efficiency. For example, the government may be sensitive to distributional or ideological concerns—government bureaucrats should not be seen as becoming too rich, even if that is what efficiency demands. Or there may be some political or symbolic argument for making all public goods free or very cheap. This might lead the government to set the price cap below y_L . Take the extreme case where the good is supposed to be free (the cap is zero). In this case, the government would actually want the bureaucrat to test those who apply for the slots (because the price mechanism will not do any screening). Here a bureaucrat who is corrupt might actually do some good: all he needs to do is to raise the price for the H types to $y_H + \varepsilon$ and scrap the red tape, and social welfare would unambiguously go up. In such cases, bribe taking would be an antidote to red tape, and they would move in opposite directions. This is the old idea that corruption greases the wheels and increases efficiency (Huntington 1968), but note that it can only happen when the government is not using its choice of rules to maximize welfare.

looking at market transactions (think of the principal as the manufacturer, the agent as the retailer, and the clients as buyers), none of these *three* defining assumptions probably apply. We now recognize that there are many transactions involving firms where the firm is not seeking to maximize short-run profits, because of multitasking, reputation, or signaling, for example, or because the transaction is internal to the firm (e.g., who should be promoted). In such cases, our first two assumptions are likely to be satisfied. However, the third key assumption (about the divergence between the willingness and the ability to pay) is less obviously applicable.

Thus, Cases I and IV probably fit the private sector best (see Sections 3.3.1 and 3.3.3). We know that there can be corruption in both these cases (Scenario 2 or Scenario 5), even if the ability and the willingness to pay are the same ($y_L = l$, $y_H = h$). However, as already observed, there will not be red tape in such cases, though shirking may occur.

Other potential sources of corruption that do not arise in our model may occur in private firms. There may be conflicts over the division of the surplus with a profit-maximizing principal—for a variety of reasons (e.g., the agents may be credit constrained), the firm may want to share enough of its realized revenues with its agents to align their incentives. This may be even more of an issue for private firms than for governments, though as discussed in Section 3.6, it is central to some things that governments do, such as tax collection.

Many reasons not in our model account for why the government may have more corruption than private firms do. One big difference between firms and the government is that even when many of the transactions take place within the firm, there is still an ultimate principal (or principals) whose business is maximizing profits. This could place a limit on the level of rents that could possibly be captured. Consider corruption in promotion decisions. This context offers opportunities for corruption in both sectors. In the government context, there are jobs that one would like to capture because they offer rents in terms of bribes from customers (e.g., the job of a policeman). Thus, both the capacity to engage in corruption and a willingness to do so exist (there are big rents). The firm context allows room for corruption, because promotions are also not allocated through a market mechanism. However, the upside gains from capturing the job are far more limited: the customers are paying market prices, and hence, there are no rents to be had from them. At best, one gets the rents from a higher paying job and, in most cases, these are nowhere near the rents to be had from having access to customers who are willing to pay a bribe.

A related point is that governments and firms are held accountable through different mechanisms. Governments have to convince voters to reelect them, but the welfare of the voters depends on a combination of many outcomes. As a result, the electorate cannot simply use single metrics, such as revenues or taxes collected, to evaluate performance. Firms, however, are (much more easily) evaluated along a single dimension—profitability. This difference generates opportunity for corruption in government that does not exist in firms. For example, consider procurement procedures. In firms, a clear mapping connects from corruption in procurement to lower profitability, which the boss typically does not like. Whereas in the government, the resultant rise in costs is probably submerged somewhere in the general budget, and while the loss of quality might be noticed by some voters, they would most likely place small weight on it in their decision of whom to vote for. Indeed, we might speculate that those who are in favor of corruption in government have a stake in arguing against any single metric of performance.

In summary, firms have less slack at the edges than governments. This lack of slack limits the room for corruption within the organization. Of course, it does not completely eliminate

corruption. Nor does it mean that all firms face little slack. For instance, poorly governed firms or those with monopoly power or other factors generates slack. We are merely speculating that qualitatively, governments experience much more slack when dealing with clients, and this slack translates into more opportunity for corruption in the organization.

3.6. Limitations of the Framework

3.6.1. *Monitoring*

A clear limitation of our framework is made clear from the discussion in Section 3.5 about the differences between external incentives faced by governments and private firms. It tells us very little about monitoring structures, other than the obvious point that better monitoring would reduce corruption. The emphasis on monitoring in theorizing corruption goes back, of course, to the classic paper by Becker and Stigler (1974). Although the insights from this paper remain fundamental, we see it more as a paper on agency problems generally and not particularly about corruption.

There is also now a literature that emphasizes the institutional aspects of monitoring. Clearly, a choice exists for who monitors (the superior bureaucrats, the community, the voters?) and how intensively (should there be pro-active public disclosures of public accounts, of the performance of individual bureaucrats, etc.?). Even though the Bardhan and Mookherjee (2006) model captures the important and basic idea that communities may have an informational advantage in monitoring (and therefore in controlling) corruption, the theoretical literature on this subject has not advanced very much beyond this point, though there is a lot of interesting empirical material available.

An important theoretical literature emphasizes the endogeneity of the effectiveness of monitoring. Lui (1986) makes the point that corruption may be harder to detect when everyone else is corrupt. Tirole (1996) shows that in a model where experimentation is costly, when enough bureaucrats are corrupt, everyone acts as if all of them were corrupt, which removes the incentive to be honest. There is also the idea that people feel less bad about being corrupt when everyone else is corrupt. To our knowledge, little rigorous empirical research has been done based on these ideas, though they are obviously important.

3.6.2. *Reintroducing Distributional Concerns: Understanding Extortion*

Another limitation of our framework is that it assumes that the government maximizes total social welfare. However, ignoring the distribution of welfare between the beneficiaries and the bureaucrats is clearly wrong in many instances. One obvious example is tax collection. Tax collection is all about who pays. In such cases, the government might prefer an inefficient outcome, because it achieves the distributional outcome better and may therefore create a more complex set of trade-offs than are otherwise permitted.

Similarly, the fact that the outside option in our model allows people to withdraw from obtaining a slot is also potentially problematic, especially because this outside option does not vary by type. Consider a tax collection example. Suppose you are trying to get a tax-exempt certificate, because you have no money. An undeserving taxpayer (a type *L*), who actually can afford to pay the taxes, does have the option to walk away: if she does not have the certificate, she can always pay the taxes and be done with it. In contrast, the deserving taxpayer (type *H*) cannot

pay the taxes. As a result, if he withdraws from trying to get the certificate, he risks prison. His outside option is worse than that of the type L .

More generally, our assumption about outside options limits the possibility of extortion. However, it has long been recognized that one reason many government functions cannot be privatized is because of the potential for extortion. We need a framework that helps explore these issues.

3.6.3. *Screening on Multiple Dimensions*

In our framework, the assumption that there is only one dimension of asymmetric information is very restrictive. The bureaucrat may want to know about both the beneficiary's type (because misallocation is punished) and his ability to pay (because the bureaucrat wants to make the most money), and the two traits may not be perfectly correlated. A simple example of what can happen in such situations is worked out in Banerjee (1997), but the general multidimensional screening case is not well understood.

3.6.4. *Modeling Corruption*

Our framework also embodies one specific view of why there is corruption in equilibrium. Corruption occurs because the cost of violating rules varies across bureaucrats. However, as discussed at some length in Tirole (1986), there are other reasons. For example, the government may recognize that in some states of the world, the bureaucrat and his clients are in position to cut a profitable private deal that the government would like to prevent but lacks the information to do so.

Why not then simply recognize that this deal will happen and make it legal? One possible answer is that there are many other states of the world where the same deal would be available, but in these other states of the world, the government is in a position to detect such behavior, prosecute the bureaucrat, and thereby prevent the transactions. However, if the courts cannot distinguish between those states of the world where such private transactions are proscribed and other states of the world where they are not, the bureaucrat could always claim that the transaction was allowed and get away with it. By banning all transactions between the bureaucrat and his client, the government is creating the possibility that the rules will be violated from time to time, but it gains in terms of being able to prosecute the bureaucrat if he goes too far.

4. Measuring Corruption

Measuring corruption is the primary challenge in the empirical literature. Without robust measures, the theories cannot be tested, the magnitudes of corruption cannot be quantified, anticorruption policies cannot be assessed, and so forth. However, measuring corruption is challenging, and even today, relatively few studies are able to credibly describe the extent of the problem. As Bardhan (1997: 1320) notes in his review of corruption, "our approach in this paper is primarily analytical and speculative, given the inherent difficulties of collecting (and hence nonexistence of) good empirical data on the subject of corruption."

The measurement challenges are driven by several problems. First, the very fact that corruption is illegal makes people reluctant to talk about it for fear of getting into trouble and, possibly, for shame. Second, the existing literature—because of the theory it draws on and how

it defines corruption—takes a transactional view of corruption. Measurement means finding out who bribed whom and by how much, which is inherently harder to quantify. Third, the traditional narrow focus on monetary transactions also makes it more difficult.¹⁹ When a government official benefits by stealing “time”—she decides not to show up for work—random spot checks can be very revealing (e.g., see Chaudhuri et al. 2006). Finally, measurement systems will evoke responses that make the measurement system less reliable. If the government has a monitoring system in place, people adjust to it and find ways around it. As a result, these measurement systems will underestimate corruption.

Despite these difficulties, many early attempts at measuring corruption relied on rich qualitative data and were occasionally backed up by numbers. These studies gave the first real evidence about the channels through which corruption occurred and possible methods to eliminate it. Wade (1982) in particular provides a detailed description of how irrigation engineers reap revenue from the distribution of water and contracts in a village in South India. The most fascinating aspect of this study was the documentation of a fairly formal system in which the engineers redistributed revenue to superior officers and politicians. To obtain transfers to lucrative posts, the junior officers paid bribes based on expectations about the amount of bribe money that can be collected from the post. Thus, the value of the bribe payment in the transfer process was higher for jobs that had greater potential for bribe extraction. In essence, the ability to take bribes in a job induces bureaucrats to bribe others to get it. This highly detailed study gives a glimpse into the pervasiveness of corruption in this area and the mechanics of how it operates. It also illustrates how corruption is interconnected throughout the entire organization and raises the possibility that rather than trying to remove one aspect of corruption, it may be necessary to invoke coordinated policies to stamp it out throughout the system. However, like all case studies, the study raises questions of generalizability. Is there as much corruption in other contexts? Under what set of circumstances do these systems come into being?

Other early studies focused on anticorruption policies. For example, Klitgaard (1988) provides several case studies of successful elimination of corruption, such as in the Hong Kong Police Force, Singapore Excise Department, and the Bureau of Internal Revenue of the Philippines. In all these cases, the levers used are intuitive from the perspective of agency theory—more intense or better monitoring, replacing individual actors, and so forth. They also all seem to involve a person at the top of each institution who was eager to implement these changes. On the one hand, these cases represent a vindication of an agency theory of corruption. On the other hand, they raise the more fundamental question: if these levers for eliminating corruption are in the choice sets of governments, why are they not implemented? Although they spark hope that corruption can be fought, these examples leave lingering questions about why conditions were ripe for these interventions but not for those elsewhere. Is what we observe due to particular institutional factors in these settings or to more generalizable features of how governments function? What particular combinations of institutions, policies, or conditions would lead to similar steps being taken elsewhere? Should we expect the same consequences of similar anticorruption policies in different settings?

19. There are exceptions. For example, Tran (2008) gathers a comprehensive set of internal bribery records from a firm in Asia to document the cost of bribe payments over time.

To address these inherent problems of case studies, the next attempts to measure corruption tried to provide consistent measures of corruption across countries. However, given the difficulty of inducing people to talk about corruption, these measures focus on collecting perceptions of corruption rather than on the actual bribes paid or the actual theft of resources. This perception-based approach has been carried out at quite a large scale, generating interesting cross-country and cross-time datasets. The Economist Intelligence Unit created one of the first such datasets.²⁰ The data collection effort consisted of factor assessment reports that were filled in by the Unit's network of correspondents and analysts. The reports were then aggregated into risk factors for about 70 countries. The factor assessment reports included, for example, a question where the respondents rated "the degree to which business transactions (in that country) involve corruption or questionable payments" on a scale of 1–10, where a high value implies good institutions (Mauro 1995: 684). Other cross-country measures on subjective perceptions of corruption followed, including the Control of Corruption measures in the World Bank Governance Indicators (a description of the measures can be found in Kaufmann et al. 2004), and measures by Transparency International (2008).²¹ Each of these indicators uses a different methodology with its own advantages and disadvantages, which we do not discuss here due to space constraints.²² The real advantage of such data is their breadth, which allows one to run large correlational studies. Mauro (1995) is an often-cited example of this kind of study. He uses the Economist Intelligence Unit measures in a cross-country growth regression equation to study the relationships among economic growth, corruption, and red tape.

While these perception-based measures of corruption provided evidence on which countries tend to report more or less corruption, many have pointed out their limitations. First, as Rose-Ackerman (1999) noted, it is unclear what the corruption indices actually mean and what a particular rank implies about the type and level of corruption in a country. For example, in the Transparency International Corruption Perceptions Index for 2008, Brazil, Burkina Faso, Morocco, Saudi Arabia, and Thailand all have the same index value. However, the value does not tell us what the form of corruption in these countries entails, nor does it indicate whether the types of corruption observed in these very different countries have different efficiency implications. For example, in the theoretical framework developed in this chapter, bribe taking can actually promote efficiency, if the problem is that the government is committed, for political or ideological reasons, to set the price cap below what it should be. Moreover, corruption often emerges as a result of government interventions designed to deal with some other distortion (see Section 3). These countries may have very different problems—why would the gap between l and y_L or between h and y_H be the same in Saudi Arabia and Burkina Faso, given their very different levels of per capita wealth? Or corruption may be a result of the government's attempt to fight some other form of misbehavior by its bureaucrats—for example, in Case I (Section 3.3.1), absent a price cap, the bureaucrat might choose the monopoly outcome, and

20. These datasets are also called the "Business International Indicators."

21. Papers that use perception-based measures of corruption in cross-country regressions include Mauro (1995), Knack and Keefer (1995), LaPorta et al. (1999), Treisman (2000), Adsera et al. (2003), Fisman and Gatti (2002), Fredriksson and Svensson (2003), Rauch and Evans (2000), and Persson et al. (2003).

22. Svensson (2005) provides a thorough description of the differences among the most common cross-country indicators of corruption.

many slots may be wasted. A price cap might move the outcome to more visible malfeasance by the bureaucrats (red tape and bribe taking) but less misallocation and less inefficiency overall. Greater corruption in one country could simply be a reflection of a greater willingness to fight corruption in that country. Because they do not supply information about the sources of corruption, these corruption indices actually tell us little about what types of governance interventions would help deal with the problems or even whether we should reward or praise governments that have less corruption by these measures.

Second, perceptions may indicate little about the actual reality of situations, because they are influenced by the way we see everything else. For example, perhaps when the economy is good, we perceive less corruption, because we are more satisfied with the government. Olken (2009), for example, compares the perception of corruption in a roads project with actual missing expenditures. He finds that although there is real information in perceptions, reported corruption is not particularly responsive to actual corruption. For example, “increasing the missing expenditures measure by 10 percent is associated with just a 0.8 percent increase in the probability a villager believes that there is any corruption in the project” (Olken 2009: 951). He also finds that the bias in perceptions is correlated with demographic characteristics, implying that perceptions of a nonrandom sample of the population may not adequately reflect real corruption levels. This bias is particularly problematic, as many perception measures are not necessarily based on random samples. For example, the measures from the Economist Intelligence Unit are based on the perceptions of foreign analysts, who may have different perceptions of corruption than the average citizen of the country. Finally, and perhaps probably most importantly for our purposes, these data are most useful for cross-country or cross-geography analysis. They are less useful for testing microtheories of corruption.

New methods for measuring corruption have been developed that solve the small-sample problem and move to more concrete measures of corruption. The first such method focuses on refining survey and data collection techniques to improve the ability to assemble data on self-reported bribes and service delivery quality. For example, Svensson (2003) analyzes a dataset that provides information on bribes paid by firms in Uganda. To encourage truth telling in the survey, it was conducted by a trusted employers’ association; it also asked carefully worded, hypothetical questions to measure corruption.²³ Hunt (2007) uses the International Crime Victims Surveys and Peruvian Household surveys, both of which contain information on bribes to public officials if the individual has been the victim of a crime.²⁴ Other studies collect prices paid for services that should be free. For example, Banerjee et al. (2004) collects data on fees paid at government health centers in India (that should mostly be free), Atanassova et al. (2008) collect data on prices paid and quantities received from the public distribution system in India and compare them to the official prices for these commodities. The main benefit of these methods is a move to measures that have actual meanings. For example, using the measure in Banerjee et al. (2004), we can estimate the bribe amounts paid at the health centers and use this information to understand

23. For example, “Many business people have told us that firms are often required to make informal payments to public officials to deal with customs, taxes, licenses, regulations, and services, etc. Can you estimate what a firm in your line of business and similar size and characteristics typically pays each year?” (Svensson 2003: 213).

24. Mocan (2008) also uses the International Crime Victims Surveys to determine what characteristics were associated with greater corruption.

how the bribes affect the allocation of health services. We can also use it as an outcome measure to study the effectiveness of anticorruption policies in government health centers. However, these types of measures are limited if individuals are underreporting bribes, and particularly if this underreporting is biased by corruption levels. Moreover, most of the time, these measures are often limited to petty corruption, because it is difficult to ask individuals about the larger bribes that they may have paid. Indeed, in many of these cases, the reports are assumed to be reliable precisely because the agents do not know how much they should have paid, and therefore do not see themselves as paying bribes. It is also clear that people might be more willing to reveal bribes that they paid in settings where the good they receive is abundant (so that they are not displacing anyone else by paying the bribe).

The second method is the use of physical audits of governmental processes. For example, Chaudhury et al. (2006) conducted a multicountry study of teacher and health worker absence, where they performed spot checks to determine whether bureaucrats were showing up for work.²⁵ Similarly, Bertrand et al. (2007) followed individuals through the process of obtaining a driver's license in India and recorded all extra-legal payments made and the rules that were broken in exchange for these payments. Barron and Olken (2007) designed a study in which surveyors accompanied truck drivers on 304 trips along their regular routes in two Indonesian provinces. The surveyors observed the illegal payments the truck drivers made to the traffic police, military officers, and attendants at weighing stations.

One of the key challenges to the audit studies is whether the observed outcomes actually reflect corruption rather than some less intentional form of bureaucratic ineffectiveness, because often there is no smoking gun (bribe overtly paid, job left entirely unattended, etc.). For example, Bertrand et al. (2007) find that there is a misallocation of licenses—people who cannot drive are able to obtain them. Could this be due to an overworked bureaucrat who does not have time to screen license candidates or due to an incompetent one who cannot distinguish between good and bad drivers? To understand this issue, Bertrand et al. collect detailed quantitative and qualitative data on how the bureaucrats behave during the licensing process. They document extreme behaviors (e.g., simply never administering a driving test), which would be hard to label as “incompetence.” Similarly, Duflo et al. (2012) measure teacher absenteeism in rural India using audit methods. Does the fact that teachers often do not come to school imply that they are consciously breaking the rules for private gain? Or are lives of these teachers so difficult that they just cannot make it to school often enough, despite trying as hard as they can? The research design provides information that allows the authors to answer these questions. Specifically, they evaluate a program that monitors the teachers and provides incentives to them based on their attendance. They find that teachers are very responsive to the incentives. That teachers respond to the incentives so strongly implies that the teachers were previously ignoring the rules and were not incapable of attending.

We refer to the third technique as “cross-checking.” The idea behind it is to compare official records of some outcome with an independently collected measure of the same outcome. One example of cross-checking is to compare how much money was released to the bureaucrat with how much the ultimate beneficiaries of the funding report have received. For example, Reinikka

25. Other such studies include Duflo et al. (2012), who measure teacher absence, and Banerjee et al. (2008a), who measure absenteeism among medical providers.

and Svensson (2005) compare data from records on central government disbursements and a public expenditure tracking survey to measure dissipation in a school capitation grant in Uganda. They find that the average school received only about 20% of central government spending on the program. Fisman and Wei (2004) compare Hong Kong's reported exports to China at the product level with China's reported imports from Hong Kong to understand the extent of tax evasion. Another way to conduct a cross-check would be to collect records from the bureaucrat documenting how the government resources were spent in achieving a task and then compare them with an objective measure of how much it should have cost to conduct the task. The difference between the two measures is, then, the estimate of how much was stolen. Olken (2007) uses this method. He calculates corruption in the context of road projects by comparing the actual expenditures reported with an independent measure of what it should have cost to build a road of that particular quality. To obtain the independent measure, he sampled each road to determine the materials and labor used, and then used local prices to cost these elements. He finds that, on average, about 24% of expenditures across the project villages were missing.²⁶

As with any other method, this one has both strengths and limitations. Its innovation lies in the fact that it creatively allows the measurement of dissipated government resources without asking the actors involved if they have paid or received an actual bribe, reducing the chance of under- or misreporting. Thus, it often allows us to move past petty corruption and perhaps look at larger scale corruption. However, it is difficult to understand whether the dissipated resources are actually corruption or simply mismeasurement in the indicators or even just a sign of bureaucrat incompetence. For example, in Olken (2007), it remains possible (though unlikely) that road quality is mismeasured or that the bureaucrats are not good at building roads. It is possible (though again unlikely) that the missing resources indicate that the bureaucrats are trying to reallocate funds to better uses. For example, in Reinikka and Svensson (2005), it is possible (although again unlikely) that the resources that should have gone to the school capitation program were actually spent on services that the community deemed more important and did not end up in the pockets of government officials. Would this result have necessarily been bad?

One way to get around these concerns is to look for correlations (motivated by theory) between the extent of dissipation and some other variable. For example, to show that the differences in reported shipments is corruption and not just mismeasurement in the shipments, Fisman and Wei (2004: 471) document that the differences are "negatively correlated with tax rates on closely related products, suggesting that evasion takes place partly through misclassification of imports from higher-taxed categories to lower-taxed ones, in addition to underreporting the value of imports."²⁷

26. Other examples of cross-checking in the developing world include the Hsieh and Moretti (2006) estimate of bribes in Iraq's Food for Oil Program; Olken (2006) and Atanassova et al. (2008) measure theft in food distribution programs using the same method, and Di Tella and Schargrodsky (2003) use it to measure corruption in hospital procurements.

27. Duggan and Levitt (2002) provide an interesting example of cross-checking in sumo wrestling. They basically show that a wrestler has a higher probability of winning than expected when the match is key to his rank. To distinguish match throwing from effort, they use theory as a guide: the effect goes away when there is

In addition to these methods recently used in the literature, there are several innovative methods being explored in current studies. Although some of the work is not yet published, such methods will surely contribute to the tools available for studying corruption. For example, Banerjee and Pande (2009) attempt to use second-hand data on which politicians have gotten rich since they entered politics to identify those who have profited from corruption.²⁸ They find that this measure correlates strongly with other, more direct (perceptual), measures of corruption (e.g., the answer to the question “do you think the politician used his office for private gain?”). Cai et al. (2009) use predictions from auction theory to argue that certain types of land auctions in China are used to promote collusion between the auctioneer and the participants, for their mutual benefit.

All these methods pick up the direct correlates of corruption, such as bribes and absence from work, rather than its more indirect ramifications. In some cases, such as teacher absenteeism, the direct consequence may be the most important. However, the point of our framework is to argue that in many situations, the bribe may just be the tip of the iceberg, with the more serious repercussions showing up in terms of misallocation and red tape. The next section discusses an example of empirical research that tries to capture the bureaucrat’s entire decision process and its various ramifications.

5. Understanding the Structure of Corruption

Most empirical research has been based on measuring the extent of bribery or shirking and on how incentives affect these behaviors. Bertrand et al. (2007) differs from much of the empirical research by focusing on the entire resource allocation problem faced by the bureaucrat and therefore looking beyond bribe taking as the measure of welfare. The basic strategy of the paper is to experimentally vary the underlying types a bureaucrat faces and use the bureaucrat’s responses to infer their chosen allocative mechanism.

Specifically, Bertrand et al. (2007) compare three randomly chosen groups of license candidates. The first group was told to obtain a license as usual, the second group was given a large incentive to obtain the license in the minimum legal time allowed (30 days), and a third group was offered free driving lessons. In our model, the second group represents a situation where h and l have both increased by the same amount. The third group represents a situation where some of those who were low types become high types.

The driver’s license case corresponds to Case IV (see Section 3.3.3). To reduce the number of possible cases, assume that $y_H = h < l = y_L$ (which, as always, is interpreted as the case where

greater media scrutiny, suggesting that it is not effort. Moreover, the next time the same two wrestlers meet, the opponent is more likely to win, suggesting that throwing future matches is a form of the bribe paid for winning a key match. Similarly, Antanassova et al. (2008) cross-check receipt of a BPL card (which in India identifies someone to be poor and allows them access to a set of redistributive programs) against actual income levels. They correlate the error rate with such features as the caste of the recipient and his or her place in certain social networks, and they argue that the correlations are what a simple theory of corruption would predict.

28. Di Tella and Weinschelbaum (2008) provide a theoretical framework for thinking about unexplained wealth as an indicator for corruption.

a substantial fraction of L types are willing and able to pay more than a large fraction of H types are). Moreover, assume $N < 1$ but $L < 0$.

We assume that the bureaucrat faces people drawn from this altered distribution of types. However, because he does not know the environment has changed, both he and the government use mechanisms that match the prior type distribution. Of course, consumers can change their behavior as a result of the treatment: subjects who are more desirous of a license can offer higher bribes, for example. In principle, this change may allow the bureaucrat to learn of the experiment and adjust his overall strategy. In practice, we assume that the samples involved are too small for the bureaucrat to change his behavior. In effect, in interpreting this experiment, we assume that it changes people's types rather than modifying the bureaucrat's anticipated type distribution.

It is easy to check that in Case IV, an equal increase in h and l , without any change in the rules, will have several different effects. L types will now want to apply even if they are assigned to a bureaucrat who is being honest (i.e., a bureaucrat whose cost of breaking the rules is too high compared to the benefit from breaking the rules). Therefore, the fraction of those who apply to an honest bureaucrat and end up getting a license should decrease. However, just because many more L types apply, many more will (just by chance) end up passing, and the average quality of those who obtain a license would decline. However, the gains from being corrupt would also be higher, which will reduce the fraction of bureaucrats who choose to be honest.

The corrupt bureaucrats (i.e., the ones who opt to break the rules), of whom there are now more, will raise their prices. The fraction of L types getting through, conditional on being allocated to a corrupt bureaucrat, should not change, but because there are now more corrupt bureaucrats, the average quality of driving among those who get a license should decline. Moreover, because there are now more corrupt bureaucrats, the average amount of testing should also decrease.

In contrast, converting some of the high types in the population (the second treatment group) to low types should improve the fraction of drivers who obtain a license when they are allocated to an honest bureaucrat, as well as the average quality of licensed drivers. Those who are allocated to a corrupt person should receive more or less the same treatment, with the licenses going to the highest bidders and perhaps some red tape experienced by those who want to pay less (H types) to discourage those who are willing to pay more from claiming otherwise.

Empirically, individuals who were offered the incentive were 42 percentage points more likely to obtain it in 32 days or fewer. However, they paid about 50% more to obtain their licenses, and they were more likely to break a rule during the process (e.g., they were 13% more likely to not take a driving test). In the end, these extra payments translated to a greater number of bad drivers on the road: those offered the incentive were 18% more likely to obtain a license despite not knowing how to operate a car. These results are entirely consistent with theoretical predictions discussed above, as long as there are enough bureaucrats around who have a relatively low cost of breaking the rules. In particular, although the decline in the quality of driving among those who have a license would happen both with honest and corrupt bureaucrats, the reduction in testing can only occur in our model if the bureaucrat is corrupt.

It is worth pointing out that one would not observe the same pattern if the bureaucrats did know that the distribution of h and l has shifted. In this case, if h and l go up by the same amount, both types would now want to be tested when they encountered an honest bureaucrat. If they instead deal with a corrupt person, both types just pay and get the license without being tested.

The average price would not change, and the fraction being tested would go up. However, the quality of driving among those who get a license would decline, because the L types who deal with the honest bureaucrat now want to be tested. This clearly does not fit the facts about price and testing.²⁹

The results of the driving-lessons treatment are also broadly consistent with the theory. Those in this group are tested more often and are more likely to have obtained a license based on passing the test. This last fact, in particular, suggests that there are some honest bureaucrats. They also pay less for the license, though much more than they should have legally. This is a prediction of our model, but only because we assumed (for convenience) that all H types have a lower willingness to pay than all L types. A more plausible argument is that the H types actually have an incentive to shop around (i.e., go to multiple bureaucrats until they find one who is honest). In fact, Bertrand et al. (2007) did observe shopping around in the data, and it is therefore a plausible explanation for why the increase in the fraction of H types reduces the average amount paid.

Bertrand et al. (2007) also provide evidence that there is a lot of red tape (i.e., pointless testing). They show that of those experiment participants, who, at least initially, tried to follow the rules (i.e., get tested, not pay bribes, etc.), there is a higher success rate among those individuals found to be unqualified to drive based on the independent test (74% compared with 62%). In other words, the probability of obtaining a license is less than 1 even for those who can drive, and it is not any higher for them than for those who cannot drive. Thus, passing the test is uncorrelated (at best) with driving ability. The testing serves no direct screening purpose.

Both these features—a probability of winning less than 1 and pointless testing—are consistent with Case IV in the scenario where slots are abundant. However, to induce pointless testing, it is important that $y_H < h$; otherwise, the price might just as well be raised up to h . This divergence between the ability to pay and the willingness to pay seems implausible in this context. The amount of money involved (about \$25) is not large for the poor in Delhi, which is where the experiment was carried out.

A more plausible story might be that the applicants do not fully understand the rules of the game and therefore think that it is easier to use the official channel than it actually is, while the bureaucrat is not in a position to directly explain to them how things really work; therefore she uses the fruitless testing to signal to the applicants that they need to readjust their expectations. This story would be consistent with the fact that no one directly pays a bribe to the bureaucrat. Those who want to use bribery go to an agent who facilitates the transaction. When someone

29. However, our assumption that bureaucrats are randomly assigned to applicants plays a very important role here. One alternative assumption would be that applicants can either choose to go through the official system knowing that an honest bureaucrat will be assigned to them with some probability, but otherwise they end up dealing with a corrupt individual who will always fail the applicant (because in the official channel there are no bribes, the corrupt bureaucrats find it at least weakly optimal to fail everyone who comes through the system). Or applicants can choose to go through the unofficial channel, which guarantees that they pay a bribe and obtain the license. In the original equilibrium of this game, it is likely that all H types will try the official channel, while the L types will choose the other way. In this scenario, only H types ever take the test and fail.

In this case, during the experiment, H types will shift toward the corrupt route and therefore end up paying more, testing less, and having an increased probability of receiving a license. However, counterfactually, average licensed driver quality will increase, because the fraction of H types who fail declines.

directly approaches a corrupt bureaucrat through the official route, the bureaucrat does not ask for a bribe and instead goes through the motions of what she is supposed to do, while presumably trying to make sure that the applicant subsequently deals through an agent.

These type of empirical results are an intriguing complement to the theoretical framework we have laid out. They focus attention on the allocative outcomes and not just on the bribes. They focus on the details of testing and not only on the transfers made. In short, they illustrate the broader view on corruption that we advocate in this chapter.

6. Combating Corruption

There is a large and growing empirical literature that studies the effect of efforts to fight corruption. For example, Fisman and Miguel (2007) find that an increase in punishments for parking violations in New York City reduced the violations among the set of diplomats most likely to violate the rules. Using experimental techniques, Olken (2007) finds that theft in road projects is greatly reduced by raising the probability of being caught. Banerjee et al. (2008a) and Duflo et al. (2012) find that strengthening incentives reduces absenteeism. Using a natural experiment in Buenos Aires hospitals, Di Tella and Schargrodsky (2003) find effects of both more stringent monitoring and higher wages on procurement prices.

Several more recent papers on this topic have also tried to go a step further and understand whether a reduction in corruption through monitoring and incentives improves the final allocation of services. In the case of the Di Tella and Schargrodsky (2003) study, less bribe taking means better procurement prices, which is the outcome of interest. Olken (2007) looks at the effect of auditing not only on theft but also on the quality of the roads that were built. Duflo et al. (2012) study whether incentives can create distortions stemming from multitasking. In other words, they are concerned that to complete the task as specified by the incentives, the agent reduces his effort along other dimensions. Specifically, they ask whether providing incentives for teachers to attend school will cause the teachers to compensate by teaching less. To answer this question, they measure not only teacher attendance as the final outcome but also the learning levels of the children. They find that the multitasking problem is certainly not large enough to outweigh the benefits of better incentives.

6.1. Institutional Structures for Monitoring

Corruption exists because there are not enough monitoring and incentives to eliminate it. What then determines the extent of monitoring and incentives?

One challenge of looking at this issue empirically is essentially methodological. What should we assume about the extent to which these rules are the product of optimization by the government? Governments may make rules to combat malfeasance by government officials, but how well do they understand the consequences of these rules for corruption?

There are two possible approaches to answering these questions. One is what might be called the “political economy approach.” This approach is taken in the theory section here (Section 3). We assume some preferences for the government and figure out how the rules and the nature and extent of corruption should vary as a function of the underlying economic environment if the government were optimizing based on those preferences. We could then look for evidence for

the comparative static implications of that model and jointly test the model and our assumption about what is being optimized.

The alternative is to assume that the forces of political economy, although important, leave a significant amount undetermined, and as a result, changes in rules can often arise as pure organizational innovations, without changes in the fundamentals. This approach leads naturally to an experimental approach to studying the effects of the rules.

Banerjee et al. (2001) implement a version of the first approach in the context of the governance of localized sugar cooperatives. They assume that the cooperative maximizes a weighted average of the profits of the various principals of these cooperatives—the different types of member farmers who grow the cane that the cooperative turns into sugar—taking into account the desire of the management of the cooperative to siphon off as much of the profits as possible. Banerjee et al. (2001) then generate a set of comparative statics predictions that map the pricing of cane and the productivity of the cooperative onto the underlying mix of farmers in the cooperative. These implications are then tested and seem to be broadly confirmed.

However, corruption in these cooperatives is essentially private sector corruption, embodied primarily by the underpricing of cane. We have yet to come across a paper that combines this political economy approach with the more complex manifestations of corruption identified in Section 3.

More importantly, in many instances, theories of political economy are simply too incomplete to be useful guides to what rules are actually chosen. The objective of a specific government at a specific point in time is some complex product of its long-term goals and its short-term compulsions. Moreover, the way it chooses rules must take into account the compulsions of all future governments. Although there is an interesting and growing literature on this subject, it is not clear that it is ready to be taken to the data.

It is also not clear how much governments understand about the consequences of the various policy choices they make or about the policy options available to them. A more evolutionary approach to policy change, where changes happen because political actors are trying to solve some local problem but the solutions often have unanticipated and often global consequences, may be more descriptively accurate. Certainly this approach fits better with the kinds of stories that one hears about how change came to China.

An advantage of this second approach is that it permits us to think of policy changes as organizational innovations that are therefore at least initially exogenous in a way that technological innovations are usually thought of as being exogenous. That is, the assumption is that the need to solve problems is a product of various forces of society, but the adoption of a particular solution at a particular point in time is less so.³⁰ The approach also makes it clear that governments might choose bad rules (rules that go against its own objectives), because it does not understand the consequences of its choices.

Several recent empirical exercises start from this point of view. For example, Besley et al. (2005) find that, in South India, there exists a relationship between holding village meetings (i.e., more community participation in the process) and better allocations of Below Poverty Line cards, which provide privileged access to subsidies and government services. Bjorkman and Svensson (2009) study decentralization in an experimental context. Rather than imposing all

30. Banerjee (2002) discusses many of these methodological issues in greater detail.

centralized rules on health centers, community meetings are held to decide the most important rules that health centers should follow and the mechanisms for the community to monitor the health centers. They find huge impacts: infant mortality rates were cut by one-third. However, Banerjee et al. (2008b) evaluate a similar decentralization program in India and find that it performs no better than the civil service–based system of monitoring teachers.

It is difficult to make anything of these vastly different empirical findings, given that we do not have a particularly good theory of how decentralization affects corruption and the distortions associated with corruption.³¹ How does decentralization change the kinds of rules that are optimal and the way in which they are violated? How does the exact nature of decentralization factor into all this?

As it is, the presumption behind the empirical literature is that decentralization is a shift of control rights into the hands of those who have more local information. The basic notion is that the community now has more information and therefore can limit the extent of malfeasance by the bureaucrat. We do see some evidence that the easy availability of information matters. In the driver's license experiment, Bertrand et al. (2007) report that there are two obstacles that bribes cannot get around: one is the requirement of showing some proof of address and the other is the requirement of waiting at least 30 days after making the initial application for a learner's permit. Neither of these seems as important as being able to drive, especially in India, where the driver's license is not always accepted as an identification. However, violations of these rules are easy to observe, whereas the inability to drive properly is something that requires another test to verify. Therefore, these are the rules that are enforced.

However, the answer to the question of what rules are violated in what way must also depend on who exercises which type of control rights and what information reaches whom, which all turns on the exact model of decentralization adopted. More generally, theoretical work mapping the effects of alternative organizational forms on the choice of rules and corruption outcomes must be a high priority if this literature is to make progress.

7. Conclusion

Where should the literature go next? We have already discussed a number of the gaps in the literature. In Section 6, we discussed the need to more tightly model learning about the system. Here, we discuss other important gaps.

7.1. Corruption and Competition

Thinking about organizational forms naturally leads to the role of competition in reducing corruption, as emphasized by Rose-Ackerman (1978). The way we modeled corruption takes as given the idea that the assignment of the applicants to the bureaucrats is random. This effectively places the applicants and the bureaucrat in a bilateral monopoly setting. However, the nature of competition among bureaucrats ought to be a policy choice governed by the nature of the underlying incentive problems. This area of study needs further exploration.

31. Bardhan and Mookherjee (2006) provide a rare exception.

In particular, competition is not always a plus. As pointed out by Shleifer and Vishny (1994), competition among corrupt distinct and uncoordinated authorities, each of whom has the power to block the application, might be worse than a single monopolistic rent seeker. Barron and Olken (2007) document this phenomenon using a unique dataset that they collected in Indonesia of the bribes paid by truck drivers at road blocks. Reduction in the number of checkpoints along the road reduces the total amount of bribes collected from them. Credible evidence on the salutary effects of competition has so far been hard to find, though no doubt the right setting to look for them will emerge soon.

7.2. Implications of Illegality and Nontransparency

One reason that corrupt bureaucrats find it hard to coordinate with one another is that corruption is illegal. This essential nontransparency has several important implications that deserve further study. First, if the applicants for the slots differ in their ability to make illegal deals for either intrinsic or extrinsic reasons, then the playing field is no longer level, which introduces important distortions. This concern is not merely theoretical. Many countries have laws that forbid their firms to pay bribes in foreign countries, which could potentially act as a constraint on foreign investment in countries with high levels of corruption (see Hines 1995).

Another fallout of this nontransparency that we already noted is the reliance on agents who facilitate bribe taking (see Roseen 1984; Bertrand et al. 2007, 2008). The theory on how the use of agents alters the nature of corruption is yet to be developed. Barron and Olken (2007) provide an interesting insight into this relationship. They observe that in Indonesia, truckers can either pay a bribe at every checkpost or pay a single bribe to an agent at the starting city. However, the contract with the agent tends to be very simple—the amount of the single bribe does not depend on the load carried by the truck—probably because of the same lack of transparency. Thus, only the most overloaded trucks pay the fixed bribe, and the shape of the total bribe paid as a function of the truck's load is concave, whereas theory suggests that the optimal penalty function ought to be convex.

A third issue is that many drivers who try to get a license without paying an agent probably do not know the rules of the game. This happens because corruption is meant to be secret. In other words, understanding the process by which the real rules of the game become (or fail to become) common knowledge between the bureaucrat and the applicants should be an integral part of the study of corruption.

Bertrand et al. (2007) actually gather data about what individuals who are trying to obtain a driver's license know about the licensing process. They find that not much is known, and more surprisingly, many applicants believe that the official process is more onerous than it actually is. They also found in their qualitative work that discovering the actual rules was surprisingly difficult, given that they change periodically.

These observations lead Bertrand et al. (2007) to speculate on whether the bureaucrats deliberately try to make the rules more complicated than they should be to extract more in rents. Atanassova et al. (2008) find that individuals who are supposed to receive subsidized allocations of foodgrains in India are misinformed about their exact entitlements, and the

qualitative evidence in this case suggests that the shopkeeper often manufactures “rules” that increase the scope for his corruption, such as that all grain must be bought on one of two days.

Thinking about this issue leads us to an interesting theoretical possibility. Is it possible that the government’s attempts to change the rules, perhaps to fight corruption, generate so much confusion among the citizens that corruption actually increases?

7.3. Learning among Bureaucrats

The emphasis on learning brings up another important issue. Although much of the work in the field has focused on innovations in fighting corruption, there has been little focus on the innovations in corruption. A change in policy and/or institutions may reduce the prevalence of corruption to start with, but over time, the bureaucrat may learn how to adapt to the new policy or institutions. For example, Camacho and Conover (2011) provide evidence that individuals were better able to game the eligibility rules for social welfare programs in Colombia as rules for eligibility became better known over time. More generally, how much of the knowledge regarding how to conduct corruption is general knowledge, versus knowledge about a specific institution?

7.4. Norms of Corruption

The idea that the rules may be important for establishing a simple norm that the courts can easily interpret suggests a further line of inquiry. Perhaps the rules that the government makes for bureaucrats have a signaling role. The bureaucrat or the citizen uses them to infer the society’s preferences and therefore to decide what they should and should not do. If the government formally allows its bureaucrats to extort money from its citizens, the citizens might take this as a signal that the moral standards of society are low, and therefore citizens feel comfortable about extorting others. This idea could explain why governments continue to have rules on their books that are violated all the time.

However, a government that has rules on the books but does not manage to enforce them is also signaling something about its view of rules and rule-governed behavior that might spill over into other walks of life. For this reason and others, corruption may have a direct social cost, which is something our model does not take into account.

7.5. The Social Psychology of Corruption

To fully understand how corruption (or lack of corruption) becomes the norm, there is a need to try to understand the psychology of when and where people feel more or less comfortable about engaging in corruption. For example, a tendency to try to legitimize corruption is often observed. It could take the form of “excuse making” (i.e., the bureaucrat not directly asking for a bribe but instead discussing the costs of her time in providing a service to a citizen). Or alternatively, the citizen may suggest making a payment in kind, rather than a monetary bribe, to make the bureaucrat feel as if she were simply accepting a gift from a happy citizen rather than engaging in an illegal act.

The concept of legitimization may be a powerful part of our understanding why there is not as much corruption in the world as there could be. For instance, even in the most corrupt countries, empirical antidotes suggest that bureaucrats will often ask for a bribe to break a rule that impedes a given citizen but will not threaten to punish him for no reason. For example, traffic policemen often ask for a bribe if a citizen has committed a violation. However, they will not necessarily ask for a bribe if the person has done nothing wrong, and yet it is not clear that the enforcement in these two cases is very different. Locating the study of corruption in the broader context of how people relate to one another and to the state may be important in getting a handle on why corruption exists in some settings but not in others.

Delegation, Control, and the Study of Public Bureaucracy

Terry M. Moe

1. Introduction

For most of the past century, the study of public bureaucracy was a theoretical backwater in political science. Public administration, its home field until recently, was heavily focused on good management and the nuts and bolts of government operation, and these concerns tended to drive out theoretical thinking. Moreover, unlike the more advanced fields of political science—legislatures, elections, public opinion—bureaucracy did not provide scholars with raw materials that were readily quantified. Legislators vote, for instance, and bureaucrats do not. This single fact had much to do with putting the study of legislatures on the fast track and that of bureaucracy on the slow track.

Theory was also impeded by a conceptual blind spot. Early studies rightly saw public agencies as strategic players in the political process, seeking out relationships with legislative committees and interest groups, nurturing their own constituencies, and otherwise engaging in bureaucratic politics (e.g., Long 1949). But scholars failed to see that the underlying *organization* of bureaucracy is thoroughly political too—for organization affects performance, and powerful actors have incentives to design and shape it to their own advantage. In the scholarship of the time, bureaucratic behavior was understood in political terms. But bureaucratic organization was not.

This nonpolitical approach to organization had deep roots. During the early decades of the twentieth century, reactions against political corruption and party machines led scholars to see bureaucracy as the savior of good government and as properly nonpolitical. They embraced the “separation of politics from administration”: the notion that, although policy is inevitably a product of politics, it should be implemented by impartial experts in the bureaucracy, which in turn should be organized for effective performance (Knott and Miller 1987).

As scholarship became more scientific, and thus more concerned with explaining the actual features of public agencies, this nonpolitical take on bureaucracy was not overcome. In fact, it was reinforced by the emerging organization theories of the era—which took their orientations from sociology, social psychology, and psychology and offered only nonpolitical explanations for why bureaucracies became organized as they did (Perrow 1986). Even the groundbreaking

contributions of Herbert Simon and James March, both political scientists, did nothing to make the theory more political. Simon and March developed an elaborate theoretical tradition—the dominant perspective on organization among political scientists from the 1950s through the 1970s—that explained formal organization by reference to the cognitive limitations of human beings, and it had almost nothing to say about how public organizations arise out of politics (Simon 1947; March and Simon 1957).

The turning point came during the 1970s, when economists began developing a new set of theories and analytical tools—transaction cost economics, agency theory, theories of repeated games—for explaining economic organization. Fairly quickly, political scientists began applying the same theories and tools to the study of government organization, and the long-stagnant theory of public bureaucracy was soon transformed (Moe 1984; Williamson 1985; Milgrom and Roberts 1992).

At the heart of the new theory is a unifying focus on the problems that politicians face when delegating to bureaucrats and on the control mechanisms they can employ in trying to ensure that bureaucrats faithfully implement public policy. Some of these control mechanisms operate *ex post*, with the authorities monitoring and reacting to what bureaucrats do in the performance of their jobs. But much of the emphasis has been on controls that operate *ex ante*, with the authorities taking action through politics to strategically organize the bureaucracy in such a way that bureaucrats are constrained to pursue the right policies. A theory of political control and delegation, therefore, is ultimately a *political theory of bureaucratic organization*: one that shows how the structural details of bureaucracy arise out of the political process and how they are connected to the strategies and motivations of those who exercise (or influence) public authority.

Today's theory has developed well beyond this simple core and addresses a wide range of contiguous topics. Most important, it sheds light on the struggle among legislatures, executives, and the courts for control of the bureaucracy in systems based on separation of powers, and it has begun to explore the delegation dynamics of parliamentary systems. This is a theory that is growing rapidly, and is increasingly best thought of as a theory of the institutional system more generally, in which the various branches of government are all integrally connected (Strøm et al. 2003; de Figueiredo et al. 2006).

My focus here is on the political theory of bureaucratic organization, and thus on delegation, control, and their implications for the structure of government. My aim is to highlight the major ideas and approaches that have oriented this literature over time, giving special attention to the light they shed—or fail to shed—on the major substantive issues they attempt to explore and explain. Along the way, I argue that there are basic analytic problems that remain to be overcome: problems that arise, in part, because the normal science that now governs the theory—a standardization that testifies to its very success—has been limiting and even misleading in important respects. All told, the progress from the early days has been astonishing. But some rethinking is in order.

The review I am providing, then, puts a spotlight on the basic analytics of the theory, while at the same time keeping it close to the reality of government—and understanding and evaluating it accordingly. For readers interested in more detailed attention to the technical details of delegation models, excellent treatments can be found in Bendor and Meirowitz (2004) and Bendor et al. (2001). My own view is that, as this literature has developed and matured, technical issues have come to the fore and essentially have come to dominate the attention of the people

who are prime movers in this field—to the point that very basic analytical and substantive concerns are no longer regarded as very interesting or important. But the tail should not be wagging the dog here. In the end, the purpose of these models is to explain government.¹

I should add that even with the more substantive themes I am pursuing here, many theoretical contributions to the larger study of public bureaucracy and its politics must go undiscussed to keep the job manageable. This applies to the literature on ex post control, which is not really about issues of delegation or organization (Hammond and Miller 1987; Ferejohn and Shipan 1990; Eskridge and Ferejohn 1992; Hammond and Knott 1996). It also applies to work on the internal dynamics of bureaucracy, which is mainly about supervisory and employee issues rather than the politics of delegation and control (Hammond and Miller 1985; Miller 1992; Brehm and Gates 1999). All this work is relevant, but the line has to be drawn somewhere.

2. Early Theories of Public Bureaucracy

Rational choice first made its mark on bureaucratic theory during the mid-1960s with the appearance of two innovative books, Tullock's *The Politics of Bureaucracy* (1965) and Downs's *Inside Bureaucracy* (1967). Both were attempts to show that much can be understood about bureaucracy, and a powerful theory someday constructed, by assuming that bureaucrats are rational actors largely motivated by self-interest.

This approach was a sharp departure from existing scholarship. It was also a quantum change in the way rational choice was then being applied to organizations generally. At the time, the work of Simon and March was the only theory of bureaucracy grounded in rational choice, and theirs was an unconventional version of it to be sure. They relaxed all its key assumptions (about rationality, information, goals), shifted the terrain from economics to psychology, and developed a theoretical tradition centered on the cognitive limitations of individuals and on how, as individuals seek to solve the problems that arise in organizational settings, these limitations ultimately give rise to organizational structure. Along the way, self-interest and its correlates—strategy, conflict, opportunism—were mostly ignored, as were their profound consequences for organization. Tullock and Downs brought these core components of rational behavior to center stage and, for the first time, argued for a full-blown rational choice theory of bureaucracy.

Although both were especially interested in government, they cast their nets widely to address a full gamut of topics on public and private organization. Tullock's is a theory of authority relationships in general. Downs's is a theory of all large organizations whose outputs are not evaluated in external markets. In each case, the analysis is informal but is still based on clear assumptions about actors and their contexts, with the spotlight on motivation. Tullock's perspective is built on the assumption that bureaucrats are motivated by career advancement. Downs creates five motivational types—conservers, climbers, zealots, advocates, and statesmen—and shows how the changing mix of these types shapes the growth and operation of bureaucracy. Even though these analyses are very different in content, their bottom lines are much the same. The

1. For a related (and highly recommended) review that also puts substance ahead of the technicalities of modeling, see Miller (2005), which is about principal-agent models and their implications for various aspects of politics.

rational foundations of bureaucratic behavior, they argue, promote excessive growth, capture, weak accountability, and related problems that work against effective government.

With these two books, rational choice made a stunning entrée into the world of bureaucratic theory, upsetting the good-government vision of public administration and charting a bold new path for analysis. Downs, especially, was widely read by political scientists and cited for what he had to say about agency life cycles, control problems, communication foul-ups, and other central issues. His typology of bureaucratic motivation, which he put to insightful use, became broadly popular.

Future work in rational choice, however, was not destined to build explicitly on either of these contributions. Their sweeping approach to bureaucracy did not provide a clear focus for constructing new theories, nor did it suggest any productive strategies of formal modeling. Many found these books exciting but also complicated and multifaceted. No one really knew what to do with them.

3. The Niskanen Tradition

What the movement needed was some sort of catalyst, a new and promising analytic basis for cumulative work. And it came in the form of Niskanen's *Bureaucracy and Representative Government* (1971), which was hailed as a pathbreaking contribution and quickly generated a cottage industry of new theoretical work.

The key to Niskanen's success was that, unlike his predecessors, he restricts his focus and simplifies with a vengeance. Although he too is interested in grand issues—the size and efficiency of government—his analysis centers much more narrowly on public agencies and their budgets, and his model is starkly simple. He assumes that bureaucrats are budget maximizers, thus endowing them for the first time with a simple utility function amenable to formal analysis. And he strips away the daunting complexities of budgetary politics by building his model around just two actors, the bureau and its legislative sponsor.

Their relationship is one of bilateral monopoly, with the bureau holding two pivotal advantages. First, its position as sole supplier gives it a monopoly over information about the true costs of production. Second, the bureau knows how much the legislature values every level of output, and it uses this information to present a take-it-or-leave-it offer (of a given output for a given budget) that it knows the legislature will accept. It has information power, and it has agenda power. These powers enable the bureau to act as a perfectly discriminating monopolist, forcing the legislature to accept an oversized budget it barely prefers to no budget at all, with any surplus kept and spent by the bureau. The upshot is that government is too big and grossly inefficient.

Niskanen's earliest critics focused on his assumption of budget maximization, arguing that bureaucrats actually maximize something else (Migue and Balanger 1974; Blais and Dion 1991). But the most telling critiques have centered on control issues. As I have suggested, bureaus dominate in his model for two reasons: they control information and they control the agenda. Yet Niskanen is not at all clear about this, and tends to merge the two factors under the general heading of information—as though it is the agency's control over information that allows it to present the legislature with take-it-or-leave-it budgetary offers, thus giving the agency agenda control. Which is not the case (Bendor 1988).

Efforts to clarify matters soon revealed that agenda control is the big chink in Niskanen's armor. The first indication came from Romer and Rosenthal (1978, 1979), who show that the power of agenda control depends on the "reversion level": the budget that would prevail if the bureau's take-it-or-leave-it offer were rejected by the legislature. Niskanen assumes the reversion level is zero, and thus that legislators must choose between the bureau's offer and no budget at all, which gives the bureau far greater power than it otherwise would have. A more reasonable assumption, more in line with the real-world budgetary process (where legislatures routinely fall back on status quo budgets in times of impasse), would have produced less gloomy conclusions about the size and efficiency of government.

The larger question, however, is why bureaus have agenda power at all. As Gary Miller and I pointed out (Miller and Moe 1983), Niskanen's model is curiously one-sided: bureaus are strategic actors, but the legislature is passive and sits by idly while the treasury is looted. An adequate model, we argued, should treat the legislature as a strategic actor too—and recognize that it has authority over the bureau and can structure the bargaining in any way it wants. Their relationship is not simply one of bilateral monopoly. It is an authority relationship, a hierarchical one, in which the legislature has the legal right to tell the bureau what to do. The legislature is the principal, the bureau the agent.

It follows that the legislature need not put up with the kind of agenda control Niskanen grants the bureau. It might force the bureau to submit a complete schedule of budget-output combinations for legislative choice rather than a take-it-or-leave-it offer, for example. It might engage in monitoring to gain information. It might impose sanctions when the bureau is caught lying. And so on (see also Breton and Wintrobe 1975, 1982). The fact is, the bureau must play the budget game according to rules set by the legislature. And in this crucial sense, it is the legislature that sets the bureau's agenda, not the other way around. A model that incorporates these new elements, we showed, leads to a more variegated—and more moderate—view of bureaucracy and government.

From this point on, Niskanen's approach to bureaucracy gave way to the new economics of organization. Much of the new work paid little or no attention to Niskanen. But some of it did, at least early on, creating what amounted to a bridge between the two—one that highlighted Niskanen's attention to budgets but understood the relationship between the bureau and the legislature in game-theoretic or principal-agent terms. Take-it-or-leave-it agenda control was out as a basis of bureaucratic power. The focus was now on asymmetric information, especially the bureau's private information about costs (its expertise); on the legislature's authority to set the rules; and on basic mechanisms of political control, such as auditing and sanctions (Bendor et al. 1985, 1987a,b; Banks 1989; Banks and Weingast 1992).

Although no longer a distinctive research program, the Niskanen tradition has clearly had a lasting impact on bureaucratic theory. Pre-Niskanen, the natural inclination among scholars was to see bureaucracy as a complex organization subject to a tangled array of authorities, constituencies, and pressures. Niskanen brought simplicity, clarity, and structure to an otherwise messy field, and in the literature to follow his distinctive stamp would be difficult to miss: bureaucracy would routinely be modeled as a unitary actor driven by a single goal, the focus would be on its relationship with the legislature, and attention would center on the key role of information—expertise—and the leverage it gives bureaucrats in pursuing their own interests.

4. Legislative Control and Congressional Dominance

During the early 1980s, political science was swept by the new institutionalism. Until then, despite the provocative work of Niskanen, most rational choice theorists were little interested in bureaucracy. For them, the rationale for studying institutions arose out of a voting puzzle: the social choice theory of voting predicted endless cycling, whereas voting processes in the real world tended to be highly stable. Why so much stability? Their answer was that institutions impose structure on the voting process, bringing order out of chaos (McKelvey 1976; Shepsle 1979; Shepsle and Weingast 1981).

As the theory of political institutions got underway, then, the natural focus was on legislatures—whose members do their work by voting, and who are elected through the votes of constituents. The theory that emerged, therefore, was a decidedly legislative theory, and the rest of the political world came to be viewed through legislative lenses. Bureaucracy nonetheless attracted great interest: for the policies that legislators adopt are empty abstractions until they are implemented, and they can be implemented in many ways depending on who controls the bureaucracy, how well, and what they want it to do. This being so, scholars quickly put the spotlight on political control of the bureaucracy—which meant, in almost all cases, congressional control of the bureaucracy.

Barry Weingast stands out as the most influential figure in the early theory of congressional control. Of his several articles on the subject, one co-written with Mark Moran on congressional control of the Federal Trade Commission is widely cited as seminal (Weingast and Moran 1983; see also Weingast 1981, 1984). The theory begins with a social choice model of legislative decision, in which a committee uses its agenda powers to engineer voting outcomes on the floor. Having thus shaped legislative policy, the committee then becomes a principal trying to ensure faithful implementation by its bureaucratic agent: wielding an array of (ex post) control mechanisms—oversight, the budget, threats of new legislation—so formidable that the bureau has overwhelming incentives to go along. The theme is one of congressional dominance.

This theme was also driven home in an influential article by McCubbins and Schwartz (1984) on the nature and potency of oversight. They argue that reelection-minded legislators, as principals, have little incentive to engage in the broadly based “police patrol” oversight of bureaucracy that the traditional literature presumed. Legislators are better off simply responding to the “fire alarms” set off by constituency groups when something goes wrong. Doing so makes the groups happy, gets them to bear the costs of monitoring, and focuses oversight on problems with electoral salience. It also produces tight control: for when the fire alarms go off, Congress’s weapons are so powerful that the bureaucracy will toe the line. Indeed, bureaus will anticipate as much and comply from the outset.

These articles, together with others arguing similar ideas (e.g., Fiorina 1981; Barke and Riker 1982), heightened scholarly interest in political control. Yet their claims of congressional dominance also provoked controversy, and for good reason. As I pointed out at the time (Moe 1987), they do not really develop a theory of control. For they never attempt to model the goals, strategies, or resources of the bureaucracy, and thus cannot shed light on its motivation or capacity to shirk. The profound importance of private information (expertise), which so empowered Niskanen’s bureau, is given short shrift here, along with the entire bureaucratic side of the control relationship. Their focus is entirely on the legislature.

Their presumption, moreover, is that budgets, oversight, and other mechanisms nicely translate into tight control for the legislative principal—when the whole thrust of the economic theory of agency is that control is costly and likely to entail substantial slippage. The theme of a well developed theory of political control, it is reasonable to suggest, should be that Congress has a very difficult time controlling the bureaucracy, and that the latter probably has considerable autonomy. This is precisely what mainstream empirical work by political scientists had long maintained (Wilson 1989).

In some sense, the problem in this early literature on political control was just the reverse of what we found with Niskanen. Niskanen overstated bureaucratic power by assuming a strategic bureau and a passive legislature. The congressional dominance theorists flipped it around, overstating legislative power by assuming a strategic legislature and a passive bureau.

5. Ex Ante Control and the Politics of Structure

The early theory of congressional dominance was a theory of ex post control, asking how legislators could prevent runaway bureaucracy by monitoring the behavior, rewarding the compliance, and punishing the noncompliance of existing agencies. Yet legislators (and presidents) also have the authority to exercise control ex ante: by imposing structures and personnel systems that promote agency compliance from the outset. Through strategic choices about *organization*, in other words, they can design bureaucracy to do their bidding.

Rational choice theorists quickly recognized as much and moved to incorporate ex ante control into their analyses. This simple step, although obvious in retrospect, may represent the most important single development in the modern theory of bureaucracy, as it paved the way for an explanation of how bureaucracy emerges out of politics and why it takes the organizational forms it does.

The study of ex ante control is rooted in issues of delegation. Several influential studies carried out early on—by Aranson et al. (1982), Fiorina (1982a,b, 1986), and McCubbins (1985)—proposed formal approaches to delegation and focused attention on some of the key questions that needed addressing. Why does Congress delegate authority to an agency rather than writing detailed laws itself that are enforceable in the courts? When it delegates, does it prefer vague mandates that give agencies great discretion or highly specific mandates that severely limit what agencies can do? And when agencies have discretion, how can Congress design their structures so as to channel bureaucratic behavior toward legislative ends?

Soon thereafter came two articles by McCubbins, Noll, and Weingast (1987, 1989) that gained widespread attention, provoked controversy, and established ex ante control as a growth industry. Their big splash was due in part to their audience. McNollgast (as they are sometimes collectively known) addressed themselves to the law-and-economics community, arguing that administrative procedures—this audience's main organizational focus—are explained not by the traditional normative concerns for fairness, due process, or equity, but rather by the self-interested control strategies of legislative actors. Such an argument grew naturally out of rational choice thinking, but it challenged convention, and it demanded and got a spirited response (e.g., Mashaw 1990).

McNollgast see the relationship between Congress and the bureaucracy as a principal-agent problem, in which an "enacting coalition" within the legislature seeks to minimize bureaucratic

“drift” (shirking). The problem arises because the typical agency has its own policy preferences, often different from those of Congress, and because it may be able to use the information asymmetry built into their relationship—owing to its greater expertise—to go its own way in policy. What can Congress do to keep the bureaucracy in line? The authors argue that, while the prior literature had emphasized *ex post* control, such efforts to monitor, reward, and sanction agencies are costly to employ and, at any rate, do not work very well. This is an implicit way of saying that the earlier work on congressional dominance—their own work—did indeed have it wrong. Their new claim is that, precisely because *ex post* control is highly problematic, Congress places great emphasis on *ex ante* control, which works much better. *Ex ante* control emerges as the key to understanding how Congress gets its way—which it continues to do, on their account—and why bureaucracy looks and performs as it does.

Properly chosen procedures, McNollgast argue, can mitigate problems of asymmetric information by forcing agencies to take certain kinds of technical or constituency information into account or to publicize their policy aims well in advance of formal promulgation—creating an early-warning system for politicians and ruling out *faits accomplis*. The Administrative Procedures Act, they argue, is a prime example of how Congress uses procedures to open up agency decisionmaking and make private information public.

Procedures also enfranchise favored constituencies by selectively granting them access and participation rights, thus injecting special interests directly into the informational and early-warning system, as well as shaping decisionmaking according to the balance of group power. In these ways, legislators stack the deck in favor of groups in the enacting coalition and ensure that changes in the interests and relative powers of groups over time are mirrored in agency process and policy. If well designed, the agency should be on autopilot: programmed to do Congress’s bidding.

In a series of articles that appeared shortly thereafter, I developed an analysis of the “politics of structure” that shares central themes with the McNollgast work—regarding the problems of information, for example, and the role of procedures in stacking the deck (Moe 1989, 1990a,b; Moe and Caldwell 1994; Moe and Wilson 1994). Yet the approach is also different in key respects and attempted to take the theory in new (at the time) directions, the most fundamental of which are discussed below. The arguments I made on their behalf are the arguments I made then and still make. As subsequent sections of this chapter show, some of these new directions have since been pursued in various ways. But some, even after all these years, remain virtually unexplored.

5.1. Multiple Principals

The McNollgast analysis submerges presidents in the enacting coalition and pays no special attention to them. But the fact is, presidents *are* special. Their powers and leadership are the driving forces of modern American government—and they are absolutely fundamental, as well, to the politics of structure. It would be odd if they were not.

Clearly, presidents have distinctive roles to play. They have the power to veto legislation, which allows them to pressure Congress for concessions that produce bureaucratic structures more conducive to their own goals and interests: structures that give them more discretion and control. They also have powers of unilateral action—due in part to their position as chief

executive—that allow them to move on their own to create favorable administrative arrangements (see, e.g., Howell and Lewis 2002; Lewis 2003). Through it all, moreover, they are operating on preferences and following strategies that make them very different from legislators, for they respond to broader constituencies, seek central control over the bureaucracy—and indeed, are threats that many legislators must worry about and guard against.

A theory with presidents, then, points to aspects of bureaucracy that bear a distinctly presidential stamp—some of them structures that presidents themselves create, on their own, to try to gain control. Regulatory review is an obvious example. So is much of the institutional presidency, a defining feature of modern American government that rational choice theorists largely ignore. A theory with presidents also emphasizes that many bureaucratic structures are designed by legislators to insulate parochial interests from presidential influence, and that presidents counter by adding structures of their own. These structures and dynamics are fundamental to American bureaucracy, and they are missed when presidents are lumped into the enacting coalition.

Much the same is true of the courts. They are not active players in the legislative process, as legislators and presidents are. But they have the authority to impose their own structures on the bureaucracy—as they have done with a vengeance, for example, in school desegregation disputes. And the expected outcomes of delegation decisions are clearly very different, and thus the politics of delegation is very different, depending on whether the courts can be counted on to backstop Congress—pushing wayward agencies back where Congress wants them—or can be expected instead to act on their own political preferences.

The more general theoretical point here is that the organization of American bureaucracy arises out of the politics of a separation of powers system. In such a system, the legislature is not the only principal that counts. There are typically multiple principals competing for control—the legislature, the president, and the courts—and they use structure not only to impose constraints on the bureaucracy, but also to insulate it from the influence of their competitors. A simple focus on the enacting coalition misses all this.²

5.2. Forward-Looking Actors

McNollgast's political actors are rational and strategic, but they do not do a serious job of looking ahead. In particular, they fail to take account of the "political uncertainty" inherent in democratic politics. If they did, their incentives and behavior would look very different than McNollgast claims. In American democracy (and in most democracies), today's power holders cannot count on maintaining their hold on public authority forever. Their future power is uncertain. As a result, they cannot commit tomorrow's authorities—who may turn out to be their opponents—to respect whatever deals are arranged, and whatever structures and policies are created, in the current period. They face a commitment problem: they want to provide a stream of benefits into the future for their own constituents, and in return receive those constituents' votes—but they cannot guarantee that the future benefits will actually be provided. Constituents, then, have good reason not to believe their promises. And not to support them or make deals with them. So what can today's power holders do? How can they commit?

2. For pioneering efforts (at about this time) to model multiple principals and their struggle to control the bureaucracy, see Calvert et al. (1989), Hammond and Miller (1987), and Hammond and Knott (1996—although earlier versions were floating about years before).

The answer is that the policies and structures being created today must be protected from future authorities and thus insulated from democratic control. The best way to do this is through ex ante control mechanisms—decision procedures, civil service rules, independent forms of organization, formal timetables—that not only stack the deck, but also lock in the bias to protect against future changes in power and authority. Today's enacting coalition, in other words, wants to ensure that *tomorrow's* legislature—perhaps led by an opposing coalition—*cannot* control the bureaucracy.³

Obviously, this logic puts a different spin on things. McNollgast's enacting coalition fixes its gaze on the bureau, which threatens to drift away. On their account, the coalition relies not only on deck stacking but also on procedures that force the bureau to *reveal* information, *open* its internal processes, and suffer outside *intervention* to keep it in check. In a world of political uncertainty, however, the enacting coalition must also cast a wary eye *on the legislature itself*, indeed on all future authorities and group opponents, and use structure to insulate against their control. Because of political uncertainty, the coalition often *does not want* openness or intervention, and it favors structures that shut out most opportunities for control by others.

Because of political uncertainty, then, the shortcomings of ex post control should prove more severe than McNollgast suggest, and they should arise from more than just the usual slippage in the principal-agent relationship. Basic obstacles to control should purposely be *created by Congress itself*, which should often have incentives to build bureaucracies with considerable autonomy that pursue the original intent of the law—and that resist Congress's own efforts at ex post control. Ex ante control, then, emerges as a two-edged sword: it promotes the control of today's Congress by rendering tomorrow's Congress weak.

5.3. Institutional Context

The McNollgast theory is Congress-centered and peculiar to the American political system. Yet there is good reason to think that different institutional systems have their own distinctive politics of structure and thus their own distinctive bureaucracies. The logic of politics in the United States should be different from the logic of politics in Britain and elsewhere. A focus on political uncertainty—which scholars usually ignore—makes the case very clearly (see especially Moe and Caldwell 1994).

Consider the American system of separation of powers. It fragments power among institutions, and its multiple veto points ensure that new laws are difficult to enact. Whatever does get enacted, however, tends to endure because separation of powers then works to its advantage, setting up obstacles that prevent opponents from changing it. This feature makes the lock-in of current interests possible: whatever protective structures are imposed to insulate today's creations from change probably cannot be lifted by opponents in the future, even if they are powerful—because supporters can likely find a way to block change. The agencies and policies they seek to protect, then, will remain protected. And the flow of benefits to constituents will endure.

In such a system, all actors therefore have incentives to rely heavily on formal structure to insulate their creations, solve their commitment problems, and solidify their political deals.

3. The importance of forward-looking rationality is emphasized throughout my own work, but it is also recognized in early work by Horn and Shepsle (1989) and in a full-length book by Horn (1995). Interestingly, Horn does not pursue the differences between presidential and parliamentary systems (see below).

Formal structure protects them against political uncertainty, ensuring that whatever is created today will endure tomorrow. And because all players have strong incentives to formalize, the bureaucracy in such a system will tend to be buried in formal rules.

Now consider a pure Westminster-like parliamentary system. In such a system, power is entirely concentrated in the majority coalition, and there are no veto points in the policy process. As a result, political uncertainty is dramatically heightened. Passing laws is relatively easy, but so is overturning them: for if the opposing coalition comes to power, it too will have concentrated power, and it will be able to subvert everything the first coalition has put in place. *Formal structure therefore has little strategic value* as a protector of interests or solution to commitment problems—and the incentives to formalize are therefore much reduced. This should tend to produce a bureaucracy that, by comparison to its counterpart in the American system, is granted more discretion and is much less burdened by formal constraints. The logic of politics is very different in the two systems, and their bureaucracies should be very different as well.⁴

Most parliamentary systems are not at the Westminster end of the continuum, of course. Some divide institutional authority in various ways (e.g., through bicameral legislatures), and some have electoral systems that often give rise to minority or coalition governments, yielding institutions whose veto points place them somewhere between the American and the Westminster extremes. For these contexts, the incentives to formalize should also tend to be somewhere between, as would the nature of their bureaucracies. The argument here is not that presidential and parliamentary systems represent dichotomous system types, but rather that the basic features of political systems generally—such as divided authority and veto points—tell us a lot about the politics of structure and about bureaucracy. The American system is not necessarily very representative. A more broadly based, more fully comparative theory is surely preferable.

5.4. Effectiveness

The McNollgast theory is about what Congress can do to prevent runaway bureaucracy, which is an important issue. The question that has traditionally been at the heart of public administration, however—the effectiveness of the bureaucracy—is given no serious attention. The presumption seems to be that, as long as agencies are under control and prevented from drifting, they will perform effectively and constituents will get their benefits.

The theory needs to deal with effectiveness head-on. Actually, the control relationship itself points immediately to potential problems for effectiveness: for when the legislature imposes structures to stack the deck and otherwise constrain agency behavior, it interferes with the agency's best applications of its own expertise and undermines its ability to perform. Moreover, particularly in the American system, political uncertainty gives the winning coalition incentives to load agencies up with burdensome formal constraints to insulate them from unwanted future influences; and, especially for agencies in complex policy areas or changing technological environments, these constraints may impede performance. Similarly, the American system's many veto points often require that the winning coalition compromise with the losing coalition in the design of agencies; but the losers often have incentives to impose formal restrictions that purposely undermine agency performance—they have incentives, in other words, to create agencies

4. The evidence suggests as much. See Moe and Caldwell (1994).

that are *designed to fail*. Still more problems arise because of competition among principals: for attempts by Congress to insulate against presidential influence will create additional layers of formalism and restriction, whose purpose is political and is likely to get in the way of effective performance.

Effectiveness should also vary with institutional context. In a classic Westminster system, burying agencies in formal rules does not work as a strategy for insulating them from political enemies—so such rules should tend not to be imposed, and agencies should be less burdened with ineffective structures. Moreover, the losers in these systems need not be granted a role in designing public agencies, and there are no competing principals to insulate against one another's influence. These features, too, suggest that bureaucracies should tend to be less burdened with structures that, in the American system, make it difficult for agencies to do their jobs.

The discussion as I have developed it actually begs a deeper question, which is: effective for what? The meaning of effectiveness turns on the specific goals that are to be achieved; and much of the politics of structure, and thus many of the formal structures that are heaped on bureaucracy to insulate and control it, are driven by the fact that different principals—today's legislative coalition, the president, the legislative losers, the future holders of power—have different political goals. Any given principal surely wants the bureaucracy to use its expertise effectively in pursuing that principal's own goals. But if other goals threaten to take priority, expertise and effective performance can become bad things, and restricting them becomes a rational strategy. Bureaucratic effectiveness is in the eye of the beholder. What is effective for principal A is not effective for principal B: it depends on whose goals are being pursued and whose ox is being gored.

6. Formal Models of Delegation

Some of the early work on political control was formal (e.g., Bendor et al. 1985, 1987a,b; McCubbins, 1985; Banks 1989; Banks and Weingast 1992; Calvert et al. 1989). But many of the basic ideas—in McNollgast's work, for example, as well as my own—were set out in arguments that, while firmly rooted in the new economics of organization, were developed informally rather than through modeling. There were advantages to doing so, as it allowed for analyses that were more wide ranging and able to shed light on aspects of political control that would likely have been difficult to explore—and doubtless would have gone unexplored and undiscussed, at least for some time—if the focus had been narrowed from the start by the technical constraints of formal models. Modeling is deductively powerful, if done right. But it can also be conceptually limiting, and there is much value in having a division of labor in which formal and informal analyses work together, with each doing what it does best.

Since the early 1990s, the literature on political control has grown considerably, and it has become much more formal. This newer work incorporates and explores some of the key foundational ideas—but not all of them—and extends the theory in a variety of ways. One stream focuses on *ex ante* control, most often the legislative decision to delegate. The other is about *ex post* control, taking the agency and its mandate as given and exploring how legislatures and other political actors can shape the behavior of existing agencies.

Models of delegation have shed light on the foundations of bureaucratic organization, and they are the focus here. As in the early work on *ex ante* control, the legislature is naturally

at center stage in these models, because it makes the laws and is in the position of creating, designing, and empowering administrative agencies. But what the newer models do, in effect, is to whittle away at the theoretical arguments of the earlier literature, reducing them to bare-bones formal representations. (They also, of course, introduce new arguments of their own.) In the process, some of these arguments are more powerfully explored—but for reasons I discuss below, some are dealt with in stilted and unsatisfying ways, and others are not really pursued at all.

One contribution is clear: these models put the earlier claims of congressional dominance firmly to rest. A central theme running throughout these newer models is that the legislature faces a trade-off between expertise and political control. All else being equal, the legislature benefits when it imposes structural restrictions, limits administrative discretion, and gains control over the agency's policy choices: maneuvers that are intended to get the agency to target the "right" goals. But these very restrictions render it difficult for the agency to adapt to changing circumstances—new technologies, new problems—and thus to use its expertise effectively, even if it does pursue those goals.

This is essentially a variation on the effectiveness dilemma we discussed in the prior section. The legislature fears that the agency will use its expertise to effectively pursue the "wrong" goals—but by imposing restrictions to get it to pursue the "right" goals, it undermines the agency's ability to pursue *those* goals effectively. The legislature's challenge, of course, is to strike the right balance between control and expertise. It is clear, however, that total political control is an extreme solution that is usually not desirable (were it possible) and would be irrational to pursue. An optimal balance would lead, in most cases, to conscious limitations on political control and thus to situations in which agencies are designed to have a measure of autonomy. Congress would not even try to "dominate."

An early formalization of this balancing act was carried out by Bawn (1995), who, as it happens, did not highlight its implications for congressional dominance. Her model contains two actors, the legislative coalition and a bureaucratic agency. The agency is assumed to have greater expertise than the coalition, and its expertise is defined by reference to a distinction between policies and outcomes—a modeling strategy that was gaining prominence at the time in the larger literature on political institutions (see, e.g., Gilligan and Krehbiel 1990) and would eventually become quite fundamental to the theory of delegation. The agency implements its congressional mandate by choosing a specific policy, located somewhere on a unidimensional continuum, and this choice of policy then generates an outcome (in terms of solutions to social problems or effects on constituents, say) that may be located somewhere else on the continuum. Mathematically, the realized outcome of agency action is assumed to be a function of the agency's implemented policy and a random error term—and it is the agency's knowledge about the distribution of the error term, and thus, more generally, its knowledge of what outcomes are most likely when it chooses a particular policy, that constitutes (and within the model, defines) its expertise.

Bawn's legislative coalition exercises control by using "procedures" to choose the level of agency "independence," where the latter is broadly defined as the agency's freedom to make its own decisions without legislative constraint. Her model shows that independence has two contradictory effects. On the one hand, the agency is better able to apply its expertise (operationalized as a smaller error variance in its estimation of outcomes) the more independence it is

granted. This effect is beneficial to the coalition. On the other hand, the agency is more likely to have policy preferences that diverge from those of the legislature (operationalized as a larger variance of agency preferences around a legislatively induced mean) the more independence it is granted. This effect threatens greater bureaucratic drift and is costly to the coalition. The coalition's optimal solution is to choose the level of independence that gives it the greatest net gains, and this level varies, depending on conditions specified in the model. When policy is especially salient to powerful interest groups, for example, bureaucratic drift threatens to be especially costly, and the optimal level of independence will be lower. In complex policy areas, the value of agency expertise to the legislature will tend to be higher, and the optimal level of independence higher. Sometimes the legislature will exercise substantial control, then, and sometimes it will not.

Although the themes of Bawn's analysis have become central to the literature, the model itself has not. Its assumptions, which express how independence is dealt with operationally, were particularly complicated and difficult to work with mathematically, and (for that reason) the model was actually set up as an exercise in decision theory, with the legislature as sole decisionmaker, rather than as an exercise in game theory that explored the interdependent decisions of the legislature and the agency.

Writing at about the same time, Epstein and O'Halloran (1994, 1996) developed a much more straightforward approach to the modeling of delegation and control. Instead of dealing with procedures and independence, and indeed, instead of dealing with aspects of agency organization in any explicit way, they collapsed all these considerations into one simple concept that became the foundation of the entire analysis: the level of discretion that the legislature delegates to the agency. They also operationalized it in an exceedingly simple way. Their approach was a conceptual breakthrough, and it blazed a path that the rest of the formal literature on delegation would ultimately follow.

Specifically, Epstein and O'Halloran assume that the legislature sets a baseline policy, p , and a level of discretion, d . (The story line is that the legislature crafts d by writing statutes that are more or less detailed in their structural constraints—but these elements are not modeled.) The agency is required to implement a policy of its own, p_A , that is within plus or minus d of the baseline policy. If the legislature has done its job right in delegating, the agency will use its expertise—its superior knowledge about the connection between policy and outcomes—to choose a policy within its discretionary range that, once an outcome is realized, proves to be better for the legislature than the baseline policy is and thus better than the legislature could have done by giving the agency no discretion at all.

Epstein and O'Halloran's *Delegating Powers* (1999) is their most comprehensive statement on the subject and is a tour de force of social science analysis: combining grand theory, an elaborate formal model, and wide-ranging empirical tests based on original data. They develop what they call a "transaction cost theory of delegation," arguing that the legislature's decision to delegate is analogous to the make or buy decision that firms confront in the private sector and is subject to the same hold-up problem. The make or buy component arises because the legislature can either make policy itself, relying on its own specialized committees to specify all aspects of policy in excruciating detail, or it can buy the policies externally by delegating to agencies and giving them the discretion to determine what those details should be. Both options come with their own costs. If policy is made by committee, there are costs of information, delay,

collective decisionmaking, and the like. However, buying policy from the agency—delegating—threatens the legislature with a hold-up problem (as they characterize it), because the agency has incentives to shirk. The legislature must therefore determine when delegation is more efficient than internal production, as judged by reference to their own political goals.

The logic at work here is a bit strained. In a typical economic analysis, the hold-up problem arises when two firms, A and B, stand to gain from cooperating—B is going to buy its inputs from A, let's say—but the deal involves investments by A that are specific to the relationship; and once A's investments are made, B has an incentive to hold-up A by threatening to renege on the deal and demanding lower prices. Because A can anticipate this problem from the outset, it may refuse to enter into the deal at all, leaving both worse off. The classic solution is vertical integration: firm B purchases firm A, overcoming the cooperation problem by bringing the latter under its own authority and control—and giving it the capacity to make the goods it previously wanted to buy.

The situation that Epstein and O'Halloran are analyzing—a situation rooted in government—is actually different. The bureaucratic agency and the legislature are *already* vertically integrated: the legislature is the superior authority, the agency is the subordinate, and the latter is not free to make its own independent decisions. The legislature might be said to have a make or buy decision, in the sense that one potential producer (the committee) is inside the legislature and one (the agency) is outside. But both producers are under the legislature's own authority from the outset and are subject to its control. It may have a hard time getting the agency to do exactly what it wants, and presumably a harder time than with the committee; but this is the case for any superior in any organization and is simply a version of the shirking problem that frustrates top-down control efforts. There is no hold-up problem in the usual sense.

More generally, the transaction cost framework, which is presented as the analytic foundation for the book, is not put to very productive use. Indeed, after devoting a good deal of attention to the transaction costs involved in producing policy—the haggling, the collective action problems, the delays, and so on—they ultimately construct a formal model that leaves almost all of these costs out and is not different or better in any distinctive way because it is “derived” from the logic of transaction costs.

That said, the make or buy framing itself, properly interpreted, is helpful. There is value in recognizing that the legislature always has the option of producing policy itself and that its delegation decisions are calculated with reference to the baseline of internal production—its costs and benefits, its problems and advantages. This may seem obvious on reflection, and indeed it was central to the way delegation was approached in the earliest attempts to model it (e.g., Fiorina 1982a,b, 1986). But when the new economics of organization took hold in the 1980s and spawned interest in political control, serious interest in the baseline of internal production fell by the wayside. The focus was simply on how the legislature could delegate to an agency and still maintain control. Epstein and O'Halloran deserve credit for reasserting the importance of the baseline and for trying to build a theory that explores it more fully.⁵

5. Their effort to do so, however, led to a game-theoretic model (described below) that is far more complicated than the simple discretionary-window component I discussed earlier, for it has a signaling model—in which the committee (as agent) makes proposals to the full legislature (the principal)—nested within it. I suspect it is for this

In the Epstein-O'Halloran model, there are three players: the legislative floor, the committee, and the agency. And there are three stages to the game: in the first, the committee gains (incomplete) information about the link between policy and outcomes, designs a bill, and sends it to the floor; in the second, the floor either enacts legislation or delegates to the agency with some discretion, d ; and in the third, the agency—which is perfectly informed about the link between policy and outcomes—chooses a final policy within the discretionary limit set by the legislature. The legislature can gain from delegating to the agency and allowing it (via d) to use its perfect information in choosing a “good” policy; but the agency has its own policy preferences and may stray from what would be best for the legislature. Rather than put up with the dangers of agency shirking, the legislature could rely on in-house production of policy through its committee; but the committee has preferences that may also differ from the floor's, and it is not as well informed as the agency, so there are problems on this end as well. Both options are imperfect, and the floor chooses delegation when it is the better option.

This model leads Epstein and O'Halloran to two basic conclusions, which then become the focus of their extensive empirical tests.⁶ They show that, all else being equal, the legislature is more likely to delegate and grant discretion to an agency (1) the more uncertain and complex the policy area, and (2) the closer the agency's policy preferences are to those of the legislative floor. The first is often referred to in this literature as the uncertainty principle. The second is often referred to as the ally principle. In moving from model to reality, they relate the ally principle to divided government: arguing that the president plays the key role in determining agency preferences, and thus that, when the president and the Congress are controlled by different parties, there is likely to be greater policy conflict (divergence of preferences) between the agency and the legislature, and less delegation and discretion. This assertion about divided government is the best-known and most influential substantive claim to come out of their research program.

In focusing scholarly attention on the simple concept of discretion and in demonstrating how discretion can be modeled and empirically studied, Epstein and O'Halloran have put an indelible stamp on this literature and contributed greatly to its progress. As is perhaps inevitable at this stage, however, their approach fails to incorporate certain aspects of delegation that are quite important and that ultimately need to be taken into account. One of these arises from a key assumption about how the agency responds to political control: they assume that, once the legislature sets the level of discretion, d , the agency chooses a policy in its own best interests—but that it also stays *within* the discretionary window. In this crucial respect, then, the agency is assumed to be *perfectly compliant*. This assumption would seem to be out of place in a model of delegation and control, for compliance should be regarded as problematic and worth explaining. A whole realm of agency choice gets assumed away, and power is attributed to the legislature that it may not have in reality.

reason that other researchers have embraced the discretionary-window framing of the Epstein-O'Halloran model but dropped the make or buy component. The lesson: the internal production baseline is clearly important to the logic of delegation, but no one has yet figured out how to model it in a manageable way, given all the other things that demand inclusion in a theory of legislative delegation.

6. Another basic conclusion has to do with the internal baseline: Congress is less likely to delegate to an agency the closer the committee's ideal point is to its own (and vice versa). But the empirical tests focus on delegation to agencies, and that is the focus of the book as well, so this aspect of the analysis is not highlighted in their empirics.

The other limitations of the Epstein-O'Halloran model have to do with its failure to move in the new directions discussed earlier:

- The president is essentially ignored, aside from their assumption—now standard—that he sets the agency's policy ideal point (always setting it equal to his own). Epstein and O'Halloran say that omitting the president is not a problem, because it does not affect the comparative statics of their model. But this is just a way of saying that their model is limited. Yes, the directional effects of policy uncertainty (the uncertainty principle) and policy conflict (the ally principle)—the two effects they focus on—would be the same, president or no. But the reality of American politics is that the president has an obvious stake in getting as much discretion for executive agencies as possible and thus in opposing (perhaps by vetoing) legislative attempts to restrict it. And any model that adds the president would certainly lead us to expect more discretion for agencies overall—a very important conclusion—as well as variations in discretion, depending on how particular agencies bear on his agenda and leadership. In general, it is difficult to see how, with the president such a powerful and central player who places enormous value on bureaucratic discretion, an adequate theory of delegation can be built by leaving him out.
- Epstein and O'Halloran's actors are not forward looking and thus are completely unconcerned about the political uncertainty associated with future shifts in political power. A new president could take office and radically change agency ideal points. A new party could take control of the legislature itself and begin redirecting public agencies. New legislators could take control of key committees and assert control over the agencies in their jurisdictions. Today's decisionmakers obviously need to recognize these possibilities and shape their delegations accordingly. To do otherwise would simply be a mistake.⁷
- Their model is legislature centered and peculiar to the American system of separation of powers. Yet it does not have a president, and it does not contain any of the veto points that make the American system what it is. (The model does contain an internal committee, but the latter is not a veto player.) It is also not designed to explore the dynamics of a parliamentary system, nor of other forms of government. So in general, what it has to say about the effects of institutional context is limited.
- The model speaks to the trade-off between control and expertise but otherwise does not explore the various ways in which political control can undermine agency effectiveness. Questions of whether agencies can actually do their jobs well and how their capacity for effective performance is affected by the control activities of politicians need to be brought more fully into the theory.

Subsequent work has helped to address these issues. Volden (2002), for instance, focuses specifically on Epstein and O'Halloran's omission of the president. Using their agency discretion framework, he develops a more general model that incorporates the president and allows agencies to have their own policy preferences that are not presidentially imposed. He also

7. Epstein and O'Halloran (1994) actually did devote a small portion of an early article to questions of political uncertainty, but the subject never became part of their research agenda and was not incorporated into their 1999 book.

departs from Epstein and O'Halloran in another significant way. He notes that, although they essentially allow Congress to start from scratch in dealing with agencies—as though the latter were brand new—the typical situation, empirically, is that Congress is dealing with existing agencies that already have policy positions and levels of discretion. Thus, Volden assumes that each agency comes with a status quo policy and a status quo level of discretion, which then serve as reversion levels should Congress decide not to act or be unable to.

Volden's analysis clearly shows that, when presidents are taken into account, agencies do indeed get more discretion. He shows, in addition, that there is an important asymmetry inherent in the dynamics of delegation. This occurs because, when an agency has a low status quo level of discretion, the president will tend to go along with any legislative attempts to increase it—but when an agency has a high status quo level of discretion, he will tend to veto any legislative attempts to decrease it. Thus, over time, increases in agency discretion tend to be difficult to reverse: they can move up much more easily than they can move down.

That such a ratcheting effect might arise out of the politics of delegation is a thought-provoking result and potentially important. And it would never have been discovered, needless to say, in a model that simply ignores the president. It is worth adding, however, that Volden's model—in a feature that embraces, rather than departs from, its lineage—assumes that actors are not forward looking. A legislature capable of looking down the road (or engaged in a long-running repeat-play delegation game)⁸ would surely recognize that today's delegation of discretion would become tomorrow's status quo level of discretion and be difficult to reverse. It would see the status quo level of discretion (and policy) as endogenous, not simply as fixed and given, and it would recognize Volden's ratcheting effect. This would affect its decisions today, probably inducing it to choose less discretion. A more complete picture awaits a model of forward-looking decisionmakers.⁹

The most ambitious attempt to build on the Epstein-O'Halloran base is *Deliberate Discretion?* by Huber and Shipan (2002). Like Volden, Huber and Shipan include presidents in their model of the American system of separation of powers. But their larger purpose is to move beyond the traditional Americanist focus of the literature to develop a comparative theory of delegation: one that explains delegation decisions across a range of institutional contexts. Like Epstein and O'Halloran's *Delegating Powers*, this analysis is a legitimate tour de force, an exercise in theory and empirics that stands as one of the landmarks in the field.

8. The delegation models common to this literature assume that the superior makes one delegation decision. For an attempt to understand delegation as a repeated game (but focused, substantively, on the relationship between the legislature and its committees, not the bureaucracy), see Diermeier (1995).

9. I should note that Volden's analysis contains an ambiguity that reflects a confusion of sorts in the larger literature. He begins his model by fully embracing the Epstein-O'Halloran agency discretion framework, but he describes it as one in which the agency is required to choose a final outcome that is within d of the baseline policy, and he constructs his own model accordingly. This is not the Epstein-O'Halloran set-up. In their model, the agency must choose its own policy position so that it falls within the discretionary region—but because the final outcome is a function of agency policy and random error, the final outcome could well fall outside that region. In Volden's model, the outcome must be inside the region, but the policy may be outside of it. The two models are very different, then, in how they define the discretionary region, but they are presented as being the same. Their differences, moreover, cannot help but lead to different conclusions about delegation, making comparison difficult.

Using an agency discretion framework, Huber and Shipan give due regard to the two main concerns at the heart of the modern literature: policy conflict between the agency and the legislature (which leads to the ally principle) and policy uncertainty (which leads to the uncertainty principle). But these factors are insufficient, they say, for understanding how statutory controls—and thus discretion—vary across institutional systems, and they highlight three additional sets of factors that need to be taken into account.

The first is the capacity of the legislature to write specific statutes, as this determines how costly it is for the legislature to restrict agency discretion; legislatures with part-time members who meet every year or two, for example, would find it very difficult to write finely tuned, well-researched statutes to control agency behavior in just the right ways, whereas professional, full-time legislatures would be much more capable of it.¹⁰ The second is whether delegation decisions involve veto players, which may be presidents but may also be a second house of the legislature. And the third consists of “nonstatutory factors”—the courts, legislative oversight and vetoes, corporatist arrangements—that can intervene after the delegation decision is made and can affect its outcomes.

Embedded in this third component is another expansion of the theory, and a particularly important one: the agency may decide to choose a policy outside its discretionary region, and thus not to comply with legislative directives. If it does go this route, there is some probability that nonstatutory factors may intervene to catch and sanction it—as might occur, for example, if its noncompliance is overturned by the courts. This probability may be large or small, depending on how well any given institutional system is set up to detect and respond to agency noncompliance.¹¹

In formalizing a broader array of influences on the delegation decision, Huber and Shipan (2002) generalize the theory. But at least as important—certainly in explaining its reception among students of government—the authors also provide insightful discussions of how the various formal components should be thought about and empirically operationalized in different institutional contexts. In a separation of powers system, for example, policy conflict is understood in terms of the contrasting preferences of the legislature and the agency, with the latter assumed to be in line with the president; but this obviously does not work in a parliamentary system, where there is no separation between the legislature and the executive. In a parliamentary system, they argue, policy conflict arises when the parliamentary majority is made up of more than one party, as it is in coalition and minority governments. In these cases, the parties will have different preferences, and those that do not control the relevant ministry (with jurisdiction over the agency) will have incentives to use statutory controls to restrict discretion. A divided majority, then, is the parliamentary analogue to divided government. Similar differences in operational meaning apply to the other key variables. It is this empirical maneuver, more than

10. Note that this is an indirect and very simple way of taking into account Epstein and O'Halloran's internal production baseline, as it allows the legislative floor to make its delegation decisions based on a recognition of how costly it would be to make all policy decisions in house.

11. See also Gailmard's (2002) analysis of bureaucratic subversion. His model allows bureaucrats to move beyond the discretionary bounds at a cost and arrives at interesting and provocative conclusions. Among them: that the legislature is actually better off when subversion is relatively cheap (because it often benefits when agencies are able to use their expertise in choosing policies better than the uninformed legislature had asked for), and agencies are better off when subversion is made more expensive (because if it is easy to subvert, the legislature tends to constrain discretion).

anything else, that makes their analysis comparative: the same theoretical concepts are given different empirical referents in different systems, and these differences are primarily what account for expected differences in delegation and discretion across institutional contexts.

The downside is that the formal models themselves are not doing enough of the work here, and are disappointing in certain respects. One problem has to do with the way nonstatutory factors are handled. Huber and Shipan lump all these factors (the courts, legislative oversight, etc.) together, assume there is a fixed probability they intervene to correct agency policy choice—and further assume that, if such intervention occurs, *policy automatically moves to the legislature's ideal point*. But why should the legislature be able to count on being perfectly backstopped (with some probability) by the courts? Why shouldn't it worry that the courts might have their own preferences and move policy to their own ideal points (Segal and Spaeth 2002)? Simplification is one thing, but Huber and Shipan's assumption creates a best-of-all-possible-worlds scenario for the legislature and ensures that it will write more discretionary laws when the probability of intervention is high. *Outside intervention is always good*. More realistic, less benign assumptions about the political environment would obviously lead to very different conclusions about delegation and discretion.¹²

These are not the only assumptions that should raise eyebrows. Huber and Shipan also assume, for example, that the probability the agency is caught and punished for noncompliance is exactly equal to the probability that nonstatutory factors will intervene, and that this probability is fixed. Fixing the probability, however, ensures that the agency's risk from engaging in noncompliant behavior has nothing to do with how "bad" its policy choices are—how far outside the discretionary range it chooses to go. This assumption is obviously quite unrealistic, and it distorts the agency's true incentives for noncompliance.

Their formal models are also disappointing for a more fundamental reason. Huber and Shipan build three distinct (but overlapping) models that can be compared and contrasted: a parliamentary model, a veto model, and a bicameral model. As a strategy for providing a comparative analysis of institutional systems, this multiple-models approach makes good sense. But there is less here than meets the eye. The parliamentary model is nothing more than a simple game between the legislature and the agency—and, shorn of peripheral assumptions, is essentially the *same* as Epstein and O'Halloran's model of legislative delegation in the United States: which, of course, is not supposed to be about parliamentary systems at all. What exactly is parliamentary about the Huber-Shipan model? Only that it lacks a veto player (namely, a president). Otherwise, it does nothing to incorporate any other distinguishing features of parliamentary government. This model is then contrasted with the veto model, which adds an executive veto, and to the bicameral model, which adds a second house of the legislature—features that are found in separation of powers systems (and, ironically, are entirely missing from the Epstein-O'Halloran model of the United States).¹³

12. Bendor and Mierowitz (2004: 301) agree that this perfect-backstopping assumption by Huber and Shipan is a problem for their analysis, essentially for the reasons I have stated—adding that it gives superiors "a perverse incentive to induce agents to shirk," so that the outsiders can catch them and bring them back to the superiors' ideal policies.

13. Note that the veto model is supposed to represent a (unicameral) presidential system, and the bicameral model is structured in such a way as to represent a separation of powers system, not a bicameral parliamentary system.

There is, at least, institutional variation to explore here, and the focus on veto points (none, one, or two) is basic and important. Still, the institutional set-up is overly spare for gaining insight into parliamentary government—particularly given that, in all three models, actors are thinking only of the here and now. They are not thinking about how power alignments might change in the future, nor are they thinking about the long-term durability of what they are creating—and so the fact that political uncertainty is especially severe in parliamentary systems (and durability a much more difficult problem less amenable to solution through formal structure) plays no role whatever. The rest of the literature is guilty of this same omission, of course. But for Huber and Shipan, the omission is more critical, for their analysis is much celebrated precisely because it aims to construct a comparative theory of delegation—and what they leave out is quite fundamental to an understanding of why delegation should differ across parliamentary and presidential systems, and why bureaucracies should differ as well.

This is an opportunity missed, and it promotes conclusions that are likely to be misleading. Indeed, their formal analysis indicates that the effects of their key variables—policy conflict, legislative capacity, the probability of intervention by outside forces—are the *same* for presidential and parliamentary systems. Empirically, differences arise because the measured levels of conflict, capacity, and intervention vary from system to system. But the underlying analytic relationships are the same, as is the basic logic of delegation. The only fundamental contrast is that, in their models, the level of discretion is always at least as great in a presidential system (all else being equal), because presidents want more of it and use their veto power to get it. As discussed earlier, however, the logic of delegation should be distinctively *different* in presidential and parliamentary systems once actors are allowed to be forward looking and take political uncertainty into account. And the implications run in precisely the *opposite* direction of the Huber and Shipan model: pointing to much less discretion in a presidential system (all else being equal).¹⁴ The empirical evidence, moreover, suggests that American bureaucracy is, in fact, far more constrained by statutory restrictions than bureaucracies in parliamentary systems are (e.g., Moe and Caldwell 1994).

Epstein and O'Halloran (1999) and Huber and Shipan (2002) are the keystones of the modern literature on political control of the bureaucracy. Both have their drawbacks, but that is to be expected in work that strives to push the envelope. There is simply too much that needs to be done, and it cannot be done all at once. The important thing is that both have clearly succeeded in generalizing the theory and framing the way political control is thought about and studied. In the years since their publications, they have stimulated a spate of new work that builds on their analytic base and elaborates the theory still further. I do not have the luxury of discussing all of these developments, but I want to spotlight several that, because of the substantive topics they address, are especially promising avenues of inquiry.

6.1. Appointments

This is a legislature-oriented literature that only minimally explores the powers and impacts of presidents. Huber and Shipan (2002) and Volden (2002) include the president as a veto player in

14. To be clear: presidents use their leverage *within* a separation of powers system to push for bureaucratic discretion—but bureaus should still tend to have far *less* discretion in a separation of powers system than in a parliamentary system.

the legislative process, but the president's power of appointment—which is obviously relevant here—has received little attention. Typically, appointments come into play only indirectly in delegation models: bureaucratic agencies are assumed to have ideal points identical to the sitting president's (or this "result" is derived from assumptions that readily guarantee it). Little is learned, therefore, about the strategic use of appointments by presidents, its impact on the legislative delegation, and the consequences for agency behavior—all of which ought to be integral components of the theory.

McCarty (2004) attempts to do something about this shortcoming, developing a model of political control in which the president and the legislature are essentially co-equal actors. For reasons that are unclear, however, he does not adopt the agency discretion framework and crafts his model instead along quite different lines. The three actors are familiar: the legislature, the president, and the agency. But the set-up is not, for it is built around budgets. The legislature has the power to make budgetary proposals for funding the agency, and it also has a role in confirming presidential appointments. The president makes appointments and can veto legislative budgetary proposals. And the agency makes policy choices under the constraint that any departure from the status quo is costly and requires budgetary funds provided by the legislature. The upshot of this last assumption is that, when the legislature grants the agency a budget, it is essentially placing bounds on how far in either direction the agency can move from the status quo. In this sense, it retains one of the trappings of the agency discretion framework, with the budget determining how much discretion the agency has.

The thrust of McCarty's argument is that there is a dilemma inherent in the ongoing struggle between the legislature and the president to control the agency. The nub of the problem is that the president cannot commit to the appointments he makes—because once the legislature decides on a budget, the president can remove his initial appointees and replace them with others whose views on policy are closer to his own. Realizing this *ex ante*, however, the legislature may decide to give the agency a smaller budget, and thus less discretion, than it would actually like to. Both the president and the legislature are likely to be worse off as a result. The dilemma could be resolved if appointment and budgetary powers could somehow be centralized in the same hands, as in a parliamentary system. But more practically, the problem can be mitigated through independent commissions, civil service, and other devices whose statutory restrictions essentially allow the president to commit. Once he is able to do so, he can effectively obtain higher levels of discretion (budgets) for the agency by trading off appointments more to the liking of the legislature.

This analysis is interesting, but it is also problematic. One reason is that the idiosyncrasies that set it apart from the rest of the literature—creating an awkward fit, and making comparison and cumulative work more difficult—are also hard to justify. A key driver of this model's results is the assumption that any agency shift away from the status quo in either direction is costly, but this does not square well with reality. A regulatory agency might find it enormously expensive to launch waves of new inspections and enforcement actions, for example, whereas cutting back on inspections and enforcement would cost it nothing—indeed, it might save tons of money. So even when agencies make important shifts away from the status quo, these shifts are not necessarily costly at all. This is especially true when the shift involves doing less work—which is precisely the way many agencies do in fact change their policies. The model's basic assumption about agencies—which, in turn, determines how legislatures and presidents deal with them, and with one another—seems off the mark.

More fundamental still, this is an article about a commitment dilemma, but whether it really captures something empirically central to the struggle for political control is debatable. Presidents certainly do not have a history—even at the margins—of making initial appointments, waiting for the legislature to make key policy choices, then firing the appointees and making new, more extreme appointments. The legislature could punish any president who behaved in this way, not only by refusing to confirm the new appointees (regardless of the latter's policy views) but also by undermining his policy agenda, launching investigations, and in myriad ways making his life miserable. And perhaps most importantly, there are heavy costs to presidents if they continually appoint and fire bureaucrats—for it creates disorganization, discontinuity, lack of expertise, and weak leadership within the agencies, and it takes time and attention from the president's own staff. Removing appointees is something presidents do not want to do.

Thus, the commitment problem at the heart of McCarty's model would seem to be a non-problem in practice and not the place to start in understanding the role of presidential appointments. Even so, this is a useful contribution, because it puts the focus squarely on appointments, argues the need for modeling their dynamics, and encourages future work along these lines. Presidential appointments need to be an integral part of the political logic of delegation.

6.2. Development of Agency Expertise

At the heart of these delegation models is the agency's advantage in expertise. How or why the agency develops its expertise, however, is left unexplored. Typically, the agency is simply assumed to have perfect knowledge of the connection between policy choices and policy outcomes, the legislature is assumed to be uninformed on this count, and the models go on to show why it is beneficial for the legislature to delegate discretion to take advantage of what the agency knows. With expertise so crucial to an understanding of delegation, though, there is good reason to explore its role in greater depth by making it endogenous to the theory, and thus a product of decisions by key actors.¹⁵

A provocative step in this direction has recently been taken by Gailmard and Patty (2007). Using an agency discretion framework, they build their model around two types of bureaucrats: the zealot who is purely motivated by policy and the slacker who is purely motivated by material gain. They use these types to shed light not only on the legislature's decision to delegate discretion but also on the bureaucrats' decisions about whether to invest in expertise and whether to continue their jobs with the agency (or leave for the private sector).

The model reveals that only the zealots have incentives to invest in expertise and stay with the government long term—and that the legislature, to take advantage of agency expertise, essentially pays for it by giving discretion to bureaucrats (the zealots) who have their own policy preferences and can be expected to depart from the legislature's ideal. Moreover, the legislature has incentives to provide these zealots with tenure in their jobs, for otherwise they would not make investments in expertise—which can only pay off with continued service to the agency over time.

15. Incentives to specialize have been explored, however, in models of legislative organization, where the question is whether and to what extent committees will choose to pay the costs of becoming experts in their substantive jurisdictions. See, for example, Gilligan and Krehbiel (1990). See also Bendor and Mierowicz (2004) for applications to delegation.

There are a few questionable assumptions here that shape the analysis. Gailmard and Patty assume, for instance, that expertise has value to the bureaucrat only within government, and that its value is zero in the private sector. For many government jobs, this is clearly not true. Indeed, the well-known “revolving door” phenomenon, in which governments lose employees to the private sector, is largely driven by the expertise these employees gain from their public service.¹⁶ The authors also assume that the private sector wage is always greater than the agency wage—which gives *all* slackers incentives to *leave* the agency very quickly (with zealots staying on), a cataclysmic result that influences the entire analysis. Yet such a blanket (and radically consequential) assumption is unwarranted; for the private sector wage advantage is more myth than reality, especially when benefits (e.g., health and retirement) are taken into account.¹⁷ It also ignores attitudes toward risk, as well as the likelihood that government jobs may selectively attract many people (including slackers) who are risk averse and willing to accept a lower government wage in return for greater job security (Brehm and Gates 1999).

These are serious problems that raise red flags about this particular model. But as a general avenue of inquiry, the Gailmard and Patty (2007) analysis is among the most innovative in the literature. It helps point the way toward a better understanding of how bureaucratic expertise may develop as an integral part of the nexus of decisions involved in delegation. And it goes further, suggesting how key components of the civil service system—such as tenure—might arise from the politics of delegation, be rational and productive for the players involved, and contribute to an explanation of bureaucratic expertise. Although the specifics of their model can be questioned, then, it encourages new work that connects delegation to the internal organization of the bureaucracy. And it gets back to the kinds of issues that were central to the control literature years ago, before formalization shifted the focus to discretion.

6.3. Bureaucratic Capacity

The usual delegation model is built around the information problem and thus around the legislature’s reliance on an expert bureaucracy to carry out policy. It is the bureaucracy’s expertise that makes it distinctive and drives much of the analysis. But Huber and McCarty (2004) rightly argue that there is another aspect of the bureaucracy—its capacity for effective performance—that deserves central attention as well. Implicitly, the delegation literature has assumed that capacity is not an issue and that all bureaucracies are highly capable. Yet even though agencies may have considerable expertise about their policy environments, they may also be quite incapable—due to mismanagement, corruption, or patronage, among other things—of carrying out policy effectively. Expertise and capacity are simply different dimensions, and both are likely to be important for understanding delegation.

The model Huber and McCarty develop is similar to the others in basic respects. The authors use the agency discretion framework, treat bureaucratic expertise in the usual way (with policy

16. Accounts are legion. See, for example, Katzmann (1981) on how young attorneys flocked to the Federal Trade Commission to gain experience in anti-trust and consumer cases so that they could move into lucrative positions in private law firms after a short time.

17. Compensation across sectors, although bundled differently, is sufficiently comparable in total value that there is considerable debate over which sector has the advantage. See, for example, Federal Reserve Bank of Chicago (2009).

outcomes partly determined by random shocks that the agency knows with certainty), and—following Huber and Shipan (2002)—assume that the agency is caught and punished with some probability if its implemented policy falls outside the discretionary region. The difference here is that the agency's implemented policy consists of two parts: an action a chosen by the agency and a random adjustment w that reflects its capacity for effective performance. Unlike the random shocks associated with expertise, the agency does not know w . But it does know the variance of w 's distribution. The larger the variance, the lower the agency's capacity for effectiveness, and the farther the implemented policy is likely to depart from the agency's chosen action a .

Given the literature's implicit focus on high-capacity agencies, Huber and McCarty center their analysis on those that have low capacity. They begin by showing that low-capacity agencies, because their own actions have so little impact on implemented policy (stemming from the high variance of w), actually have little control over their own fates—and this reduces their incentive to even try to comply with legislative policy directives, making them harder to control. This implication is interesting, but they go on to derive conclusions that are even more instructive. For instance, they show that the ally principle, long at the theoretical core of the delegation literature, tends to fall apart once capacity is taken into account. The legislature can often obtain better policy outcomes by delegating to competent agencies with distant political preferences than to low-capacity agencies that are closer by.

They also derive much more general implications for institutional reform. They show that, although politicians always benefit from reforms that enhance bureaucratic capacity, their incentives to engage in such reforms are weakest in systems populated by low-capacity agencies. In these environments—which appear in some areas of the United States but are quite common in Latin America and other developing regions (Geddes 1994)—politicians have reduced incentive to develop their own policy expertise, reduced incentive to bolster institutions (such as courts) that would improve bureaucratic compliance, and enhanced incentive to politicize the bureaucracy: all of which create a drag on reform and tend to keep the system in an incompetency trap.

Overall, this is a remarkable analysis. Bureaucratic agencies are the government's means of carrying out public policy, and their capacity for effective performance is clearly central to how any rational politician, interest group, or citizen would go about understanding them or assessing their value. Yet the delegation literature has focused all its attention on the information problem and brushed capacity aside. Huber and McCarty have now put a spotlight on it and shown that it does indeed have far-reaching theoretical consequences. In so doing, they have taken a key step toward moving the theory away from its American origins and making it truly comparative in scope, because low-capacity bureaucracies are a serious problem throughout the world. This analysis not only sheds new light on these non-American contexts, but it also shows that the logic of delegation—and reform—may work quite differently in such settings than scholars had previously thought.

7. Discussion

The theory of public bureaucracy has made dramatic progress over the past few decades. From the pioneering work of Downs and Tullock to Niskanen's theory of the budget-maximizing bureau to the more recent theories of political control and delegation, the field has put to-

gether a sophisticated analytic base for understanding how the organization and performance of bureaucracy arise out of politics. The modern literature is defined by work that is formal and game-theoretic, and its trajectory has propelled it from the realm of early breakthroughs into the realm of normal science. Modelers in the field now see themselves as building incrementally on a common analytic foundation, and they agree on what good work looks like.

The most influential achievement is the analytic foundation itself, whose rigor has allowed this literature to move beyond informal argument to deductively powerful theories with testable implications. The most basic of these implications—the ally principle, the uncertainty principle—are the cornerstones of the modern field and central to how the dynamics of delegation are understood.¹⁸ But the literature has also expanded its horizons over time, as scholars have sought to incorporate a range of actors and topics—presidents, courts, appointments, bureaucratic capacity, legislative capacity, bicameralism, the endogenous development of agency expertise—that are clearly relevant to the politics of delegation and demanding of attention. Today’s theory, as a result, is a less legislature-centered and more broadly institutional approach that explores key features of the American separation of powers system and extends to parliamentary governments as well. Along the way, the legacy of congressional dominance has weakened, as formal models have clearly shown that legislators face a trade-off between control and expertise, that it is rational for them to accept imperfect control, and that agencies should often have substantial autonomy.

All literatures have their problems, and this one is no exception. Despite the expansion of the theory, the legislature is still the center of its political universe, and other institutional actors—the president, the courts, even the bureaucracy—are given far less serious attention than they deserve. Consider the president. It is not unusual for delegation models to ignore his veto power—even though the president clearly benefits from agency discretion and can reject legislation that does not provide enough of it. These same models typically assume that the agency has policy preferences identical to the president’s, implicitly claiming that he has no problem getting the agency to do his bidding—which is far from accurate and diverts attention from the fact that, as chief executive, the president has his own problems controlling the bureaucracy. Some of these problems arise because Congress is trying to control it too. But many arise simply because top-down control is highly imperfect in any hierarchy, including the executive branch.

18. Bendor and Meirowitz (2004) explore the robustness of the theory of delegation by examining how well its better known implications stand up as fundamental assumptions are varied. They show that the ally principle stands up quite well, but that (not surprisingly) it does not hold under all conditions. For example, when information varies across bureaucrats—which can happen when bureaucrats are not perfectly informed, information is costly, and some specialize more than others—then political superiors may pass up an incompetent ally for a competent agent whose ideal point is farther away. To take another example, they show that, if agents can precommit to particular policies—which is precisely the point, for instance, of setting up an independent central bank (a bureaucratic institution) for monetary policy—then superiors may find it advantageous in some cases to delegate discretion to bureaucrats whose ideal points are not close to their own. See also Bendor et al. (2001). As for the uncertainty principle, Bendor and Meirowitz show that it is a robust conclusion and that the value political superiors place on (bureaucratic) expertise has little to do with attitudes toward risk—the superiors do not, in particular, have to be risk averse for the principle to hold. The decision to delegate is mainly driven by their desire to achieve policies close to their ideal, and by other factors (e.g., the variance of the random shock) that are separate from attitudes toward risk.

Both give presidents strong reasons to use his powers—of the veto, of appointments, of unilateral action—to impose structures that enhance his own control. Indeed, much of the organization of the federal bureaucracy was created by presidents or their appointees, not Congress (Howell and Lewis 2002; Lewis 2003). A theory that aims to explain the organization of public bureaucracy, then, needs to treat presidents as the pivotal actors they are, not as a planet orbiting the legislative sun.¹⁹

The courts have also been marginalized. If they are incorporated at all, they tend to be treated as faithful backstoppers of the legislature, beefing up its power.²⁰ But judges clearly have preferences of their own, they act on them, and there is a large empirical literature on judicial behavior that documents as much (e.g., Segal and Spaeth 2002). Like presidents they can take unilateral action, without legislation, to impose their own structures on the agencies. And like presidents they have serious control problems to worry about and address: for they cannot count on having agencies faithfully obey their written orders, or indeed obey them at all. Ultimately, then, this literature needs to incorporate all the major institutional actors as (roughly) co-equal players and model the dynamics of their interactions. The legislature, the president, and the courts all have authority over the bureaucracy; they all have problems controlling it; and they all are involved in imposing structures to engineer more desirable behavior and policy outcomes. This is what the theory ought to be about, not just delegation by legislatures.

Even though the legislature is the star player in this literature, it has actually been explored in surprisingly little depth. Congress is a complex institution with two houses, two parties, huge numbers of committees (several of which may be relevant to any given decision), and hundreds of members driven by parochial interests; and it is plagued by severe transaction costs when it attempts to take action. As such, it is not an actor in the same sense that the president is. Yet despite the centrality of transaction costs to the new economics of organization, and notwithstanding Epstein and O'Halloran's claim to have developed a transaction costs theory of delegation, Congress is modeled as a coherent actor that instantaneously, smoothly, and flawlessly makes optimal decisions in pursuit of its well-defined policy objectives.²¹ By uncritically going down this modeling path, the formal literature fails to recognize Congress's nature as an institution and is out of sync with what are supposed to be its own theoretical origins. Theorists ought to be trying to model the very ponderousness and decisional difficulty that make Congress what it is—and that cannot help but shape the larger struggle for control.

19. For a recent attempt to explore explicitly presidential effects on the politics of delegation, see Wiseman (2009). Wiseman argues that, when the president can engage in review and adjustment of agency decisions subsequent to delegation—notably, through the regulatory review activities of the Office of Information and Regulatory Affairs (OIRA)—both the president and Congress can actually be better off. According to Wiseman, this reasoning helps explain why OIRA continues to survive.

20. This is true of the delegation literature (Huber and Shipan 2002), but it is also true of the work on ex post control. The courts are portrayed as Congress's helpers. See Ferejohn and Shipan (1990) and Eskridge and Ferejohn (1992).

21. Epstein and O'Halloran (1999) begin to get at these internal decision problems in their make or buy framework, and Huber and Shipan (2002) do too by recognizing variations in legislative capabilities, but these are not attempts to model the truly burdensome transaction costs that afflict Congress, and they only scratch the surface. I should add that legislatures in parliamentary systems are much less burdened in this respect—a variation of theoretical consequence that ought to be central to this literature.

And then there is the bureaucracy itself, which, despite its universal role as the agent in these analyses, has actually received very little attention. The early work on *ex ante* control—by McCubbins, Noll, and Weingast, Moe, and others—was explicitly about bureaucratic organization. It argued that legislatures (and presidents) used various aspects of organization—the location of the agency, its decision criteria, its decision processes, appointments, personnel rules, rules for appeals, interest group participation, reporting requirements, and more—to gain control over agency behavior. My own work, moreover, also put the focus on bureaucratic effectiveness and how it tends to be undermined by politically imposed structures. But these organizational concerns are less central today. With the recent formalization of the theory, the focus is on how much discretion the bureaucracy is delegated. Various aspects of bureaucratic organization are still discussed—informally—as the means by which discretion is restricted. But they are not explicitly modeled, and they are not explored in terms of the different effects they might have on bureaucratic behavior. They are essentially lumped together into one homogeneous mass, as the structural means by which discretion is restricted. This characterization does not tell us much about why agencies are organized as they are, nor about how their politically imposed structures affect their capacity for effective performance. For now, the organizational aspects of bureaucracy have gotten organized out of the formal theory.²²

It seems clear that, with the focus and momentum that normal science imparts to a research community, the theory will naturally be expanded and improved over time along most of the dimensions I have just discussed. So in this sense, progress is inevitable. Yet normal science is constraining as well as empowering, because its consensus on analytics inherently produces a research dynamic that pushes the theory in “normal” directions—and pushes it away from other avenues that, even if potentially productive, are not compatible with the accepted way of thinking about things. Over time, as the field is guided by this framing, a kind of path dependence sets in that makes certain kinds of progress more difficult to achieve. An obvious example is the one I just discussed: precisely because this literature is now built around the concept of discretion, all aspects of bureaucratic organization get telescoped into this one concept, propelling inquiry in directions that are less about organization than they might otherwise be.

Another troubling constraint built into the normal framing, an exceedingly consequential one, is that actors are not forward looking. It has long been part of the working knowledge of the field that, because tomorrow’s power holders may be very different from today’s—different policy agendas, different ideologies—rational actors in a position to design bureaucratic agencies have incentives to look ahead and take this political uncertainty into account. The greater the likelihood their enemies may gain power in the future, the more they will have incentives today to adopt restrictive structures that shield “their” agencies from unwanted influences. But even though this forward-looking logic could not be more basic to rational behavior and is often discussed, it is simply omitted from formal models of delegation and control. Among those doing the modeling, this omission is not regarded as a problem, or even an issue worth pointing out. It is normal.

22. Some of Ting’s (2002, 2003) work, however, links delegation to issues that are explicitly organizational—exploring, for example, how superiors might try to use redundant bureaucratic agents (multiple agents doing the same tasks) to obtain better outcomes and increase effectiveness (Ting 2003), and how superiors might be able to obtain better outcomes by assigning different jurisdictions to different agencies (Ting 2002).

In essence, then, existing models assume that their actors behave in rather stupid ways. They are fixated on the present, as though politics is never going to change.²³ When the legislature makes its delegation decisions with an eye to the president—assuming, for instance, that he alone determines the agency's policy preferences—it is looking only at the current president and ignoring the fact that he will soon be out of office, replaced by another person. And another and another. If legislators want to maximize the long-term benefits to themselves and their constituents, it is obviously a big mistake for them to base their entire calculation on the sitting president alone. Would it have made sense, in 2007 and 2008, for the Democratic Congress to make its delegation decisions under the assumption that the only president of relevance was George W. Bush, when they knew for certain he would be gone by January 2009? Of course not. *But this is just what the existing models of delegation assume.* And because it is normal, no one thinks twice about it.²⁴

This problem is pervasive and carries over to the literature's attempt to build a comparative theory of delegation. Parliamentary governments are not all alike. But it is surely the case that, in most of them, there are far fewer veto points than in the American system; it is much easier for the government to pass new laws; and because of this, the current government needs to be very concerned that its creations will be undermined or destroyed when the opposition

23. To be more accurate: legislators do think ahead, in the sense that they need to ponder what agencies are likely to do with whatever discretion they are granted. But legislators do not think ahead in other basic respects, for example, by recognizing that the sitting president and the agency's presidential appointee are temporary and will be replaced by others with perhaps very different policy preferences. Also, legislators do not think ahead with regard to themselves: today's legislators need to be concerned about what will happen down the road if opposing legislators grab the reins of power and take control of the agencies being created today. In short, existing models allow the players to be forward looking about agency compliance and shirking, but not about the structure of power and control.

24. The most notable exception—outside of one attempt by Epstein and O'Halloran (1994) to model political uncertainty—is the formal treatment given to the concept by de Figueiredo (2002). His analysis is not about delegation per se but about whether interest groups will favor overturning one another's policies when their party gains power, and whether they will insulate their agencies (and suffer the inefficiencies that might go along with it) in separation-of-power systems that allow such restrictions to endure. He argues that insulation is pursued by weak groups, not strong ones, in separation of powers systems and that groups often respond to political uncertainty in parliamentary systems by cooperating and thus agreeing not to overturn one another's policies. He also argues that, in general, political uncertainty works somewhat differently than I have suggested in my own work and is less likely to produce insulation and bureaucratic inefficiency. This is not the place for me to write out a response, needless to say. I do think that there is much to agree with in de Figueiredo's basic conclusions about the effects of political uncertainty, although he has a tendency to couch them in more extreme terms than is warranted. Despite his categorical claims about the model's clear-cut implications, there is actually no clear, definitive way to translate some of his mathematical results into statements about the empirical world—because it involves, for example, interpreting what it means for a given parameter to be “sufficiently high.” My own view is that softer versions of his stated conclusions are more likely on the mark: that weak groups have greater incentives to insulate than do strong groups, and that groups in parliamentary systems are sometimes able to cooperate in not overturning one another's policies. These conclusions are entirely compatible with my own logic (e.g., Moe and Caldwell 1994). More generally, however, the main point to drive home here is that de Figueiredo's model is just one of many ways that political uncertainty might be modeled—and other reasonable approaches would surely lead to different conclusions. The bottom line is that more scholarly work is needed on political uncertainty. It is a concept that—unless we want our actors to behave stupidly—should be taken seriously, integrated into our models, and debated.

comes to power. Simply burying agencies in formal restrictions does not work very well, as such restrictions can be lifted by the next government. American lawmakers need not be nearly as worried, because they are protected by all the checks and balances built into their system: whatever they create and embed in formal structures will tend to endure. Thus, when actors look forward, the logic of delegation is clearly very different across these political systems. Yet the existing literature does not allow them to look forward, and it entirely ignores this fundamental source of cross-system difference. The same is true, interestingly enough, of recent parliamentary analyses that are entirely informal, and thus are not constrained by the need to simplify and mathematize their key ideas. They are very informative in describing how delegation operates in these systems, how linear and hierarchical it is compared to the American case, the key role of parties, and the like—but they pay no attention to political uncertainty and its crucial implications, staying very much within the normal science bounds (Strøm et al. 2003).

Finally, I want to mention one more aspect of the normal framing that I find especially important but have not discussed at all to this point—because it is completely missing from this literature. The normal assumption is that bureaucrats are *subordinates* in the hierarchy of government, pure and simple. In terms of public authority, of course, this is accurate and makes perfect sense. But it systematically diverts attention from a feature of democratic politics that has clear relevance to control and delegation. In a democracy, political superiors are elected; and this means that, if ordinary bureaucrats can get organized to take collective action in politics—through public sector unions, for example—they *can exert political power over their own superiors*. When this happens—and it regularly does, in the United States and throughout the developed world (Blais et al. 1997)—they can play major roles in determining who gets elected and what policies the latter pursue once in office. This being so, the kind of “control” that political superiors want to exercise may often—depending on the specific group and the power it wields—tend to favor bureaucratic interests: by favoring policies and structures, say, that promote job security, enhance autonomy, protect established programs, and lead to higher spending and taxing. In contrast, the normal way of thinking about bureaucrats assumes that they have no *political* power at all: bureaucrats are difficult to control, and have a measure of power, because they have *informational* leverage over their superiors. They are experts. The idea that they may also have political power and that, in some realms of behavior, politicians may actually be agents of the bureaucrats—and acting as such in their delegation decisions—is entirely foreign and never seriously considered. As a result, an important part of the delegation story is missed, and theorists tend to underestimate what bureaucrats can do to get their way (see Moe 2006).

8. Conclusion

There is reason, then, for both enthusiasm and concern in assessing the contributions of formal models to the study of public bureaucracy. Tremendous progress has been made, and along the way one of the most traditional and underdeveloped fields in all of political science has been transformed into a juggernaut of cutting-edge work. In important respects, the trajectory continues to look promising, and will likely take the theory further beyond its legislature-centered origins to capture some of the distinctive dynamics of separation of powers and parliamentary systems. But just as formal models are powerful tools in the development of theory, so they are

also powerful means of constraining it. As their influence has taken hold, they have generated a normal science that inherently mobilizes research around certain sets of ideas—and discourages the pursuit of others, including some that are quite important to an understanding of control, delegation, and bureaucracy.

The real challenge for scholars in the years ahead, therefore, is not simply to push for incremental progress along the same trajectory. It is to push against the constraints, to be open to abnormal ideas, and to think actively about shifting the theory onto new paths that might be more productive.
